The areas affected by land subsidence (LS) have become the subject of many studies in recent years. The purpose of this research is to analyze LS and its main natural causes in the Volturno River plain. In this study, the geological and geotechnical characteristics of the subsurface are investigated using subsurface data, i.e. boreholes and cone penetrometric tests (CPT), to interpret the stratigraphic architecture of the plain and assess its susceptibility to subsidence. The Volturno river plain is a peculiar study area for studying LS, due to the presence, in the subsoil of the entire Volturno alluvial plain, of a thick, continuous level of pyroclastic deposit (the Campanian Grey Tuff - CGT - dated 39 ky B.P.). The CGT represents the bedrock surface for the following Holocene deposition and is considered as an incompressible base. A careful geological and depositional reconstruction was carried out combining information from geomorphological evolution and stratigraphic investigations. The spatial arrangement of Holocene depositional facies was reconstructed, as well as that of the different lithologies, which showed the presence and spatial distribution of compressible materials such as clay, silt and peat. These data were spatially superimposed on the present subsidence map reconstructed with InSAR data, highlighting the relationship between the different subsidence rates and the composition of the Holocene fill, suggesting that the greatest subsidence in the lowlands is related to the potential for compressible soft soils affected by both primary and secondary consolidation.

Subsequently, the geological data regarding depositional and lithological characteristics were associated to the penetrometric data from the CPT. This analysis showed that different facies associations may have a similar lithological composition but have surprisingly dissimilar geotechnical behavior. This latter provides valuable input for the evaluation of the paleo-compaction rates for the different lithofacies during their deposition. The results obtained provide a more advanced understanding of the evolution of the floodplain and coastal plain of the Volturno River reconstructed on a purely stratigraphic basis in the previous analyses, providing more information on the main depocentres or processes that occurred following the aggradation and progradation phases that led to the formation of the present day Volturno delta plain. A further study was conducted combining InSAR and subsurface data (CPT) to assess primary and secondary consolidation coefficients and thus understand the relationship between natural and anthropogenic causes and how these contribute to the variability of subsidence rates within the plain.

The study offers a comprehensive and multidisciplinary reading of the various factors that influence the natural behavior of sediment deposition and compaction dynamics in a floodplain and coastal plain. It provides a comprehensive overview of the stratigraphic architecture of the subsurface of the northern Campanian plain and, consequently, its connection to past and ongoing land subsidence, thus providing an important contribution to support the planning of interventions in the Volturno River plain to manage the impacts on the environment and buildings resulting from subsidence.

Storm-induced coastline sinkholes monitored by means of uncrewed aerial systems (UAS) in the gulf of Trieste (NE Italy)

Busetti A., Corradetti A., Leone C., Rai P., Zini L. & Calligaris C.*

Dipartimento di Matematica, Informatica e Geoscienze, Università di Trieste.

Keywords: coastline sinkholes, climate changes, UAS monitoring.

In the last decades, there has been a growing discussion within the scientific community regarding extreme events attributed to climate changes, implying the occurrence of increasingly intense and more frequent catastrophic phenomena. The latter do not exempt Italy, which is grappling with severe weather conditions, including torrential rainfalls, intense thunderstorms, alluvial events, strong winds, landslides, forest fires during extreme heat, etc. Among the other, coastal areas, represented by the long shoreline of the Italian peninsula, are one of the most susceptible environments. Here, several interactions occur between natural and anthropogenic inputs, as well as between marine and terrestrial processes, making these areas particularly susceptible to rapid morphological changes. During extreme weather conditions, such as high sea water levels, strong winds, and high waves with crests oriented parallel to the coastline, important natural phenomena such as coastal erosion and landslides can be triggered. This convergence of factors occurred in the Gulf of Trieste (NE Italy) between late October and early November 2023, mimicking an episode that already occurred in the area in November 1969. In particular, four storm surges events with peak winds between 14.3 m/s and 19.5 m/s, blowing from the southwest (from 200 to 240 degrees from the north) hit the area. Among the hardest-hit areas were the Barcola waterfront and the Sistiana Bay (coastline of approximately 4.5 km) counting million euros of estimated damages. The present study focuses on the Sistiana Bay where the occurrence and evolution of 10 sinkholes were monitored since before the onset of the extreme weather. The maximum diameter reached by these features was between 1.4 and 6.86 m (with an average of 4.06 m) corresponding to surface areas between 1.03 and 17.04 m² (8.26 m² in average). The monitoring involved the acquisition of several aerial images using UAS (specifically, a DJI Mavic 3T RTK drone) that were repeated 6 times between September 29 (2023) and February 13 (2024). Each set of images was processed using Agisoft Metashape to generate Structure from Motion-Multi View Stereo (SfM-MVS) photogrammetry-derived products, including 3D models, digital elevation models, and orthophotos. In conclusion, this study contributes to shedding new light on the time-space evolution of these catastrophic geomorphological features in coastal settings under extreme weather conditions, thereby aiding in the formulation of actions toward coastal defence and monitoring.

Anatomy of a small sinkhole near the Adriatic coast

Campanale F., Liso I.S., Parise M. & Spalluto L.*

Dipartimento di Scienze della Terra e Geoambientali, Università di Bari "Aldo Moro".

Corresponding author email: luigi.spalluto@uniba.it

Keywords: sinkholes, stratigraphy, karst hydrogeology.

Coastal sinkholes characterize many sectors along the Adriatic coastline, with variable size and depth, and involving different lithologies. As regards the mechanisms of formation, they are typically originated as cover-collapse sinkholes (*sensu* Gutierrez et al., 2014; Parise, 2022), involving the Quaternary calcarenite and the calcirudite deposits unconformably lying on the Cretaceous bedrock. This is the case for Puntore Cave (PU 377 in the regional cadastre of caves in Apulia, available at http://www.catasto.fspuglia.it), which connection to the surface consists of two small openings created by collapses. Within the cave, the floor is marked by widespread breakdown deposits, and by a small water lake. In the past, man excavated an artificial gallery to easily reach the subterranean environment, and use the water for irrigation of the surrounding fields. This contribution describes the stratigraphy of the cave, its main speleogenetic characters, the morphometry, and the first phases of monitoring of the water so far carried out, including the preliminary analysis of the stygofauna (Galmarini et al., 2023). Quaternary calcarenites and calcirudites cropping out at Puntore Cave consist of poorly lithified and weathered bioclastic packstones, grainstones and floatstones belonging to the Calcarenite di Gravina Fm. They are classified as soft rocks having complex rock fabrics and diagenetic features (Festa et al., 2017). As a result, their peculiar petrographic features, such as grain-packing, matrix content, pore size and pore-size distribution, type and abundance of sparry cement in pore spaces contribute to define the peculiar physical and mechanical behaviors and the resistance to weathering processes of carbonate rocks. Preliminary data suggest that bioclastic grainstone, having large and interconnected pores partly filled by granular cements, is the most prone lithotype to be affected by weathering processes. Consequently, it is inferred that the subsequent rapid decay of the mechanical properties of this lithotype may have played an important role in triggering the sinkhole formation.

Ground deformation induced by piezometric levels fluctuations in the plain of the Sarno River (southern Italy)

Coda S.*[1], Davino S.[2], Abagnale G.[3], Di Martire D.[1] & Allocca V.[1]

[1] Dipartimento di Scienze della Terra, dell'Ambiente e delle Risorse, Università di Napoli "Federico II".

Keywords: piezometric level fluctuation, ground deformation, DInSAR.

Ground deformations associated with fluctuations in groundwater levels have been recognized on a global scale, posing georisk to human activities and urban settlements in certain instances (Tang et al., 2022). Mismanagement of groundwater resources exacerbates hydrogeological imbalances, often resulting in overexploitation. Subsidence induced by groundwater extraction is well-documented in the scientific literature (Galloway, 2013). Conversely, uncontrolled cessation of pumping can trigger groundwater rebound phenomena, causing piezometric levels to recover and possible ground uplift (Coda et al., 2019). In this study, the pyroclastic-alluvial plain of the Sarno River, extended over about 170 km2, was investigated through an integrated analysis of meteorological, hydrogeological, and ground deformation data. Firstly, a 3D hydrostratigraphic model of the aquifer was developed using Rockworks 17 (RockWare Inc.), based on 165 stratigraphic logs and 122 well data from open-source databases and a field survey conducted between July and October 2021. Furthermore, at the basin scale, a multitemporal estimate of the water balance and spatio-temporal analysis of piezometric levels was carried out in the period 1978-2021. Radar data from four different satellite constellations, i.e. ERS-1/2 (1993-2000), ENVISAT (2002-2010), COSMO Sky-Med (2011-2014), and SENTINEL-1 (2016-2020), were interpreted and processed using the Differential Interferometry SAR (DInSAR) technique to produce multi-temporal maps and time series of ground vertical deformation. For the investigated period (1978-2021), a significant reduction in groundwater recharge at the basin scale was observed, quantified at approximately 0.57 m^3/s, mainly attributed to the strong increase in urbanized area (from 31% to 76%) and reduction (from 69% to 24%) of rural areas. The spatiotemporal analysis of piezometric levels and soil deformations revealed a clear cause-effect relationship between piezometric lowering and subsidence, and piezometric rising and ground uplift. Fluctuations in piezometric levels were recorded with spatially heterogeneous distribution, ranging from -14.0 m to +16.0 m with rates ranging from -1.0 m/year to +2.0 m/year. The main causes of these processes were attributed, in addition to temporal variations in effective infiltration, to reductions and/or relocation of industrial and drinking water withdrawals. Satellite data showed correspondence in the spatiotemporal distribution between the areas affected by subsidence (up to -1.8 m, period 2003-2010) and piezometric decreases, and between uplift (up to +1.2 m, period 2003-2010) and piezometric increases. The rate of vertical ground displacement appears to be controlled by local hydrogeological and hydrostratigraphic conditions, linked to aquifer type (phreatic or semi-confined), the magnitude of piezometric fluctuation, and the thickness of the most compressible and deformable layers.

Keywords: Natural Risk, San Martino Valley, sinkhole.

This research pertains to the findings of a study conducted under a Collaboration Agreement between the "Metropolitan City of Rome Capital" (CMRC) and the "National Institute of Geophysics and Volcanology" of Rome (INGV). The study focuses on the geophysical analysis of deformation phenomena observed at a selected test site within a *sinkholes-prone* area in the metropolitan area of Rome (Central Italy). The study area corresponds to the San Martino Valley (near the Capena village, about 30 km North of Rome), where the "Lago Puzzo" sinkhole-lake (classified with ID 58009 in the national database; https://sgi.isprambiente.it/sinkholeweb) occurs; it showed a multiphase evolution well documented in historical times, coupled with the presence of similar morphologies along the valley (Nisio, 2008, and references therein). The study area is located close to the middle Tiber River valley, south of the on Mt. Soratte carbonate horst, belonging to the Sabina tectonic units and bounded by extensional faults. The San Martino Valley, a depressed area where a thick plio-quaternary sedimentary cover overlays the tectonically lowered carbonate bedrock, is interpreted as the surface expression of a N20° striking high-angle transtensional fault (Faccenna, 1994).

In October 2020, a low intensity earthquake, characterized by a shallow hypocentre, occurred in this area; moreover, roars have been clearly perceived by resident population several times in the following months. The site, located in correspondence of relevant infrastructures (a high-speed railway line, an overhead power line, provincial roads and urbanized areas), deserved thus a particular attention. The investigation, based on an interdisciplinary approach, is aimed to evaluate the geo-structural model of the occurrence and to decipher its evolutionary stages. The remote sensing data (SAR) allowed outlining and quantifying the movements (InSAR analysis). The seismological spectral analysis techniques have characterized the recent seismic event occurring in the Capena area, whereas the geophysical investigations (e.g., ERT, magnetic and gravimetric surveying) have illuminated the subsurface structure. These latter have highlighted a clear connection among the regional and local tectonic framework, a shallow and fractured carbonate bedrock and the overlaying Plio-Pleistocene cover. This connection is also clearly testified by geomorphological and geochemical marks. The results offer valuable insights into understanding the mechanisms of deformation, predicting the future evolution of the phenomena, and potentially forecasting their spatial migration. Consequently, this study represents a significant step towards the refinement of hazard evaluation methodologies.

Subsidence in the Po Plain (Northern Italy) during the last 500 ky

Demurtas L.*[1], Bruno L.[1] & Amorosi A.[2]

Keywords: subsidence, Pleistocene, Po Plain.

Subsidence controls the evolution of alluvial and coastal plains, the most densely populated areas of the planet. Recent high-resolution technologies, such as satellite interferometry (INSAR) and GPS surveys, permit the precise measurement of subsidence over yearly to decadal scales. The values obtained with these techniques include the contribution of natural and anthropogenic subsidence. The calculation of natural subsidence is based on the recognition and dating of key marker horizons in the geological record. Seismic profiles typically provide information about subsidence over millions of years. In contrast, relatively poor information is available on subsidence over intermediate time scales (thousands of years).

The Po Plain, the most populated alluvial and coastal plain in Italy, is a rapidly subsiding foreland basin that preserves a thick record of Quaternary deposits. In this area, we calculated subsidence rates (SR) over different time intervals since the Middle Pleistocene. SR calculations relied on a detailed stratigraphic framework obtained through sediment core correlation, constrained by pollen data and absolute ages (14C, IRSL and ESR). Coastal and lagoon deposits, reflecting chronologically constrained marine ingressions related to the Middle Pleistocene interglacials, were selected as stratigraphic markers (paleo-sea level indicators) for SR calculations. SR were calculated by dividing the elevation of the stratigraphic markers (referred at sea-level at the time of accumulation), by their age of deposition.

The results show minimum SR above the main tectonic structures (thrust-related folds) in the subsurface of the Po Plain, and maximum values away from the buried anticlines, beneath the Adriatic coastal plain. This particular SR distribution likely reflects the combination of two controlling factors: (i) tectonic activity of the buried structures, (ii) enhanced compaction of highly compressible sediments in distal settings.

The approach used in this work can potentially be applied to other subsiding basins with a well-preserved sedimentary record, and provides data on subsidence over intermediate time scales.

Sinkhole development along the Apulian coastlines, within the framework of the project Fu.Co.Ka. (Future scenarios in Coastal Karst)

Esposito L.[1], Fiorillo F.[1], Leone G.[1], Caputo M.C.*[2], De Carlo L.[2], Masciale R.[2], Passarella G.[2], Turturro A.C.[2], Andriani G.F.[3], De Santis V.[3], Lollino P.[3] & Parise M.[3]

Keywords: sinkholes, coast, karst.

This abstract is dedicated to studying coastal karst areas in Apulia focusing on the effects deriving from the dissolution processes acting at the interface between freshwater and saltwater, within the framework of the PRIN project "Future scenarios in coastal karst: saltwater intrusion, loss of water resources and sinkhole development as effects of climate changes (Fu.Co.Ka.)". Apulia is among the most remarkable karst regions in the Mediterranean Basin, with over 80% of its territory constituted of soluble carbonate rocks outcropping, and about 900 km of coastlines. It represents therefore an ideal place where to study the climate change impacts on coastal karst, and which outcomes might be useful for other coastal areas, in the Mediterranean as well as in other parts of the world.

The high fragility of coastal karst is related to its hydrogeological peculiar characteristics, the direct link between the surface and the underground, and the facility in contaminating the groundwater and in favoring the development of sinkhole processes. In this latter regard, the presence of karst voids poses the need to investigate the instability processes, and their effects at the surface. Within caves, the rock materials are strongly susceptible to water-induced weathering processes, which are responsible, first, of local failures, and, through progressive stopping, may later reach the ground surface in the form of different types of sinkholes (Gutierrez et al., 2014; Parise, 2019, 2022). Assessing the stability of underground karst caves is a complex task, due to the variety of involved factors, the many uncertainties in predicting the cave evolution, and the likely interaction of the instability features with the overlying infrastructures at the surface. This latter is a very important issue in highly attractive tourist sites such as the coasts of Apulia.

The main driving factors for sinkhole occurrence in coastal settings are detected through investigations with DTMs and detailed mapping, characterization of local geology and geomorphology, and geo-structural surveys. Detailed surveys are being carried out using advanced laser scanning devices, integrated by drone flights for the outside environments, aimed at searching for correlations between surface features, evidences of instability (subsidence, flooded areas, erosion, sinkholes), cave levels and underground morphologies. This activity may also contribute to reconstruct the evolution of the water table, and its relationship with the landscape evolution, both at the surface and underground. A specific focus is further given to documentation of some of the precursory signs of likely failures in cave systems, such as extrusion wedges and bulging from the walls, that may represent the first warning signs for future sinkholes. Given the relevant role of seastorms in the triggering of cliff failures and coastal sinkholes, this aspect, too, is taken into account for a full understanding of the driving forces acting on the examined coastal stretches.

Artificial cavities and risk assessment: the case study of the Cloister of Sant'Agostino (Caserta, Italy)

Fabozzi M.A.* & Molitierno E.

Dipartimento di Ingegneria, Università della Campania "Luigi Vanvitelli".

Keywords: underground artificial cavities, ERT, stability assessment.

The presence of underground voids represents a serious problem that affects many urban centers in Italy and that often compromises the stability of urban structures. In order to keep people safe and reduce economic losses, it is necessary to accurately identify the presence of these underground spaces and to monitor their behaviour, to manage the risks related to the unpredictable trigger of sinkholes or soil subsidence. This is even more dramatic when it happens underneath buildings of historical and cultural interest.

The research presented herein refers to the study case of the Cloister of Sant'Agostino (XVI century), located in the historic center of the city of Caserta, very close to the the Royal Palace Garden (Damiano et al., 2023). The whole structure has recently been the subject of a restoration project, for its inclusion in a tourist circuit, which required investigations inside the cloister. The cloister presents phenomena of instability in the flooring and on some portions of the portico that surround it. Underlying the uncovered area of the cloister - and for approximately 2/5 of the corresponding surface area - there is an underground cavity of anthropic origin which includes a cistern for rainwater storage.

For the accessible part of the cavity, a laser scanner survey was conducted in order to highlight the spatial relationships that exist between the void in the subsoil and the elevated structures that insist on it. In addition, to understand the true extention of the cavity, electric tomography (ERT) investigations were carried out. To define the geological and geotechnical model of subsoil, numerical methods were applied to estimate potential crisis areas, with preliminary assessments of the influence of the presence of the cavity on the stability of the subsoil.

This study was carried out by integrating research between applied disciplines (geology, geotechnics, speleology, cultural heritage) and provide indispensable support both for the management and mitigation of geological risks in urban areas and for the sustainable reuse of hypogea thus contributing to enhancing the cultural and tourist promotion of a territory.

Building a database for the analysis of sinkholes related to artificial cavities: the case study of Altamura (Apulia, Southern Italy)

Fracchiolla R.*[1], Bonamassa G.[2], Liso I.S.[1], Lollino P.[1], Lorusso G.[2] & Parise M.[1]

[1] Dipartimento di Scienze della Terra e Geoambientali, Università di Bari "Aldo Moro".
[2] Comune di Altamura, Altamura.

Corresponding author email: rocco.fracchiolla@uniba.it

Keywords: sinkholes, susceptibility, database.

The Altamura town (Apulia, Southern Italy) has been severely affected by collapse sinkholes during the last decades, particularly at some new urbanized areas around the outskirts of the historic part of town. The ground failures occurred in correspondence of the extensive network of man-made underground galleries, used as mines and calcarenite quarries. Weathering, water infiltration, pipeline leakages and anthropogenic actions such as ground vibrations due to traffic, as well as additional loads of new buildings, triggered failures in the cavities below the urban area, causing the sinkhole formation.

This study aims at evaluating the sinkholes susceptibility at Altamura, in collaboration with the local municipality. Specifically, the probability of future collapse events occurrence will be investigated. The analysis proceeds throughout various phases: first, the construction of a dedicated database in GIS system, containing all the relevant information about geology, hydrogeology, and rock geotechnics parameters. This geodatabase will be integrated with data related to the underground galleries, as their geometry (cave maps and sections, as surveyed by cavers) and stability conditions, as the presence or absence of failures and/or damages within the subterranean systems. To proper assess the stability conditions of the system, the outcomes from periodic interferometric surveys will also be included in the analyses. Eventually, some information about past occurred sinkholes will be considered, like location and occurrence time. The database will therefore represent an archive from which to extrapolate additional data of scientific interest to perform new analyses, also based on quantitative approaches. The final goal will be the realization of a sinkhole susceptibility map, a useful tool for authorities and planners in charge of the management of the territory.

Acknowledgements: This study was carried out within the RETURN Extended Partnership and received funding from the European Union Next-GenerationEU (National Recovery and Resilience Plan – NRRP, Mission 4, Component 2, Investment 1.3 – D.D. 1243 2/8/2022, PE0000005).

GNCA database for stability assessment of artificial cavities

Guarino P.M.*[1], Belvederi G.[2], Licata V.[1], Perrotti M.[1] & Roma M.[1]

[1] Dipartimento per il Servizio Geologico d'Italia, ISPRA, Roma. [2] Società Speleologica Italiana.

Corresponding author email: paolomaria.guarino@isprambiente.it

Keywords: artificial cavities, GNCA, stability assessment.

Dealing with territorial planning, the complexity of subsoil setting represents both a resource and a constraint. For this reason, the collection, the standardization and the sharing of information about the conditions of the cavities are recognized as crucial elements for the assessment of the risk of collapse and, consequently, to implement mitigation interventions.

From this perspective, the Italian National Geodatabase of Artificial Cavities (GNCA) represents a free access digital tool (ISPRA & SSI, 2023) which contains a set of information such as the location of the cavity and, for many of them their underground configuration. Specifically, the database provides plan maps, sections and field survey reports of the artificial cavities documenting the geological and geometrical features.

The present work highlights, on the one hand, the usefulness of the GNCA to share available data on cavities' features for researchers, technicians and stakeholders to manage the risk associated with them.

On the other hand, a comparative study on the assessment of roof stability is analysed to evaluate the safety of cavities collected in GNCA.

To this aim the stability charts adopted and proposed by de Silva et al. (2023) and by Mevoli et al. (2024) have been considered. The farther evaluates the stability of the roof by considering the uncertainties of geotechnical properties of the rock in terms of spatial variability and discontinuities. The latter provides a preliminary safety margin evaluation based on the quantitative assessment of the geometrical features and taking in account the strength parameters of the rock material of cavities.

The salient ingredients accounted, in both methods, used are the characteristic length of the cavities, the thickness of the roofs, the strength parameters of the rock and the field stress affecting the roof. A major part of the above data was retrieved from the GNCA set of attributes searching, for each cavity in the database, the suitable two-dimensional sections on which to apply the mentioned stability charts. Finally, the results are represented in terms of stable/unstable conditions.

Summarizing, the conjunction of GNCA data and the application of such tools let outline the stability frame at the urban scale. Nevertheless, to refine a proper judgement for decision makers, the analyses should be delved deeper by downscaling the focus and by detailing the cases, especially, considered critical by the preliminary assessment.

Keywords: sinkhole susceptibility, social vulnerability, mitigation strategies.

Sinkholes have to be considered one of the most typical features in karst settings, given the soluble nature of rocks. Since their attitude to be carved by man to build artificial cavities, collapse sinkholes (Gutierrez et al.,2014) may also occur in no karst areas, like volcanic soils or soft carbonate rocks. In both cases, the rapid kinematics of collapse sinkholes is associated with the absence of clear precursory signals, representing a serious issue in terms of hazard for local communities. In this context, underground quarries within soft calcarenite rocks are one of the most relevant and diffused artificial cavities prone to collapse. Altamura (Apulia Region) is one of the Apulian municipalities showing an extended network of underground voids that have been dug in the past to extract calcarenites. In recent years, sinkholes occurred at some galleries of the underground quarry net (Parise et al., 2013), generating fear and discomfort in the population. For this reason, investigating the social vulnerability of the population living above the void network becomes of primary importance to understand the main factors influencing the capacity of a specific community to anticipate, cope with, and recover from a disaster (Frigerio & De Amicis, 2016). In particular, the interaction between the sinkhole susceptibility and the socio-economic environment can provide a first detailed map of the sinkhole risk context that can be used as a tool for emergency planning and that can play a crucial role in the mitigation strategies to prevent loss of life and infrastructure damage. Our work investigates the correlation between the sinkhole susceptibility and the social vulnerability in the urban area of the Altamura town through a multidisciplinary approach. Based upon the evaluation of different integration levels, which includes the sinkhole susceptibility and the social vulnerability, a set of engineering mitigation strategies (grouting, local reinforcements or piled foundations), coupled with cost assessment, is also analyzed to help local authorities and inhabitants to deal with sinkhole hazard.

Sinkholes in the Campo Soriano karst plain (Central Italy)

Mastrobattista P.[1], Guarino P.M.*[2], D'Angiò D.[2], Fiano V.[2] & Pompili R.[2]

[1] Parco Naturale Regionale dei Monti Ausoni e Lago di Fondi.

Keywords: Campo Soriano, karst, sinkhole.

The karst plain of Campo Soriano extends for approximately 1km2 in the southern sector of the Ausoni Mountains (Central Italy), in the territory of the municipalities of Sonnino and Terracina.

This area was declared a Natural Monument in 1985, because of its significant landscape and geomorphological uniqueness due to the presence of numerous types of epigean (karren, hum, sinkholes) and hypogeal karst morphologies.

Indeed, the Campo Soriano area is a karst plain located at an average altitude of 300 m above sea level, delimited by reliefs a few hundred meters higher. The subsoil of the plateau is made up of Cretaceous limestones and dolomitic limestones, covered by a residual deposit (*terra rossa)* with a thickness varying from a few tens of cm to just over 1 m, in the areas of greatest accumulation.

The area has still active karst phenomena highlighted by recent sinkholes. The surface waters are drained from the numerous ponors and cavities that develop along the main fractures, with a predominantly vertical trend, such as the two locally called "Chiavica di Zì Checca" and the "Chiavica del Cervaro", as well as many other minor cavities.

The superficial development of the sinking phenomena under study are linked to the network of cavities surveyed over decades by speleological associations (Bellatreccia et al., 2020).

In this work, the analysis and census of sinkholes phenomena was carried out, through field surveys, cartographic analysis, and the study of aerial photos. For some sectors, the processing of images taken through photogrammetric surveys with drone has allowed the development of 3D models. Some corrosion grooves on the walls of the hums are also described, interpreted as signs of ancient ground surfaces and witnesses of the evolution of the plain through subsequent sinkings.

A user-friendly and mechanically-based method to assess the stability of underground caves: the iSUMM abaci

Mevoli F.A.[1], Fazio N.L.[2], Perrotti M.[3], Parise M.[4] & Lollino P.*[4]

[1] Istituto di Ricerca per la Protezione Idrogeologica, CNR, Perugia. [2] Istituto di Ricerca per la Protezione Idrogeologica, CNR Bari. [3] Istituto Superiore per la Ricerca e la Protezione Ambientale.

Keywords: sinkhole hazard, numerical modelling, abaci, safety factor.

In the recent years, an increasing number of sinkhole events related to man-made underground caves has been observed in several contexts of urban and peri-urban areas of the Italian territory, which induce significant risk conditions in terms of human lives as well as damages to the anthropogenic environment. Frequently, such caves have been dug within very soft porous rock formations, as for example the calcarenite deposits, even at shallow depths, and later on, after some decades, abandoned. The low values of the mechanical strength of such rocks, along with their proneness to weathering and consequent degradation of the strength, represent an important controlling factor of the instability processes leading to the sinkhole development. It follows that developing quantitative methods that can be considered as reliable for the assessment of the cave stability conditions is urgent for planning and management policies of the territory.

Based on a previous scientific work presented by these authors, which proposes abaci for the assessment of proneness to instability of underground caves according to the cave geometrical features and rock mechanical properties (Perrotti et al., 2018), the present contribution discusses a recent enhanced formulation of the abaci (iSUMM, innovative, Straightforward, User-friendly, Mechanically-based Method) that introduces the opportunity to evaluate the range of the safety factor values with respect to a potential failure mechanism. Such an advanced version of the abaci has been derived from the results of a wide set of parametrical finite element analyses and, therefore, allows to calculate in a fast way a mechanically-based indication on the safety margin against the rock mass failure. It follows that the application of the abaci can be used as a quantitative tool to assess sinkhole hazard in a preliminary way, to be used in analyses at wide scale, and, eventually, followed by detailed studies developed with more advanced methods at the local scale. This work presents the numerical procedure that has been adopted to derive the enhanced version of the abaci and the validation performed based on a large set of underground cave case studies.

Natural and anthropogenic sinkholes in volcanic areas an underestimated hazard

Nisio S.[1], Madonna S.*[2], Ruggiero L.[1] & Gentili F. [2]

[1] Dipartimento per il Servizio Geologico d'Italia, ISPRA. [2] Università della Tuscia.

Keywords: natural and anthropogenic sinkholes, volcanic areas, nuclear waste.

In Italy, volcanic regions are susceptible to sinkhole hazards due to the unique interplay of volcanic activity, hydrogeological dynamics, the rise of geothermal fluids, and human activities. The new sinkhole census databases that ISPRA is developing as part of the PNNR Geosciences-IR project (WP.3.2) highlight the widespread of this natural or anthropogenic phenomenon. Despite this evidence, the possibility of developing natural sinkholes in volcanic areas is still little considered. Even a part of the scientific community tends to confine the sinkhole phenomenon only to the forms that develop on karst and pseudokarst lithologies. A striking case of this trend is, for example, the exclusion of sinkholes that can develop in volcanic areas in the guidelines designed for identifying nuclear waste storage sites. This omission has contributed to considering the plateaux of Latium inactive volcanic districts as particularly suitable sites for that purpose. This study utilises geological surveys, remote sensing data, UAVs, and historical records to map and analyse the distribution of some particularly significant sinkholes that have opened on volcanic rocks in the Latium region and correlate their occurrences with geological, geomorphological and hydrological conditions. The aim is to highlight the complex dynamics of sinkhole formation in Italian volcanic areas and provide a framework for risk assessment and management of volcanic plateaux, which are often considered stable areas in terms of geomorphology. For this reason, it is essential to define the types, sizes, and mechanisms that trigger these phenomena, which can affect not only large urban areas such as Rome or Naples but also rural or suburban areas. The sinkhole risk is widely underestimated, especially in these areas, because they are less populated and urbanised. Still, it can become very high where high-risk industrial installations, special or nuclear waste dumps, strategic infrastructure, motorways, and railways occur. In the Latium volcanic plateaux, millennia of anthropic activity have shaped and flattened the relief forms and tend to obliterate the recent tectonics. The sinkhole distribution associated with the presence of hydrothermal vents and structures such as fissure ridges in travertine can help redefine an overall picture of the complex dynamic evolution of these areas and could provide clues about neotectonics activities. Anthropogenic factors, both in urban and suburban areas, indirectly increase the sinkhole's hazard by changes in the hydraulic and hydrogeological regimes and directly through the excavation of anthropogenic cavities, underground hydraulic works, or diverting and channelling water streams. Mitigation strategies are essential for minimising sinkhole impacts in these vulnerable regions. This research advocates for integrated sinkhole hazard management approaches combining geological assessments, land-use planning, and public awareness programs.

Collapse sinkholes at Palude del Capitano (Nardò, Italy)

Keywords: coast, sinkhole, karst.

Coastal zone can be described as highly dynamic environments given the simultaneous action of marine and terrestrial processes. This is particularly true in coastal karst, due to the soluble nature of rocks and the wide presence of underground voids, likely prone to sudden collapses also in consequence of wave actions. Sinkholes (Gutierrez et al., 2014) widely characterize coastal karst environments, especially along low-topography and flat coastlines. The mixing between freshwater-saltwater enhances the carbonate dissolution making faster their evolution, and leading to a rapid geomorphological evolution of coast, as well (Liso & Parise, 2023).

This is widely the case in Apulia (SE Italy), an almost entirely karst peninsula with more than 850 km of coastline. Along its Ionian side, Palude del Capitano represents the perfect example to observe and study such collapse phenomena. It is a wide wetland showing several collapse sinkholes flooded by brackish water. There, a detailed survey of the sinkholes recognizable from the surface has been carried out. The activity highlighted the importance to characterize the overall karst systems, including also the minor sinkholes and the main sets of fractures and conduits within the calcarenite rock mass. These, as a matter of fact, seem to exert a strong control on the future evolution and enlargement of the wetlands. Furthermore, diver surveys show the presence of extensive systems of flooded galleries and passages where it is also possible to recognize water bubbles coming from the bottom of the wetlands. The aim of this research is the comprehensive characterization of predisposing, preparatories and triggering factors that influence the sinkholes occurrence. To reach such a goal, many activities have been planned and will be performed at the study area. These include geophysical surveys to assess the spatial distribution and development of underground karst voids, not accessible to man; drone flights to provide the morphometric parameters of sinkholes, the current distribution of collapses, and monitor through multi-temporal surveys their likely evolution; traditional geological surveys at the surface; hydrogeological monitoring of the water within the wetland system; and, eventually, biological investigations through sampling and analysis of biotic and abiotic parameters using multiparametric probes .

Keywords: Cardona, geomorphology, remote sensing.

The Cardona Diapir in the NE sector of the Ebro Cenozoic Basin (Spain) is an actively rising salt extrusion initiated by the unroofing of the crest of a salt anticline by the entrenchment of the Cardener River. Here, the potash-bearing Cardona Saline Formation (late Eocene) flows towards the diapir driven by both erosional unloading and overburden loading (Pérez-Villar et al., 2024). The diapir has been subjected to intense halite and potash mining since Neolithic times (Weller, 2002), involving the creation of extensive underground galleries, and drastic hydrological changes, including the flooding of the mines by the Cardener River in 1998. An in-depth geomorphological study was carried out combining detailed mapping and remote sensing techniques. The interpretation of orthoimages and LiDAR-derived terrain models together with thorough field surveys allowed the production of cartographic sinkhole and landslide inventories, as well as the detection of subsidence damage on human structures. A Differential Interferometry SAR (DInSAR) analysis was carried out to map and assess the kinematics of the ground instabilities. These products were confidently interpreted thanks to the detailed maps based on direct field observations. Additional analyses were performed by decomposing the DInSAR data in horizontal and vertical components (Cascini et al., 2010). The latter reveals five sectors with different behaviour within the area: i) the floor of the river valley dominated by dissolution-induced subsidence; ii) the central sector of the extrusion with prevailing diapiric uplift at ca. 2 cm/yr; iii) the Old Slag Heap with incomplete data due to artificial surface changes; iv) the NE sector of the Salt Mountain, characterized by surface lowering related to rapid dissolution at salt outcrops; and v) the Bofia Gran karst depression with uplift rates of around 0.5 cm/yr. Displacement time series were compared with daily precipitation data, highlighting that the uplift related to salt flow shows a rainfall-independent steady behaviour, whereas dissolution-induced subsidence and especially solutional lowering at salt outcrops show unsteady patterns and positive correlation with the precipitation. This work shows that the Cardona Diapir is a highly dynamic and complex area with the superposition of localized hazardous processes on general and continuous diapiric uplift. The integration of DInSAR and detailed field mapping is essential to resolve these complex ground displacement patterns and to produce the basis for preventing the associated hazards and risks.

Keywords: coast, sinkhole, karst.

The coastlines of Apulia (southern Italy) are intensely affected by development of sinkholes, favoured by a variety of predisposing and preparatory factors, that also include the saline intrusion due to mixing of fresh and saltwater along the coast (Liso & Parise, 2023). They represent sites from unique morphodynamic and environmental value (Mastronuzzi et al., 2015). In low coastal settings, such as those characterizing long stretches in the Gulf of Taranto and its surroundings, there is therefore a high number of sinkhole phenomena, showing different stages of evolution: from incipient sinkholes, with initial but still not fully developed failures, to collapse sinkholes partly dismantled by the successive action of seastorms and waves. Sinkholes have been mapped and analyzed, as concerns their stages of evolution, in the stretch south of Taranto, and this contribution illustrates the present situation, also taking into account the vulnerability of infrastructures. These latter, given the high tourist attraction of the area, include houses, communication routes, beach resorts, but also several sites of interest as concerns the cultural heritage, with archaeological sites and remains located along the coast, and directly threatened by the occurrence of instability and sinkhole processes.

Land subsidence in the Italian coastal plains: an overview

Ruberti D.*[1], Buffardi C.[1], Da Lio C.[2], Donnici S.[2] & Tosi L.[2]

[1] Dipartmento di Ingegneria, Università della Campania "Luigi Vanvitelli".
[2] 'Istituto di Geoscienze e Georisorse, CNR, Padova.

Corresponding author email: daniela.ruberti@unicampania.it

Keywords: land subsidence, Italian coastal plains, Late Pleistocene-Holocene stratigraphy.

Land subsidence (LS) is the gradual or sudden sinking of the ground surface, due to a variety of processes amog which the consolidation of sediments and thus the rearrangement of earth materials in the subsurface as a result of increasing effective stress.

Although LS occurs in different geographical settings, this phenomenon poses a major threat to low-lying coastal plains that are already facing the effects of climate change, i.e. sea-level rise and extreme rainfall events. LS increases the vulnerability of low-lying coastal areas to flooding and storm surges and causes severe damage to infrastructures and natural and historical heritages, which in turn harms economic production and coastal ecosystems.

The causes of LS are multiple, both natural and induced. Those of anthropogenic origin are fairly well known and well documented. The natural ones, slow and silent (few mm/yr), are harmless but uncontrollable.

With this contribution, we provide an overview of the LS affecting the coastal plain systems of the Italian peninsula.

Coastal plains were considered by selecting the maximum land elevations of 10 m above mean sea level. For this purpose, we used TanDEM-X 30m Edited Digital Elevation Model (German TanDEM-X mission) acquired between 2010 and 2015. Then, land subsidence was investigated over the periods 2015-2021 and 2018-2022 using the European Ground Motion Service (EGMS) from Copernicus, which provides ground movement data obtained by SAR Interferometry on Sentinel-1 images. Purely vertical displacements obtained by combining ascending and descending acquisition geometries were used.

Subsequently, the Italian coastal areas most subject to LS were highlighted and the potential mechanisms driving the phenomenon have been reported. Particular attention was paid to the lithological and stratigraphic characteristics of the Late Pleistocene-Holocene successions. The overlay of the main trends of subsidence with the litho-stratigraphic data suggests that the vertical ground deformation is partly controlled by the lithology and stratigraphic architecture of the geological units and, in particular, by the presence of compressible materials (such as peat and organic-rich clay), which are subject to primary and secondary consolidation. Obviously, discriminating the main driver requires more in-depth on-site analyses and the characterization of the geotechnical properties of the sediments are required, as compaction does not occur simultaneously for each layer, depending on the stratigraphic position (i.e. age and depth) and spatial distribution. In this regard, it appears of paramount importance a detailed reconstruction of the vertical stacking of the sedimentary units and their variation over short distances.

While these results are still preliminary, they provide a basis for a better understanding of LS drivers in the coastal-deltaic plains and have the potential to support the management of impacts caused by this phenomenon.

Artificial cavities and sinkholes in the hydrographic district of the Southern Apennines of Italy: findings, architectural variability and risk assessment

Ruberti D.*[1], Fabozzi M.A.[1], Liso I.S.[2], Lollino P.[2], Vennari C.[3], Vigliotti M.[1], Capasso G.[4], Corbelli V.[4] & Parise M. [2]

[1] Dipartimento di Ingegneria, Università della Campania "Luigi Vanvitelli", Aversa. [2] Dipartimento di Scienze della Terra e Geoambientali, Università degli Studi di Bari "Aldo Moro". Corresponding author email: daniela.ruberti@unicampania.it

Keywords: artificial cavities, hazard, sinkholes.

The territory managed by the Hydrographic District of Southern Apennine (Autorità di Bacino Distrettuale dell'Appennino Meridionale - ADAM), in southern Italy, is subject to highly critical situations of the physical-environmental system and risk induced by natural and anthropogenic phenomena; the geological hazards include those connected to the presence of cavities in the subsoil. These represents a serious problem, especially in intensely urbanized areas where the stability of urban structures is often compromised by the presence of underground voids, locally forming a well developed network of cavities , produced by decades of excavation activities. Aimed at developing a District Basin Plan and the related Management Plan relating to the topic of Cavities, a scientific collaboration agreement was signed between the ADAM, the Department of Earth and Environmental Sciences of the University of Bari Aldo Moro (DiSTeGeo) and the Engineering Department of the University of Campania Luigi Vanvitelli (DI). Objectives of the research project are the census, analysis and evaluation of the cavity system on the territory of the district. An accurate research was conducted as regards all documentary sources that could provide information on the presence of cavities. The great heterogeneity of the data acquired made it necessary to identify a homogenization and cataloguing system to be connected to the classification provided by the National Commission on Artificial Cavities of the Italian Speleological Society (Galeazzi, 2013; Parise et al., 2013), which takes into account the construction typologies and those structural elements susceptible to trigger sinkholes. Since the municipalities included in the District are 1632, a "top-down" approach was chosen for the identification of the presence of possible artificial cavities, starting from the analysis of the Lithological Map of Italy and selecting those lithologies potentially affected by activities of excavations. The data were managed in a GIS environment; through the creation of queries, information was obtained about the spatial distribution of cavities of anthropogenic origin by municipal area. In parallel with the activities described above, data relating to documented sinkholes that occurred in the ADAM territory were collected, deriving from previous studies (above all the DiSTeGeo chronological catalogue; Vennari & Parise, 2022) and research commissioned by the Civil Protection Service of Apulia. By analyzing the available data, the spatial distribution of the documented sinkholes connected to artificial cavities was obtained throughout the territory considered. The work is still in progress and many portions of the territory are still without data, or need to verify what has been identified with the survey framework set out herein. However, the acquired data is populating a DB which will constitute a unique document in Italy, including all aspects relating to artificial cavities which will form the basis for subsequent analyses, aimed at defining procedures for preliminary evaluation of the stability conditions of artificial cavities, detailed assessment at two pilot areas within the ADAM territory, including modeling analyses, and to establishment of actions addressed toward mitigation of the risk related to sinkholes.

Mapping sinkhole susceptibility in Italy: a machine-learning approach for risk assessment and management

Ruggiero L.*[1], Ciotoli G.[2], Mori F.[2], Varone C.[2], Moscatelli M.[2] & Nisio S.[1]

[1] ISPRA, Roma. [2] Istituto di Geologia Ambientale e Geoingegneria, CNR, Roma.

Corresponding author email: livio.ruggiero@isprambiente.it

Keywords: natural sinkholes, mapping techniques, machine learning.

Sinkholes, often underestimated geological hazards due to their localized nature, present a direct threat to the vulnerability of aquifers, resulting in fatalities and property damage. Civil protection officials and urban planners encounter difficulties in forecasting the timing and locations of these sudden collapses. Developing a sinkhole susceptibility map becomes very important, necessitating an understanding of the controlling factors and spatial distribution patterns to mitigate adverse effects and implement strategic land use changes. This study aims to produce an initial sinkhole susceptibility map for the Italian region using a machine-learning modeling algorithm. Drawing on over 2900 cases from the ISPRA sinkhole inventory, we modeled sinkhole occurrences based on known presence locations. A conceptual model was devised, incorporating 10 conditioning variables (predictors), comprising seven continuous and three categorical variables. Dummy variables were derived from categorical ones, and the Variance Inflation Factor (VIF) was utilized to identify and eliminate predictors with minimal impacts on prediction quality, such as redundancy. Model accuracy was evaluated using receiver operating characteristic curves (ROC). SHAP diagrams were employed to spotlight factors strongly associated with sinkhole formation, encompassing the presence of CO_2 emissions, low elevation areas, clastic-alluvial sedimentary cover, seismicity, and high fault density. The resulting probability map for sinkhole occurrence delineated areas with very high and high susceptibility, notably the Padana Plain (northern Italy), the Thyrrhenian coast area from northern Tuscany to southern Campania, and the Umbria region. Integration with shape files of Italian municipalities facilitated the identification of areas with higher susceptibility, estimating the extent covered by different susceptibility classes. This comprehensive approach enhances comprehension and proactive management of sinkhole risks in Italy.

Autocompaction as a main driver of coastal depositional environments

Teatini P.*[1], Baldan S.[1], Cosma M.[2], Da Lio C.[2], Donnici S.[2], Ferronato M.[1], Mazzia A.[1], Minderhoud P.[3], Tosi L.[2] & Zoccarato C.[1]

Keywords: natural land subsidence, coastal depositional environments.

Natural environments such as coastal wetlands, lowland river floodplains, and deltas are formed by sediment, transported by watercourses and the sea, and deposited over century to millennium timescales. These dynamic environments host vulnerable ecosystems with an essential role for biodiversity conservation, coastal protection and human activities. The body of these landforms consists of unconsolidated sediments with high porosity and compressibility. Consequently, they often experience significant compaction due to their own weight, that is, autocompaction, which creates an important feedback within the geomorphological evolution of the landform. This work aims to provide a comprehensive 4D (i.e., 3D, including time) perspective to address this issue, incorporating data interpretation techniques and novel numerical modeling tools that account for the dynamic interplay of sedimentation and compaction. The novel NATSUB3D finite element model (Xotta et al., 2022) is used to simulate the evolution of two main case studies: the Mekong Delta in Vietnam (HIETE Project, funded by CaRiPaRo) and the salt-marshes of the Venice Lagoon in Italy (RESTORE Project, funded by PRIN PNRR 2022). To address the complexity of sedimentation-compaction history, we explored alternative methods for combining lithologic bore logs with sediment geochronological data. Through advanced interpolation techniques we derive delta-specific 3D sedimentation rate history that goes beyond the available spatial and temporal measurements. This new information, coupled with the geomechanical properties, forms the primary input to NATSUB3D. The simulator combines a 3D groundwater flow module with a 1D compressibility module to reproduce the Holocene delta evolution of a 3D domain using an adaptive finite-element mesh, properly simulating accretion and natural consolidation which govern the dynamic elevation evolution. The models are calibrated to match the present-day surface elevation and provide estimates of current natural compaction rates resulting from Holocene evolution. Furthermore, they can be used as tools to evaluate future compaction and consequent relative sea-level rise following ongoing sedimentation, sediment enhancing strategies, or sediment decrease following engineering intervention as the MoSE gate in the Venice Lagoon. The modeling procedure can be easily adapted to different deltaic/coastal environments with only minor modifications to accommodate site-specific data.

Xotta R. et al. (2022) - Modelling the role of compaction in the three-dimensional evolution of depositional environments, J. Geophys. Res. - Earth Surface, 127, e2022JF006590, https://doi:org/10.1029/2022JF006590.

Updated inventory of anthropogenic sinkholes in Naples (Italy)

Tufano R.*[1], Bausilio G.[1], Di Martire D.[1], Guerriero L.[1], Annibali Corona M.[1], Nisio S.[2] & Calcaterra D.[1]

Keywords: inventory, cavities, triggering factors.

Anthropogenic sinkholes, due to their spatial and temporal distribution, are among the most relevant issues in the densely urbanized municipality of Naples (Italy). Between October 2023 and March 2024, more than 15 events occurred in the city of Naples: among them the high-magnitude (i.e., high diameter and depth) event that occurred on 21 February 2024, while not resulting in any fatalities, once again drew attention to the importance for the municipality to have an adequate mitigation plan for such kind of geological hazard. For a comprehensive susceptibility analysis that aims to predict the spatial probability of the process, the inventory of anthropogenic sinkholes in the city of Naples has been updated including 316 new events in the period February 2010–March 2024. Considering the previous inventory of sinkholes in the city of Naples (Tufano et al., 2022), collecting events up to June 2021, the final consistency of the updated inventory is 504 sinkholes between 1880 and 2024. A systematic procedure based on i) analysis of media sources to identify the event, ii) field survey to define the correct location, iii) detection of size (i.e. diameter and depth), and where possible the triggering mechanisms, was carried out to catalog the most recent sinkholes. Based on such procedure, in the period July 2021-March 2024, 15 events have been collected through the examination of online newspapers and 28 from local daily reports. Including the information about these newly inventoried events, the triggering factor analysis reveals that 41.6% of sinkholes were triggered by rainfall, 13.9% by aqueduct and sewer leaks, 1.9% by maintenance works, while in 42.6% of cases the trigger remains undetermined.

The morphological analysis indicates a diameter median value of 1.5 m, and a depth median value again of 1.5 m, according to the data of previous inventory. However, although no variation was observed in the magnitude of the events, the spatial analysis reveals a migration of sinkholes occurrence in the western sector of the city (i.e. municipality 10 - Bagnoli, Fuorigrotta, and western sector of municipality 1 - Chiaia, Posillipo, S. Ferdinando) previously less affected by these instabilities. In this area, the network of underground cavities is less developed, so the increase in sinkholes can be mainly related to the progressive degradation of mechanical properties of tuff bedrock coupled with water infiltration action occurring during intense rainfall.

Therefore, it is important to continue with the inventory of these phenomena because, as highlighted by the number of the latest events, other sectors of the city are showing an increase in susceptibility for such phenomena.

Keywords: sinkholes, machine learning, GNSS monitoring.

A sinkhole, a naturally formed circular depression often linked to a complex underground drainage system, is a distinctive feature of karst landscapes. Our research focuses on the North-Western mountainous sector of FVG Region in NE Italy, specifically in the Alta Val Tagliamento Valley within the Enemonzo municipality, in the hamlet of Quinis. The study site rests upon alluvial fan deposits extending over the fluvial terraces of the Tagliamento River, with dissolution and subsidence processes favoured by the presence of Triassic and Permian evaporites, notably from the Carnian period, distributed throughout the valley. The Quinis area features a significant phreatic aquifer with substantial water table fluctuations, influenced by both effective infiltration and seepage from streams and rivers, exacerbating the phenomena.

Hydrological studies indicate high annual rainfall (1600-2000mm/y), contributing to subsidence risk. Even if it is a small village, within the years, Quinis experienced different types of collapse events. A slow surface subsidence pattern attributed to the gradual settling of surface materials through natural fissures and conduits within the bedrock, take to the formation of cover suffosion processes.

Sometimes sinkholes developed also as abrupt collapses as in 1960s when two impressive phenomena took place in correspondence of the Tagliamento riverbed. The dimensions were 15m in diameter and 10m depth for the first one occurred in 1962 and 45m in diameter and 15m in depth for the second one, occurred in 1964.

Several geophysical methods like ERT, 2D GPR, 3D GPR, Reflection Seismic, PS-InSAR, as well as hydrogeological investigations are previously used to study the phenomenon in this region. Currently, thanks to the GeosciencesIR PNRR project, further researches are ongoing in the area. A total station, equipped with a GNSS antenna, installed in the centre of the Quinis village will allow to record indirect data regarding ground displacements (vertical movements) by monitoring the benchmarks present on selected buildings. Inductive electromagnetic methods in the frequency domain will provide information on the presence of sinkholes in poorly urbanized areas by means of electrical conductivity maps at various depths down to about 10 m from the topographic surface.

The use of CTD divers (which record electrical conductivity, water level and temperature) allowed in the past and continue to give information about the groundwater fluctuations which are the engine of this type of phenomena in this area.

Finally, an attempt to construct a susceptibility map focusing on the inhabited area is realised by using machine learning techniques.

A research to study the unstoppable subterranean journey of microplastics

Balestra V.*[1-2-3], Fiorucci A.[1-3], Marini P.[1] & Bellopede R.[1]

[1] Dipartimento di Ingegneria dell'Ambiente, del Territorio e delle Infrastrutture, Politecnico di Torino. [2] Biologia Sotterranea Piemonte – Gruppo di Ricerca. [3] Underground Karst Laboratory of Bossea Cave – S.O. Bossea C.A.I.

Keywords: microplastics, caves, pollution.

Microplastics (MPs) are a global problem, contaminating remote areas too. However, different environments are poorly studied, such as subterranean ones and karst areas, despite the global drinking water sources and the environmental heritages. MPs can endanger the fragile subterranean ecosystems, be consumed or assimilated by animals, damage speleothems, and pollute karst aquifers.

The aim of this multidisciplinary research is to investigate MP pollution in waters and sediments in karst surface and subterranean environments from a geological, biological and environmental point of view, in order to monitor the state of ecosystems.

Samples from different European karst areas were collected and investigated, from show caves to unexplored caves, from surface watercourses to groundwaters. The sediments of three Italian show caves (Bossea, Borgio Verezzi and Toirano caves, Piedmont and Liguria. Italy) were analyzed, highlighting the presence of high amount of MPs along tourist paths and in speleological areas. Surface and subterranean waters of Bossea karst system showed MP pollution in all examined samples, underlining the importance of the entire aquifer karst systems monitoring, even susceptible to contamination by surface pollutants. Different protected aquatic surface (spring) and subterranean (caves) environments of the Classical Karst were analyzed in order to verify micropollution in habitats hosting particularly protected species such as the olm *Proteus anguinus*. All samples highlighted high values of MPs and anthropogenic microfibers. Sediment samples in not jet explored caves of Abruzzo region, Italy, were collected to verify MPs pollution even in underground environments not directly affected by human presence, showing still little threatened habitats by MP pollution. Samples from different caves in Herzegovina and Slovenia, and from Italian springs with different karst characterizations will be analyzed too, in order to understand MP transport in active karst systems and deposition in vadose zones. Other micropollutants linked to MPs will be analyzed too. Alongside, specialized hypogean crustaceans from Bossea karst system were analyzed in order to understand micropollutants ingestion even in subterranean habitats (Sforzi et al., 2024).

Karst areas and caves are one of the most important and well-known geological features in the world, fragile and unique ecosystems with an exceptional scientific, cultural and environmental value, as well as an important economic resource. Monitoring of these environments is fundamental for their conservation and to propose new strategies for the protection and conservation of karst habitats.

Sforzi L. et al. (2021) - (Micro-)Plastics in Saturated and Unsaturated Groundwater Bodies: First Evidence of Presence in Groundwater Fauna and Habitats. Sustainability, 2024, 16(6), 2532, https://doi.org/10.3390/su16062532.

Monitoring of lampenflora growth on speleothems exposed to LED lights in show caves

Balestra V.[1-2-3], Peruzzi A.[1], Marini P.[1] & Bellopede R.*[1]

[1] Dipartimento di Ingegneria dell'Ambiente, del Territorio e delle Infrastrutture, Politecnico di Torino. [2] Underground Karst Laboratory of Bossea Cave – S.O. Bossea C.A.I. [3] Biologia Sotterranea Piemonte – Gruppo di Ricerca.

Keywords: show caves, lampenflora, LED lights.

Speleothems, geological formations by mineral deposits that accumulate over time, are the major show caves attractions. However, they are often subjected to alterations linked to tourism, including the so-called "lampenflora". Lampenflora is a community of photosynthetic microorganisms, mainly diatoms, cyanobacteria, and green algae, which sometimes also include mosses, ferns and higher plants, carried into the cave by tourists, water, gravity, air circulation and animals.

Lampenflora development on speleothems in show caves is due to the installation of artificial lights, which allow the photosynthetic activity in an otherwise dark environment. The lampenflora growth causes physico-chemical and aesthetic damage to speleothems, and changes the subterranean ecosystem modifying the food chain and damaging the autochthonous organisms. Moreover, microorganisms activities can release acid substances that lead to the deterioration of the formations surface.

Although in recent years lampenflora presence has been increasingly monitored in show caves from a biological point of view, geological modifications on surface of speleothems are less studied, such as the impact of the new LED lamps. This work aimed to give operational indications after two-year of sutdies to verify lampenflora growth after the installation of LED lights systems, and evaluate changes in calcite crystal habits over time, due to lampenflora growing. Homogeneous speleothems slabs without lampenflora were used for the test, as natural substrate, totally compatible with the formations in the examined cavity. Different slabs were positioned in several points of the cave along the tourist paths, at different distances and angles from the LED lamps. In this work, first results applied to Bossea cave, Italy, were reported such as example of application of this protocol. The results of this preliminary study can be the starting point for future and more complete monitoring in show caves, useful for the protection of the geological and environmental heritages.

Technological innovation and environmental monitoring for the evaluation of the bearing capacity in tourist caves

Cossu Q.A., Arca B., Cinus D.*, Ferrara R., Arca A., Ventura A. & Duce P.

Keywords: showcave, carrying capacity, monitoring.

Environmental assets can be important economic resources for territories, but their management should be focused on the maintainance of the natural heritage, through adequate control procedures, which would allow keeping the impacts that may derive from their use within reversibility thresholds. In tourist caves, impacts are connected both to preliminar infrastructure interventions and to the ordinary attendance of visitors, which can potentially induce a modification of the natural conditions of the internal atmosphere, with several potential effects deriving from it, due to the introduction of warm air and in particular CO_2, emitted by tourists into the cave. Monitoring of this gas therefore becomes an indispensable measure to quantify such modifications and, together with a scientific approach that combines several applications provided by information technology, can allow the development of site-specific anthropogenic carrying capacity thresholds.

As part of the environmental monitoring actions carried out by the Showcave project in Sardinia, the volumes of cave atmospheres were estimated using 3D laser scanners. This data, together with other parameters related to CO_2, such as its natural background concentration in the atmosphere, the average human hourly production, and concentration thresholds preliminarily defined, for example using the EU indoor air quality guideline values (0.15%) and the recommended guideline values to preserve the geological component and for safeguar visitors (1%), allowed the assessment of site-specific anthropogenic loads in the project caves open to tourism (Nettuno, Bue Marino, and Su Marmuri caves).

The results of the analysis of the collected data and the estimates of carrying capacity illustrate a situation that may be critical for the Nettuno cave, with exceeding of both the daily (1,500 ppm) and seasonal (10,000 ppm) carrying capacities. However, monitoring data do not show critical levels of carbon dioxide for Nettuno and Bue Marino caves, as when the tourist flow stops at the end of the day, CO_2 levels return to natural values. Su Marmuri cave deserves greater attention instead, where, although flows remain below carrying capacity thresholds, the particular characteristics of the cave do not allow CO_2 to naturally flow out of the system; therefore any potential increase in tourist visits will need to be carefully evaluated in terms of carrying capacity thresholds. The work highlighted the capabilities of environmental monitoring tools and technologies, that can enable the objective assessment of several parameters useful for the sustainable management of caves.

Sustainable speleology and cave conservation

Caves, with their complex and intricate nature, are not only geological marvels but also delicate ecosystems teeming with life and can constitute cultural heritages susceptible to protection. However, human interaction with caves, driven by tourism, exploration, cultural and scientific interest, has brought forth a myriad of challenges for their conservation. This overview aims to dissect such challenges, explore the methodologies devised to mitigate human impact, and delve into the collaborative efforts, involving various stakeholders in safeguarding these unique environments. The challenges in cave conservation are manifold, stemming primarily from the detrimental effects of careless human activities. Graffiti, vandalism, littering, and inadvertent damage to geological formations pose significant threats to the delicate equilibrium of cave ecosystems, finely tuned over millennia. To address these challenges, the philosophy of minimal impact speleology is the guiding principle for cave conservation (Gillieson et al., 2022); it emphasizes responsible exploration practices aimed at minimizing anthropogenic disturbances (Capitanio et al., 2022). Techniques such as gentle cleaning, graffiti removal, and substrate-specific restoration methods may be employed to mitigate the impact of human activities while preserving the integrity of cave ecosystems (Werker & Hildreth-Werker, 2006). Additionally, promoting awareness among speleological communities and tourists is crucial for fostering a culture of environmental stewardship and responsible cave exploration. The recognition of caves as unique habitats supporting diverse flora and fauna is critical to cave conservation. Cave-dwelling species, adapted to the subterranean environment, are particularly vulnerable to disturbance caused by human activities. Thus, conservation efforts must prioritize the protection of these species, employing measures to minimize habitat disruption and mitigate the introduction of alien/invasive species. Collaboration among various stakeholders is essential for the success of cave conservation efforts. Speleologists, environmental conservation groups, local authorities, and local communities all play crucial roles in safeguarding these fragile environments. By pooling their expertise and resources, these stakeholders can develop conservation strategies tailored to the specific needs of each cave system.

In conclusion, cave conservation requires a holistic approach encompassing scientific research, community engagement, and sustainable tourism practices. By adhering to the principles of minimal impact speleology and fostering collaboration among stakeholders, we can ensure the preservation of these extraordinary environments for future generations. This overview underscores the urgency of prioritizing cave conservation and highlights the collective responsibility we all share in protecting these natural wonders.

Speleogenesis and hydrostructure development in conglomerate-dominated sedimentary sequences: the “Castel Sotterra” Cave

Fioraso M.*[1] & Riva A.[2]

[1] Dipartimento di Scienze Fisiche, della Terra e dell’Ambiente, Università di Siena.
[2] Dipartimento di Fisica e Scienze della Terra, Università di Ferrara.

Corresponding author email: m.fioraso@student.unisi.it

Keywords: speleogenesis, karst hydrogeology, conglomerate karst.

The Montello Hill is located in the south-alpine fold and thrust belt, which evolved from a foreland basin in Oligocene-Miocene to fluvial plain in the Neogene passing through an intense and rapid landscape evolution. The Montello hill represents an isolated low-elevation plateau, uplifted by the active Montello Thrust. The outcropping substrate is composed mainly by a succession of Pleistocene conglomerate beds alternated to sandstone and siltite layers. The relief has been sculpted by erosion of the Piave river, attested by the incisions of Biadene and Nervesa, and modified by karst processes. These latter are widely recognized in the epikarst, dominated by solution sinkholes and karst valleys, and underground. Well-developed multi-level caves form hydrological connections between the summit plateau and springs along Montello border.

The “Castel Sotterra” Cave is the most extended cave in the Montello Hill, ~ 7 km long and 125 m deep. The cave is the fourth largest cave in conglomerate in the world and its importance is related both to the possibility to investigate the bedrock geology and the speleogenetical processes in non-carbonate rocks. Along with exploration and topographic survey of speleological purpose, a sedimentological-structural investigation of the bedrock and underground climate data acquisition have been conducted.

The speleogenesis is primarily controlled by the lithology, due to different strength and the compositional heterogeneities of Pleistocene conglomerate’s matrix and pebbles, and by the presence of fracture networks. Multiple series of sub-horizontal inception horizons developed in meandering proto-conduit in fractured conglomerate beds. The enlargement of phreatic conduits and the successive entrenchment forming steep canyons is directly related to the interplay between landscape evolution and tectonic uplift. Large meandering conduits developed along fine-grained beds may contribute to the failure of large portions of the rock mass. Underground collapses are one of the most distinctive features in the evolution of conglomerate karst. Diffuse failures can intercept different cave levels and lead to the formation of new cave passages.

The cave is active in terms of geomorphological processes and neotectonics. Meander entrenchment, rock failure and offset along strike-slip faults are recognized. The bottom of the cave reaches the expected water table level, nevertheless the hydrologic connection with the main springs is yet to be proven. The presence of a karst phreatic zone is documented only at Forame and Casselon Springs, reaching about 20 meters of depth, but appears poorly developed elsewhere probably due to the high rate of tectonic uplift. The “Castel Sotterra” Cave represents an example of extremely fast landscape evolution, where Pleistocene fluvial deposits went through diagenesis and karstification in a short time due to Piave river incision and uplift by thrusting, impacting on groundwater circulation.

CALIGOLA: a project for enhancing the knowledge of underground archaeological sites in the Palatine Hill through the integration of geological and geophysical data with new technologies

Gaudiosi I.*[1], Livani M.[2], Simionato M.[1], Mancini M.[1], Tentori D.[1], Paolella L.[3], Gozzi M.[1], Pennica F.[1], Polpetta F.[1], Stigliano F.[1], Trapasso F.[1], Di Monda D.[4], Terzo M.[5], Argiolas F.[1], Croce P.[3], Piro S.[6] & Moscatelli M.[1]

Keywords: 3D model, virtual vs real, underground cultural heritage.

This work illustrates the activities carried out within the CALIGOLA Project, a research program funded by the Lazio Region and MUR (Minister of University and Research) with the goal of improving the set of skills and technologies dedicated to the protection and fruition of Cultural Heritage. Situated at the top the Palatine hill in Rome, the Central *Cryptoporticus* comprises hypogea structures that are the object of this investigation. They are part of a complex underground archeological site pertaining to the Domus Tiberiana, the first dynastic palace re-built by Nerone after the fire of 64 AD. To address the collapse and subsidence risk affecting the examined area, stabilization measures are necessary. These measures aim to consolidate underground anthropogenic and natural cavities, including water drainage tunnels and voids resulting from the extraction of building materials. In order to enhance our understanding of the geological risks faced by the monument, a 3D geological model of the superficial and shallow subsoil portion of the area, comprising the man-made structures and caves, was created. This model is based on the analysis and elaboration of a large amount of geological data, such as geological cross-sections, geological map and boreholes. Additionally, it incorporates the 3D model of the underground Central Cryptoporticus, obtained through laser scanning, along with geophysical data, such as new Ground Penetrating Radar (GPR) prospections, Electrical Resistivity Tomographies (ERT) and ambient noise measurements carried out during field work in 2023-2024. The 3D model also comprises geophysical and geotechnical data acquired over time on the Palatin hill (Mancini et al., 2014; Moscatelli et al., 2014). This novel methodological approach combines subsoil and laser scanning data for reconstructing precise, realistic, high-resolution, small-scale 3D models, beneficial for studying historically and\or archeological sites. In this case, it aids identifying instability factors concerning the structures and detecting new, unexplored underground cavities. The information derived from the use of velocimetric sensors capable of detecting the three components of motion in a wide range of frequencies and with high dynamics enrich this approach. Concepts from dynamic buildings identification have been adapted to characterize the dynamic response of the three excavated sections of the Cryptoporticus. Simultaneously, the digital representation of this Cultural Heritage has facilitated the development of a virtual model and game-based learning experience. This activity addressed a prestigious case study in the direction of disseminating knowledge of mitigation measures aimed at reducing the impact of disasters on Cultural Heritages (Gaudiosi et al., 2022). It may be meant as a new way to encourage the preservation and conservation of historical and archeological sites, aligning with the principles of the Nara declaration (NDWG, 1994).

Metals discharge from underground mine drainage of Argentiera Pb-Zn-Ag mine, NW Sardinia, Italy

Idini A.*[1], Masala O.[2] & Sanna L.[2]

[1] Dipartimento di Scienze Chimiche, Matematiche Fisiche e Naturali, Università di Sassari. [2] CNR-IGAG, Cagliari.

Corresponding author email: aidini@uniss.it

Keywords: acid mine drainage, CRM recovery, environmental mineralogy.

Mining activities have affected, even in ancient times, numerous areas of the national territory. The footprints of its presence are often evident and sometimes visually impactful, as exploitation of underground georesources implies the modification of the original environmental configurations. These changes can be both superficial and underground and involve a series of hazards that remain even when the activity ends. Among the risks associated with mining work, the pollution of superficial and/or deep aquifers stands out.

This study focuses on assessing the metal load discharged from the abandoned mineral district of the Argentiera (NW Sardinia, Italy). During the last century, this mine was one of the most important Italian silver ore body, associated with Pb-Zn-Ag-Sb sulphide mineralization. After the Roman open air mining works, the ore exploitation extended into several kilometres of interconnected underground tunnels. Its drainage is discharged through a gallery at 4 m asl along the coast into the Mediterranean Sea. From this artificial spring, currently partially occluded, a small stream characterised by water with a red colour with abundant precipitation of amorphous Fe(III)-(oxy)hydroxides flows out with a significant metal load.

At the sampling site, the physico-chemical parameters (pH, temperature, total dissolved solid) were measured with a portable Hanna HI 991301 probe. Water samples were collected in pre-cleaned bottles after 0.4-µm filtering and fractions for cation analysis were acidified with suprapure-grade 1% v:v of nitric acid 65%. Mine drainage has a temperature higher compared to the annual average air temperature (21.0 °C for water), conductivity (TDS) >4 mS/cm and the pH is <6.0. For metals composition, diluted water were analysed by inductively coupled plasma-optical emission spectrometry (ICP-OES) (Varian 710-ES). Among the major dissolved components, calcium (Ca) is the dominant cation, exceeding sodium (Na) concentration. Minor elements such as potassium (K), and silicon (Si) were detected. Results show that the mine drainage of Argentiera contains high concentrations of (Fe), magnesium (Mg), manganese (Mn), chromium (Cr), cadmium (Cd), arsenic (As) and very high concentrations of zinc (Zn). All these metals are potentially toxic elements and pose a serious risk of ecosystem contamination. On the other hand, Mn-Cr-Cd and As are recognised as Critical Raw Materials by the European Commission because of their strategic importance in green-transition technologies. Further investigation should be addressed to understand the environmental impact and to explore the viability of CRM recovering from this Acid Mine Drainage (AMD).

Karst and cave environment conservation in the Alta Murgia National Park

Mastronuzzi G.*[1], Fiore A.[2], Parise M.[1-3], Tropeano M.[1] & Tarantini F.[4]

[1] Dipartimento di Scienze della Terra e Geoambientali, Università di Bari "Aldo Moro". [2] SIGEA APS, Roma.
[3] International Union of Speleology, Postojna, Slovenia. [4] Parco Nazionale Alta Murgia, Gravina, Bari.

Corresponding author email: giuseppe.mastronuzzi@uniba.it

Keywords: karst, cave, conservation.

The karst environment, among the most fragile and vulnerable on Planet Earth, often hosts remarkable natural resources, thanks to the widespread network of caves that acts as a very special treasure chest where it is possible to preserve sediments, deposits, fossils and human remains that at the surface have been eroded or buried by weathering and the action of atmospheric agents. High fragility of karst is at the origin of severe impacts occurring on such environment, due to a variety of natural and anthropogenic processes (Gutierrez et al., 2014). Karst caves are therefore a precious place, to which explorers, cavers and scientists should approach only keeping well in mind their uniqueness, and the need to preserve as much as possible such delicate settings.

The Alta Murgia National Park, located in inland Apulia, covers a wide sector of Apulia region, entirely developing in karst settings, and hosts extraordinary sites of geological, palaeontological and anthropological interests. Among these, the limestone surface with thousands of dinosaur footprints at the Pontrelli quarry; the whole skeleton remains of a Neanderthal within the Lamalunga Cave, entirely covered by, and embedded into, calcite speleothems; and the Altamura Pulo, a huge collapse sinkhole that has become one of the symbol of the Park. Karst plays therefore a fundamental role in the geological relevance of Alta Murgia, and should be worth of particular care in the park management action, especially as concerns the need to protect the geological heritage. This is particularly true in the case of the Lamalunga Cave, since in recent years many attempts have been carried out, aimed at extracting from the cave part, if not all, of the skeleton. Even though such attempts were made in the name of "Science", and the need to fully study the remains outside of their environment, many doubts arise on the effective possibility to successfully carry out such actions, which inevitably will produce irreversible damage to the cave environment, and with high probability the destruction of the remains themselves. As scientists, geologists, cavers, and managers, we present in this contribution our clear position against such actions, and toward the need to preserve the cave system and the deposits therein preserved by nature, also taking into account the need to safeguard them for future generations.

Keywords: underground tourism, professional education, show cave management.

Tourist caves are among the most important geotourism resources in the world, attracting nearly 80 million visitors a year to more than 1200 sites. Some estimates of their economic importance report revenue of around 2 billion euros. Among the 50,000 natural Italian caves, several are suitable for touristic use and today over sixty natural cavities can be visited, attracting more than 2 million visitors every year. Despite these numbers, the management of tourist caves is currently not regulated and for this reason the International Union of Speleology (UIS) and the International Show Cave Association (ISCA) have drawn up guidelines on appropriate standards for the sustainable development of show caves. However, small local communities and public and private caves' managers have difficulty in applying these good practices.

Aware of this limitation, the training of qualified planners was tested within the doctoral school in Architecture and Environment of the University of Sassari with a course in "Tourist management of underground environments" offered to students of the master's degree in Urban, Environmental and Landscape Planning/Policy Development. This educational activity had the objective of providing essential environmental knowledge for the sustainable design and planning of show caves, giving students the opportunity to extend their skills on the cave habitat and its dynamics, as a cognitive tool for correct development of an underground tourist environment.

The course lasted 20 hours for 2 CFU divided into theoretical (14 hours in classroom) and field lessons (4 hours in a show cave). The course program discussed topics related to the origin and the physical features of the underground habitat and its ecology to give an environmental background to the students. The anthropic impacts linked to the tourist use of underground environments and how these must be monitored to prevent permanent damages of the landscape were addressed. Particular attention was given to the choice of the materials that must be used for both internal and external infrastructures (lighting systems, pathways, etc) and to the Italian legislation regarding the workers/visitors health in underground environment. Furthermore, the experience in a show cave provided the students with the opportunity to verify their acquired knowledge and to stimulate the in-depth analysis of the topics for the final examination that took place through a written report or slideshow presented for the suitability assessment.

This university course pursued the objective of show caves sustainability as educational contribution to the ecological transition in which the conservation of georesources is a necessary and transversal condition for the pursuit of the prosperity and well-being goals identified by the European Green Deal, with which this course shares the strategy aimed at protecting, conserving and improve the EU's Natural Capital.

Radon monitoring in underground workplaces. The case of Sardinia region (Italy)

Ruberti N.*[1], Esposito M.[2] & Sanna L.[3]

[1] Dipartimento di Architettura, design e urbanistica, Università di Sassari. [2] U-series.
[3] Istituto di Geologia Ambientale e Geoingegneria, CNR, Cagliari.

Corresponding author email: n.ruberti@phd.uniss.it

Keywords: radon survey, underground workspaces, indoor radon.

Among the main geological factors affecting human health there is the geogenic release of radon from soil and rocks that poses a serious risk of ionizing radiation exposure to the population. This natural radioactive gas can quickly diffuse underground and dissipate into the atmosphere or enter through cracks or open spots inside buildings, where it can be accumulated. In Italy, the indoor concentration of radon is regulated by Law 101/2020, which establishes a reference level of 300 Bq/m3 (200 Bq/m3 for dwellings constructed after 2024), expressed as the annual average value of radon activity concentration in the air. This regulation applies to indoor workplaces, specifically to all underground spaces. Measurements on the ground floor and in the basement are carried out only in the areas defined as at risk (the reference level is exceeded in 15% of buildings) by the Italian national and regional radon action plans. Currently, three Italian regions have an action plan in place to reduce the population's radon exposure. Since 2019, Sardinia has identified the radon priority areas with Dgr n. 7/49 including municipalities where the probability of exceeding the 300 Bq/m3 level exceeds 30% of the buildings, recently updated with the requirements of the national reference level (Dgr n. 20/71 of 2022).

Considering that the distribution of financial services over a region depends on population density and economic activities, in this study data from radon concentration measurements in some underground workplaces of different bank companies in Sardinia were analysed as a possible criteria for radon risk assessment. Radon activity measurements from 36 bank buildings located in 17 municipalities spread throughout the island were collected. The CR-39 detectors were exposed in a total of 262 indoor spaces, used by employees and/or accessible to the public. The duration of the monitoring was two or more consecutive periods (e.g., two semesters) to cover an entire solar year of exposure, otherwise, the dosimeter was directly exposed for an entire year. In some cases, multiple data were recorded for a single room, depending on its volume, and a weighted average of the different measurements was determined. The annual concentrations recorded in the last 10 years range from 8 to 1,630 Bq/m3. The analyses show that only approximately 6% of the monitored rooms exceed the limit set by Italian regulations. Among those underground workspaces that exceed the reference level, not all are located into Sardinian priority areas. Furthermore, data exploration shows that in some buildings there is high variability between rooms belonging to the same floor. These results hint at the difficulty of accurately predicting indoor radon concentrations and highlight the importance of performing radon monitoring to protect workers' and public's health.

Moisture on underground walls in abandoned mines as source of acid drainage

Sanna L.*

Istituto di Geologia Ambientale e Geoingegneria, CNR, Cagliari.

Corresponding author email: laura.sanna@cnr.it

Keywords: mine drainage, sulphate dissolution-precipitation, condensation water.

The mining exploitation over the centuries has led to several kilometres-long networks of underground tunnels dug into the rocks at different levels that now are an environmental challenge in remediation of abandoned mining sites. In fact, the interaction of groundwater with exposed mineralization could produce water pollution, one of the most important issue associated with mines' closure. The nucleation of secondary minerals over gangue and host rocks and the discharge of acid drainages are clear evidence of this process, that could have negative effects on terrestrial and marine ecosystems. Moreover, in metals sulphide ore bodies, mine drainages generally have a sulphate-dominated composition and are heavily contaminated with toxic elements that can persist for long periods. This latent environmental risk is to be expected for the abandoned mineral district of the Argentiera mine (NW Sardinia, Italy). Its Pb-Zn-Ag sulphide ore mineralization consists mainly of galena and blenda-bearing hydrothermal veins hosted in Palaeozoic phyllites, exploited up to 360 meters below sea level. Currently, the mine drainage outflows along the coast with a significant metals load discharging into the Mediterranean Sea. Within the ancient underground mining works secondary minerals cover seasonally mine walls as crusts, coatings and minethems. Their minerogenesis is related to precipitation from metals-bearing solutions by evaporation-driven oxidation of the polysulphides dispersed in the host rock and in dump materials that fill the mine voids. Most of the detected crystalline phases are ephemeral sulphates and the typical paragenesis is copiapite-melanterite-epsomite. The occurrence of secondary sulphates over mine walls and their dissolution-precipitation cycles were investigated by micrometeorological techniques. Continuous measurements of the underground temperature and relative humidity were compared with data of the external atmosphere. The sulphate minerals occurrence were detected by monthly field-work during winter that coincides with the time of relative humidity decrease. On the other hands, these salt efflorescence disappeared since the late spring, during the whole summer, and until November. For this period the underground atmosphere is over saturated in air water vapour and water droplets were observed on the mine walls. This rock moisture is related to vapour condensation brought by external air masses entering into the shallow part of the mine. As the interaction between condensation water and sulphide materials generates acid drainages that potentially increase the solubility of toxic elements, these results contribute to understand contamination pathways occurring at abandoned mining sites.

Disentangling natural signal from anthropogenic contribution in the temperature dynamics within show caves

Sanna L.*[1], Pusceddu C.[2], Sanna U.[2] & Floris G.[2]

[1] Istituto di Geologia Ambientale e Geoingegneria, CNR, Cagliari. [2] Gruppo Grotte Fluminese, Fluminimaggiore.

Corresponding author email: laura.sanna@cnr.it

Keywords: cave monitoring, sustainable management, cave microclimate.

Caves are natural underground spaces in the Earth Critical Zone with complete dark environment developed in rock. These confined habitats are characterized by a reduction in fluctuation amplitude of environmental parameters (such as temperature, relative humidity, air currents, food availability, water level, and so on), compared with surface landscapes. This feature makes karst systems a vulnerable environment where even minuscule differences can be a significant factor negatively impacting subterranean ecosystems. A baseline parameter for all studies related to evaluation of cave's vulnerability is the observation of cave air temperature trend, that thanks to the availability of better continuous monitoring devices with high frequency sampling and high accuracy and resolution can detect even low variability. Moreover, understanding cave temperature dynamics is of major importance for the improvement of sustainable management of show caves, in which anthropogenic thermal influences linked to tourism due to the heat brought into by the lighting system and human body can noticeably affect cave microclimate.

The aim of this study was to understand the impacts of both visitation and external atmosphere in Su Mannau, a show cave receiving around 15,000 visitors per year, in the Geomineral, Historical and Environmental Park of Sardinia (Italy). This cave system develops in Cambrian carbonates with large rooms and long tunnels for more than 8 km in length, with mostly horizontal profile and only few vertical drops. The first 600 m of the cave is equipped with tourist path for visits, opens seasonally from April to October. The underground air temperature was measured at 10-minutes intervals with HOBO U23 Temp/RH datalogger (accuracy: ±0.25°C; resolution: 0.04°C) at three different locations, two along the tour route and one in the wild part of the karst system, 800 m distant from the cave entrance. Data from cave atmosphere were compared to hourly air temperature from surface, measured within 100 m outside of the cave opening. Year-around monitoring at all cave sites shows both daily and annual temperature fluctuations that decrease increasing the distance from entrance. Daily temperature variations are less than 1 °C, a stable regime compared to nearby surface locations that in summer vary daily by more than 15 °C. Results show a direct correlation of cave and external temperatures during the warm season when the modification of the ventilation regime due to cave morphology causes the entrance of external air into the cave. This micrometeorological condition leads to a rhythmic daily oscillations in cave temperature, even in remote passages, strongly associated to the outside atmosphere but with a hourly delay. No anthropogenic source of temperature rise attribute to visitation was detected, except for a single occurrence in spring when tourist presence reached more than 500 units in only a day. Fortunately, the cave recovered during night closure.

A long-term analysis of mining-induced sinkhole activity in Gavorrano (Tuscany, Italy) by remote sensing and field data

Tinagli L.*[1], La Rosa A. [2] & Paoli G. [3]

[1] Studio Luca Tinagli Geologia. [2] Dipartimento di Scienze della Terra - Università di Pisa.
[3] CISUP - Università di Pisa.

Corresponding author email: ltinagli88@gmail.com

Keywords: mining-induced sinkholes, remote sensing, subsidence.

The failure of underground cavities and the formation of sinkholes is a major hazard at both active and dismissed mining areas that may cause important social and economic losses for the communities leaving nearby. Monitoring ground motions at mining area has been proved to successfully reduce the occurrence and the consequences of sudden sinkhole collapses. However, while most active mines are constantly monitored today, the ground instabilities around historical and dismissed mining areas often remain disregarded. In Italy, more than 2400 abandoned mines have been reported. In southern Tuscany (Italy), the Gavorrano area is a well-known mining district that was exploited during the 19th century for pyrite (FeS2) extraction. According to mining reports, the pyrite extraction was accompanied by underground failures of cavities, sometime followed by the formation of fractures at the surface. Today the area shows important evidence of sinkhole activity, with the major Monte Calvo sinkhole dominating the landscape of Gavorrano. However, the spatio-temporal evolution of the sinkhole phenomena, the relationship with mining, and the potential ongoing sinkhole activity in the area remained unclear. In this study, we used a multidisciplinary dataset of historical mining reports and maps, aerial images, high-resolution Digital Surface Models (DSMs), field measurements and InSAR observations to conduct a long-term spatial and temporal reconstruction of ground deformation around the sinkhole prone area in the mining district of Gavorrano. We identified the three sinkholes of Monte Calvo, Valsecchi, and Ravi, with the latter two never reported in literature. The three sinkholes have a spatial correlation with the underground cavities and galleries of major mines. InSAR observations between 2016-2022 also revealed that an area of ~ 700 m × 400 m around the Monte Calvo sinkhole is still subsiding with rates of ~5 mm/yr. Conversely, no clear evidence of deformation is observed at Valsecchi, Ravi, and the nearby city of Gavorrano. Our observations suggest that the sinkhole activity in Gavorrano has been induced by the mining activity in the area and that subsidence is still ongoing at Monte Calvo. The comparison between long-term and short-term deformation indicate that surface velocities are slowing down in Gavorrano and that the sinkhole is stabilizing. However, the occurrence of future sinking episodes cannot be ruled out if the underground stability conditions change for example after further cavities failures.

Relationship between air-rock-water temperatures in karst caves and surface temperatures

Vigna B.*[1-2] & Balestra V.*[1-2]

[1] Dipartimento di Ingegneria dell'Ambiente, del Territorio e delle Infrastrutture, Politecnico di Torino.
[2] Underground Karst Laboratory of Bossea Cave – S.O. Bossea C.A.I.

Corresponding author email: valentina.balestra@polito.it

Keywords: karst caves, monitoring, air-water-rock temperatures.

In karst caves air-rock-water temperatures are rather constant over time compared to the surface considerable thermal variations. The significant differences between the outside air temperatures and the in-depth ones, environmental parameters and karst system morphology, trigger the air circulation in the fracture networks. Air has a very low thermal inertia, therefore, if still, it quickly reaches a sort of equilibrium condition with the rock, assuming the rock temperature in absence of significant circulations. The greater thermal exchanges take place near the cave entrances, conditioned mainly by the speed of the incoming air flows. Into depth, temperature of the infiltration waters plays a dominant role in subtracting heat from the limestone masses, which have a lower temperature than the other rocks.

To better understand these processes, the Paleolab of Politecnico di Torino began a series of research through the installation of data loggers for air-rock-water temperatures monitoring in karst caves of southern Piedmont, Italy, characterized by very different environmental conditions. Almemo multiple-channel sensors with temperature probe (accuracy: 0,01; resolution 0,001°C) are used in Bossea cave, TinyTag sensors with temperature probe (accuracy: 0,02; resolution 0,001°C) are used in other caves. In collaboration with Arpa Piemonte, part of the project concerned the monitoring of cavities characterized by the presence of underground glaciers showed a rapid reduction in the last decade, linked to the increase in surface temperatures. In collaboration with S.O. Bossea C.A.I., another part of the project involved the installation of over 50 air-rock-water temperature probes at the "Giovanni Badino" Climatological Research Centre to examine the relationships between surface and in-depth temperature variations. Finally, in collaboration with the Speleo Club Tanaro, the third project concerns the temperatures monitoring of caves characterized by considerable air flows, for examine at different distances from the entrances the relationships between the air and the rock temperatures induced by these air circulations.

Anthropogenic impact assessment in show caves through environmental parameters monitoring

Vigna B.*[1-2] & Balestra V.[1-2]

[1] Dipartimento di Ingegneria dell'Ambiente, del Territorio e delle Infrastrutture, Politecnico di Torino.
[2] Underground Karst Laboratory of Bossea Cave – S.O. Bossea C.A.I.

Corresponding author email: valentina.balestra@polito.it

Keywords: showcaves, monitoring, environmental impact assessment.

As part of the national project PRIN SHOWCAVE, aimed at the study of the anthropogenic impact in show caves, environmental parameters were monitored in three important cavities (Toirano and Borgio Verezzi caves in Liguria, and Bossea cave in Piedmont, Italy). Air-water-rock temperatures and CO_2 air concentrations were detected every 10 minutes, groundwater level variations with hourly intervals.

Air temperature variations are significant not only to assess the tourist passage and light impacts, but also because they allow to understand the air circulation in the cavities. By placing temperature probes outside and at the entrances of the caves it is easy to observe periods with evident variations related to daily thermal fluctuations (intake phase). In the blowing phase, air temperature values remain rather constant over time, flowing air coming from deep areas of the cavity, characterized by a remarkable constant thermal values.

The three examined caves showed different situations. Bossea cave has a unique entrance (one-entrance circulation), and is characterized by several convective cells related to the cave morphology and the air cooling due to the inner collector. Toirano caves are two cavities (Bàsura and S. Lucia Inf. caves) connected through an artificial tunnel. The difference between the high and low entrances is about 20 m with a mild air circulation (multi-entrance cave), highlighted by the different temperature values detected at the two entrances. Borgio Verezzi cave has four entrances with an elevation gain of few meters which guarantees a mild air circulation (multi-entrance cave).

The monitoring of the CO_2 values carried out in the cavities showed a daily impact linked to the tourist passage, with an obvious temporary increases related to the number of visitors. However, the air circulation inside all monitored cavities allowes a decrease in CO_2 concentrations. Moreover, collected data highlighted a significant CO_2 air concentration of natural origin in each monitored cave. In Toirano caves, about 8,000 ppm of CO_2 were detected in a not-touristic area, coming from the deep karst networks. In the other two cavities, part of the CO_2 come from the depressurization of the waters circulating in the saturated network of the karst system, near the tourist paths.

Thanks to the data collected in three consecutive years, it was possible to evaluate a rather reduced anthropogenic impact in the three show caves.

List of endangered caves and karst, an initiative from the International Union of Speleology

Keywords: karst, cave, conservation.

Karst systems and caves are very precious places, hosting remarkable natural resources and historical and cultural heritage sites and remains. All people exploring such settings, including cavers and scientists, should therefore approach karst keeping well in mind the uniqueness of these sites, and the need to preserve as much as possible such delicate settings. Since many years the International Union of Speleology (UIS) has released a Speleological Code of Ethics, aimed at protecting caves and karst, that provides the basic information for responsible caving and scientific sampling. As a further action, UIS in collaboration with the International Union for Conservation of Nature (IUCN) recently released the second edition of the Guidelines for Cave and Karst Protection (Gillieson et al., 2022), furthermore reinforcing the issues above. In detail, as reported by the UIS-IUCN guidelines, any person wishing to undertake research in caves should be able to either demonstrate they are familiar with cave environments and the local Minimal Impact Caving Code, or that they are working with experienced cave scientists who will ensure adherence to the code, with an emphasis on minimal sampling methods for fauna, speleothems and sediments. All of this is especially true for caves located within reserves or national parks.

Preservation of caves, and of the karst environment as well, must be stressed also as concerns scientific research, which actions should always be carried out with extreme care, considering as main priority the conservation of the karst environment, and the fact that destruction of remains is an irreversible action, resulting in loss of part of the human and cultural heritage.

The UIS Bureau has recently created a working group dedicated to develop a list of endangered caves and karst, aimed at increasing the awareness about the necessity to safeguard the delicate and fragile karst setting, both at the surface and underground. Through information coming from the UIS Delegates in the many countries within UIS, we are collecting a variety of indication about karst sites worldwide that are in danger, or threatened, by human actions. These latter are often being carried out irrespectively of the peculiar nature of karst terrains, and of the remarkable importance of the resources therein contained, starting from groundwater. The main goal of such an activity is raising awareness about fragility of karst among the communities living in karst, and to carry out actions to inform people, and force land planners and managers to take into the due account the geological and hydrogeological peculiarity of karst.

Sharing seismological data related to historical earthquakes in Italy

Antonucci A.*, Rovida A. & Locati M.

INGV, Milano.

Corresponding author email: andrea.antonucci@ingv.it

Keywords: historical seismology, open data, open science.

Historical earthquake investigation in Italy has produced a huge amount of data on the seismic history of its territory. These data are collected and organised in ASMI, the Italian Archive of Historical Earthquake Data (Rovida et al., 2017), which today grants access to information on more than 6500 earthquakes that occurred in Italy and surrounding areas from 461 BCE to 2021 CE. ASMI collects and provides instrumental and macroseismic earthquake parameters from current and previous catalogues and macroseismic intensity data from different historical studies, together with their bibliographic metadata, with a total of 459 data sources. The multiple datasets provided for each earthquake can be easily compared for the compilation of the Italian Macroseismic Database DBMI and the Italian Parametric Earthquake Catalogue CPTI. ASMI represents the Italian node of the European Archive of Historical Earthquake Data AHEAD (Rovida & Locati, 2015), which in turn is the European node for the collection and distribution of historical earthquake data within the Seismology Thematic Core Service (Haslinger et al., 2022) in the framework of the European Plate Observing System EPOS. ASMI is accessible through a dedicated web portal that allows querying its content by either earthquake or data source. Through the query by earthquake, it is possible to select a single earthquake from a list. Once an earthquake is selected, all available information, in terms of parameters from earthquake catalogues and macroseismic intensities from archived studies, is displayed. Data from various external databases (i.e. Euro-Mediterranean Tsunami Catalogue EMTC, Italian ACcelerometric Archive ITACA) is also provided thanks to extensive use of DOIs identifiers and APIs (Application Programming Interfaces) allowing direct access to their content. The query by data source lists all bibliographic citations and grants access to the study as a PDF file, a link pointing to the original document, and a list of the investigated earthquakes. An alternative way for directly accessing ASMI data is through different web services according to the specific type of data (i.e. parameters, intensities, bibliography). Detailed earthquake parameters can be accessed using three distinct API standards: fdsnws-event, OGC WFS (Open Geospatial Consortium Web Feature Service), and OGC WMS (Web Map Service). Macroseismic intensity data can be accessed using a RESTful service providing a QuakeML 2.0 output. The bibliographic citation of data sources can be accessed using another dedicated RESTful service to output JSON, XML, and plain text format. In addition, a QGIS plug-in (QQuake; Locati et al., 2021) was developed to provide easy access to ASMI data when working with the QGIS software. Most features of ASMI were designed with the FAIR data principles, a step required for the adoption of the Open Science paradigm.

GeoChem: structure and tools of a database for geochemical data of volcanic areas

Cacciola L.*[1], Corsaro R.A.[1], Reitano D.[1], Federico C.[2] & Messina G.[2]

[1] Istituto Nazionale di Geofisica e Vulcanologia, Osservatorio Etneo, Catania.
[2] Istituto Nazionale di Geofisica e Vulcanologia, Palermo.

Corresponding author email: lucia.cacciola@ingv.it

Keywords: geochemical metadata, volcano monitoring, open science.

In the last decades, the advances in analytical chemistry and the development of techniques of sampling and measurements in the different geochemical spheres (lithosphere, atmosphere, hydrosphere, pedosphere), have significantly increased the amount of data (Jochum et al., 2005).

New additional information is required, first to make geochemical data reproducible and reusable (as requested by the FAIR principles) and, second, to broaden the use of applied methodologies of data collection and analysis. This work describes the design principles employed in creating a comprehensive conceptual scheme for a geochemistry database, fitting the wide range of geochemical data on fluid and rocks, obtained by in situ measurements and/or laboratory analyses. The main objective is to define a standard model for rock and fluid geochemistry, by introducing specific metadata, which consists of different macro levels, containing the sample information, different types of materials and a list of possible analyzed parameters organized in different category (Corsaro & Miraglia, 2020).

In the implemented database, the representation of gas and rock samples differs, principally, for types of materials and categories of the analyzed parameters. The implemented metadata model makes easier the scientific data integration and FAIR data management; furthermore, it contributes to Open Science using fields which have been already standardized by the scientific community (e.g. IGSN sample code). Finally, the model allows a fruitful organization of multidisciplinary data acquired for monitoring activity of volcanic areas (Puglisi et al., 2022).

The main effort of this work is focused in developing a data structure able to provide an efficient geochemical data management framework, available through web services (e.g. RESTful API). This structure gives access to a diverse range of geochemical data and products, and it is also compliant with the EPOS Data Portal requirements.

The CARG Project's experience in sharing geological data

Carta R.*, Battaglini L., Clemente F., Lo Faro S., Petricca P. & Schvarcz T.

Dipartimento per il Servizio Geologico d'Italia, ISPRA, Roma.

Corresponding author email: roberta.carta@isprambiente.it

Keywords: CARG project, PNRR, geological data.

The Geological Survey of Italy, through the CARG Project, produces the Geological Map of Italy at a scale of 1:50,000 and has so far produced about 280 geological maps and 30 geothematic maps, covering 45 percent of the national territory. Thanks to new funding, a new phase of activity has begun that will lead to the realization of geological coverage of about 60 percent of the Italian territory.

The products related to each geological map consist of Rasters, Explanatory Notes and Databases (Artioli et al., 1997; Battaglini et al., 2009). As part of the activities of WP2 - Geological and geothematic mapping and modeling within the PNRR - GeoSciences IR, it is planned to create services and app that make these data accessible according to FAIR principles. Geological Sheets and related Explanatory Notes will be identified through the assignment of Digital Object Identifier - DOI.

The geological databases of the single Geological Sheet, through data transformation and decoding procedures to make them interoperable in the context of different applications and uses, will be provided in open source formats, such as GeoPackage format, and for each of them the metadata will be filled in according to the RNDT standards, which will be followed by the assignment of the Digital Object Identifier - DOI.

The three products of CARG Project are then findable, downloadable and viewable, and through their identifiers it is possible to highlight their relationships with each other. Currently the Geological Database at the scale 1:25,000 is published on the Geological Survey Portal as a WMS service; after INSPIRE harmonization process, WFS and Atom download services, defined according to international standards (OGC), will be implemented.

Another of the products provided within PNRR - GeoSciences IR project is the app for viewing and querying the CARG geological maps. This is an application for Android and iOS mobile devices through which it is possible to view the Geological Sheets and consult the information contained in the databases. Contents related to geological and geomorphological elements and resources and prospecting are displayed.

In order to make this data more available, a new website is being developed to increase the accessibility of CARG data by users. These new web pages within ISPRA's institutional website, will provide access to the Geological and Geothematic Sheets of the CARG Project, the related Explanatory Notes and Databases, allowing visualization through map browsing, and downloading of products indexed through the DOI.

The geological knowledge, accessible through these platforms, provides an immediate and comprehensive view of the existing data in specific area, enabling further planning where necessary or filling information gaps and providing a fundamental tool for land use planning and actions.

Harmonization of the new release of Earthquake Environmental Effects Catalogue (EEE Catalogue) in the context of Research Data Infrastructures

Castorina G., Manganello P.L.*, Blumetti A.M., Guerrieri L. & Congi M.P.

Dipartimento per il Servizio Geologico d'Italia, ISPRA, Roma.

Corresponding author email: paololino.manganello@isprambiente.it

Keywords: EEE Catalogue, geopackage format, data harmonization.

The purpose of this work is the implementation of the new release of the EEE Catalogue (a database of Earthquake Environmental Effects), which will be accessible through the GeoSciences IR and MEET Research Infrastructures. In this regard, for the data that become part of such Research Data Infrastructures the harmonization in accordance with the INSPIRE Directive and FAIR (Findability, Accessibility, Interoperability, Reuse) principles is mandatory.

The EEE Catalogue is a database compiled at global level, collecting information about environmental and geological effects induced by recent, historical and paleoearthquakes, including primary effects (e.g., surface faulting, tectonic uplift), as well as secondary effects (e.g., ground subsidence, ground cracks, slope movements, liquefaction, tsunamis, hydrogeological anomalies). The observed relevance of EEEs as a major source of damage, in addition to vibratory ground motion, corroborates how the knowledge of these types of effects can be fundamental for seismic hazard and intensity assessment. Therefore, the EEE Catalogue can be regarded as an useful source of information for land planning, especially in areas of high seismicity.

The first version of EEE Catalogue was launched in 2011 and was designed in PHP (Hypertext Preprocessor) format. The structure of this catalogue is based on collecting data at three different levels of increasing detail, corresponding to three different layers: Earthquake, Locality, Site. The Earthquake features contain general information on the seismic event. The Locality features provide information on a specific locality where some coseismic effects have occurred. The Site features contain information at the site of each earthquake environmental effect. The structure of the catalogue is completed by Country features, consisting of point geometry. At present, the EEE Catalogue contains information on EEEs associated to 202 earthquakes, 1553 localities, and 4605 sites.

In order to facilitate worldwide compilation, the GeoPackage structure was planned to be used for the new version of EEE Catalogue. This structure represents an open and standards-based format for transferring geospatial information developed by the Open Geospatial Consortium (OGC). This format presents several advantages including platform independence, versatile data support, large storage capacity, and maintenance of relations between database tables.

Due to unchecked data entry the database underwent an initial review. Because of the requirement to enter new records into the database, new code lists were implemented, through which a specific database field is filled by a list of predefined attributes. The main challenge of the new release consists in the semantic standardization on the basis of standard vocabularies (e.g., INSPIRE, GeoSciML). The attributes which are not present in any standard vocabularies will be written and proposed on the INSPIRE Register Federation.

Advancing seismological and geodetic data management at the OGS

Cataldi L., Zuliani D., Barnaba C.*, Magrin E., Di Bartolomeo P., Bernardi P., Galvi S., Moratto L., Tunini L., Saraò A., Poggi V., Comelli P., Rossi G. & Picozzi M.

Istituto Nazionale di Oceanografia e di Geofisica Sperimentale - OGS, Trieste.

Corresponding author email: cbarnaba@ogs.it

Keywords: data management, seismology, geodesy.

The Istituto Nazionale di Oceanografia e di Geofisica Sperimentale - OGS houses a large amount of seismological and geodetic data, some of which gathered digitally since the mid-1990s. Within our archives lie diverse data types, including time series data, station metadata, and event metadata (bulletins), sourced from both permanent and temporary networks (Bragato et al., 2021; Priolo et al., 2015) . Currently, these data are accessible via various internal (e.g., Real-time Antelope, Oasis, http://oasis.crs.inogs.it, Rts, https://rts.crs.inogs.it, Frednet, http: //frednet.crs.ogs.it) and external services (e.g., EIDA https://eida.ingv.it).

The need to optimize internal data usage and improve user-friendliness, alongside our dedication to upholding FAIR principles in data sharing and preservation, has led us to develop a roadmap for data governance that we are ready to implement. This effort aligns with our strategy to leverage the capabilities of European Research Data Infrastructures (RDIs) to organize our databases systematically.

Our seismological data service is facilitated through the SeisComp Suite and embodies innovation and accessibility, marking a stride forward in seismological data management and dissemination. In this presentation, we introduce the state-of-the-art of seismological data services, which have been realized in alignment with the WebServices standards outlined by the International Federation of Digital Seismograph Networks (FDSN).

Additionally, we present the service related to the GNSS data and products (Tunini et al., 2024), which are recorded by the Friuli Regional Deformation Network and are distributed through a dedicated repository housed within our Institute. The repository is made accessible through the GNSS Linkage Advanced Software System (GLASS Fernandes et al., 2022), developed as part of the European Plate Observing System (EPOS) project. GLASS serves to collect, validate, and distribute GNSS data and associated metadata across Europe.

It is noteworthy that within this framework, our organization, OGS, oversees the Central and East European GNSS Node within EPOS (CEGNxEPOS), presently in a pre-operational stage (https://gnss-metadata.eu/site/distributor). Although still in progress, partial dataset retrieval is feasible. Completion of the full sharing procedure with CEGNxEPOS is anticipated by the end of 2025. Access to the node is currently available at http://gnssdata-epos.ogs.it.

The CARG project towards 3D geology: definition of standards for the construction, consultation, and distribution of three-dimensional geological models

Congi M.P.[1], Petricca P.[1], Castorina G.*[1], Tomassetti L.[1], Roccatello E.[2] & D'Ambrogi C.[1]

[1] Dipartimento per il Servizio Geologico d'Italia, ISPRA, Roma. [2] 3DGIS Srl, Padova.

Corresponding author email: giuseppe.castorina@isprambiente.it

Keywords: 3D geological models, CARG project, FAIR principles.

The Servizio Geologico d'Italia (SGdI), alongside traditional geological sheets and subsurface geological maps, is strongly promoting the production of 3D geological models. Indeed, in the framework of the CARG Project (Geological map of Italy at 1: 50,000 scale) and other projects participated by the SGdI, more than 35 geological 3D models will be produced in the coming years. To collect and distribute these models according to FAIR principles (Findability, Accessibility, Interoperability, Reusability), the SGdI is implementing the "Geological 3D subsurface models database" and the dedicated 3D web viewer "GEO-IT3D – Modelli geologici 3D in Italia". A three-dimensional model is a complex set of geometric, parametric, descriptive information, and their relational schemas. The challenge has been to define the model data structure to make it as simplified as possible, but at the same time comprehensive, well-constrained, and interoperable, to be adaptable to a wide range of users varying from professionals to local government agencies, to researchers. Furthermore, the web viewer extends also to non-geologists the possibility to navigate and interact with the geological models through tools for user-defined spatial queries (i.e. cross-sections, maps, and virtual boreholes). Here we present the data schema and file structure of 3D geological models that will be hosted on the SGdI database. The geological model consists of textual description files, geometry files (points, surfaces, volumes), and data tables with descriptive attributes, geometric and kinematic parameters gathered in a single archive. Parameters description adopts and possibly extends INSPIRE and GeoSciML Geology-based data model and codelists. The data schema and file structure, together with the implementation of controlled vocabulary, will benefit from the activities carried out in the Next Generation EU-funded projects GeoSciences IR and MEET. Dedicated ISOstandards-compliant metadata and DOI persistent identifier will guarantee the findability of the 3D geological models. Finally, the "GEO-IT3D" web viewer (https://geo-it3d.isprambiente.it/), developed in the framework of the CARG Project, will allow to access, navigate and query the 3D geological models in real-time, as well to carry out complex spatial queries by the users (i.e., synthetic borehole, vertical and horizontal sections). Models are also available for download through OGC APIs and are released under CC-BY open license.

How to organise a rock repository of volcanic samples: a proposal of metadata model

Corresponding author email: rosanna.corsaro@ingv.it

Keywords: rock repository, volcanic samples, metadata model.

Volcanological community manages different types of data which consist of continuous or discrete measurements and observations acquired by ground based networks and remote sensing instruments, or during field surveys and laboratory analyses. In particular, one of the activities performed during the fieldwork is the sampling of rocks.

A sample is a "physical object" which deserves to be archived before a part of it will be addressed to laboratory analyses. Therefore, the use of an international system, as the IGSN (International Geo Sample Number), which uniquely and globally identifies rock samples, is progressively spreading in last years. Here we design the structure of metadata for a rock repository of volcanic samples, which include most of the IGSN metadata, but integrate them with supplementary information thought for monitoring and research activities of the volcanological community.

The metadata structure that we propose comprises two types of descriptors. The "General Metadata" include the basic information of a sample, and the "Specific Metadata" deal additional details essential to characterise the volcanic context.

"General metadata" comprise information on the sample's identification, geolocation, collection and archiving.

"Specific metadata" encompass all the volcanological facets associated with various conditions and methodology of sampling. In particular, we treat: i) Syn-eruptive sampling: samples are collected during an eruption (or soon thereafter) and primarily consist of lava flows and pyroclasts; their study is crucial particularly for volcano observatories and Institutions in charge of the volcanological/petrological monitoring. ii) Stratigraphic sections: samples are from stratigraphic sections, which are vertical sequences formed by the accumulation of volcanic products. iii) Dredge: samples are collected during dredging operations, which are fundamental for characterising submarine volcanic structures and related products. iv) Boreholes: boreholes are drilled into the Earth's crust, penetrating the sedimentary cover to extract core samples, allowing the investigation of layers up to hundreds of metres below the surface.

The long-term curation of collected materials is an important investment for the future. As a matter of fact, it guarantees the possibility to preserve rocks in order to avoid repeated sampling, uses rocks that could be no longer sampleable, and allows to reproduce science by repeating laboratory analyses.

The aim of this work, based on discussion within the EUROVOLC project, is to provide the basic information for populating in the future a relational database for the description of different volcanic samples, physically located in different rock repositories and Institutions, in order to facilitate future sharing between different groups of scientists and more complete volcanological studies.

The Isotope Virtual Research Environment developed within ITINERIS Project: example of mixing modelling

Di Giuseppe P.*[1], Perrone E.[1], Gennaro S.[1], Agostini S.[1], Trumpy E.[1], Baneschi I.[1], Boschi C.[1], Cornacchia I.[2], Pennisi M.[1], Regattieri E.[1], Rielli A.[1], Salvadori M.[1-3], Vezzoni S.[1] & Provenzale A.[1]

[3] Dipartimento di Scienze della Terra, Università di Pisa.

Corresponding author email: paolo.digiuseppe@igg.cnr.it

Keywords: virtual research environment, isotopes, mixing modelling.

Applications of conventional (e.g., H, O, C, N, and S), as well as non-conventional stable (e.g., B, Li, Fe, Cu, Zn, and Mg) and radiogenic (Sr, Nd, and Pb) isotopes provide unique opportunities to evaluate deep geology and critical zone processes. One of the most important environmental issues affecting human development in the twenty-first century are represented by human-induced climate change, which can be successfully addressed using isotope compositions. A considerable number of studies have been published on isotope geochemistry applied to geological and critical zone processes, and their number is ever-growing. In the light of this, an inventory of stable and radiogenic isotopes becomes a fundamental tool to track processes involving fluids, minerals and rock evolution and origin, as well investigations on soils and plants and other pools.

A national database on environmental isotopes is still missing so far, and data and information still unfaire and scattered across various sources and institutions, generating difficulties in data and information recovery. In the framework of the ITINERIS Project (PNRR), the Work Package 8.9 is aimed at building the ISOTOPE Virtual Research Environment (VRE), which will pioneer the establishment of Italy's first comprehensive national VRE service encompassing the national database on stable isotopes. The new Isotope VRE incorporates tools for analysis, interpretation, and modelling services allowing researchers and Stakeholders to retrieve coordinated information and analysis tools.

One of the most common model to unravel biogeochemical processes consists of quantifying the contributions of multiple sources to a mixture, using isotope data along with chemical compositions. Given the isotopic compositions of diverse sources, isotopic mixing models can be used to calculate the relative source proportions. Here, we present a new application capable of calculating, quantifying, and showing the outcomes of two- and three-component mixing dynamics.

The first results demonstrate the great usefulness that the creation of the Isotope VRE can have in understanding processes occurring on Earth Systems such as mixing. Other mathematical approaches will became available soon. For this reason, the creation of the Isotope VRE is aimed to provide to the scientific community an isotopic data sharing set in a virtual research environment able to offer a series of powerful tools to understand and interpret environmental processes.

EIDA Italian node: seismic data curation preservation e dissemination

Fares M.*, Carluccio I., Danecek P., Della Bina E., Franceschi D., Mandiello A., Maniscalco M., Pintore S. & Tavani F.

Istituto Nazionale di Geofisica e Vulcanologia INGV, Osservatorio Nazionale Terremoti.

Keywords: quality, fairness, data life cycle.

The EIDA (European Integrated Data Archive) node hosted at Istituto Nazionale di Geofisica e Vulcanologia (INGV) holds more than 140 TB of seismological waveform data. A set of data curation practices are in place as a guarantee of a robust and reliable preservation and dissemination of quality data.

Archived data originates from a seismic network inventory and requires a continuous update of all station and network related metadata.

Our system has a modular design by leveraging, whenever possible, existing open-source solutions. Tasks are managed by adopting a customised ticketing system, for injecting and tracking the changes and managing any station's faults. The station metadata and channel responses are managed using an XML database to store StationXML documents natively and an implementation of the fdsnws-station web service standard is based on it. Our GUI leverages Grafana creating an intuitive dashboard to present an overview of the system status of all components.

We have deployed a Policy Enforcement Point in order to apply our policies and quality assessment before archiving any data.

Our preservation policy is also based on a replication (synchronised copy) at a long-distance storage (~200 Km) and a backup copy in a tape library.

The EIDA node run by INGV disseminates data through websites and webservices (https://eida.ingv.it/, https://webservices.ingv.it/).

To enhance our services for users we are adding significant computational resources and an adequate processing and analysis framework combining the open source Apache Spark and ObsPy, creating a "computational archive" where storage and computational resources converge.

MUDA: the dynamic geophysical and geochemical MUltiparametric DAtabase

Ferrari E.[1], Massa M.[1], Rizzo A.L.[2], Lovati S.*[1], Scafidi D.[3], Puglia R.[1], Varchetta F.[1], Figlioli A.[1], D'Alema E.[1], Mirenna S.[1] & Luzi L.[1]

Corresponding author email: marco.massa@ingv.it

Keywords: multiparametric monitoring, open data.

Nowadays increasingly consciousness on the interaction between tectonics and crustal fluids dynamics is lacking simultaneous monitoring of the relative key factors. Changes in water chemistry and levels, spring discharges, soil flux regimes (e.g., CO_2, CH_4, radon) and compositions of dissolved gases in water are well documented in the literature (e.g., Chiodini et al., 2020; Wang & Manga, 2021; Gori & Barberio, 2022), as being pre-, co- and post-seismic modifications as well as being markers of the local tectonic stress acting in the crust. However, geological differences among sites require specific knowledge of crustal fluids response to seismicity.

In this framework arose MUDA (geophysical and geochemical MUltiparametric DAtabase, https://muda.mi.ingv.it), a new infrastructure of the National Institute of Geophysics and Volcanology (INGV, www.ingv.it) serving geophysical and geochemical multiparametric data, designed and developed in the framework of Dynamic Planet-Working Earth project (https://progetti.ingv.it/it/pian-din).

MUDA is a dynamic and relational database based on MySQL with a web interface realized in php using a responsive design technique. The multiparametric data are stored and organized using a table-structure able of correlating different types of data that allow possible future integration with new type of data acquired through both real-time and off-line transmission vectors.

MUDA collects information from different types of sensors, such as seismometers, accelerometers, hydrogeochemical sensors, sensors for measuring the flux of carbon dioxide on the ground (CO_2), sensors for detecting the concentration of Radon gas and weather stations with the aim of making possible correlations between seismic phenomena and variations in environmental parameters.

MUDA daily publishes multiparametric data updated to the previous day and offers the chance to view and download dynamic time series for all available data and for different periods, up to a maximum of 30 days. For longer periods, users can request data to muda@ingv.it.

The research infrastructure of GeoSciences: from datasets analysis to harmonization process

Funaro M.*, Congi M.P., Campo V. & Manganello P.

ISPRA, Roma.

Corresponding author email: marina.funaro@isprambiente.it

Keywords: inspire, fair, harmonization.

Nowadays, the relevance of open data is growing widely as a consequence that their benefits and value are largely recognized. In this regard, research data infastructures have a key role for the assumption of the Open Science paradigm.

In this context, the GeoSciences IR project aims at creating a research infrastructure for the Italian Geological Surveys Network (RISG), which represents the coordination network between the Geological Survey of Italy, part of the Italian Institute for Environmental Protection and Research (ISPRA), and the Regional Geological Surveys. Different types of products will managed into the research infrastructure: datasets, metadata, services, vocabularies, publications, software, and applications. These products cover several issues: geological and geothematic mapping and modeling, landslides, sinkholes, hydrogeological risk mitigation, satellite and in-situ monitoring, active and capable faults, sustainable mining, and land use and consumption. For all the products that will become part of the GeoSciences IR the harmonization in accordance with INSPIRE Directive 2007/2/EC and FAIR (findable, accessible, interoperable, reusable) data principles is mandatory. Within the project workflow the work package 6 (WP6) is responsible for open data and data harmonization.

The WP6 purpose is collecting and analyzing all the datasets produced by the operating units of thematic WPs. All these datasets are subjected to an analysis to define process of semantic and geometric harmonization.

In order to achieve its objectives, the WP6 group is pursuising different actions: source data model and information content analysis, target data model analysis, mapping tables creation. The result is the final data model design (by going through semantic enrichment), dataset transformation, validation (INSPIRE validator) and sharing. Dataset and services metadata fallows same validation flow. Moreover, one of the major challenges of GeoSciences IR is represented by the semantic standardization on the basis of standard vocabularies (e.g., INSPIRE, GeoSciML). The dataset attributes which are not currently available in any standard vocabularies will be written and subsequently proposed to the Agency for Digital Italy (AgID), which maintains the INSPIRE Italia Registry.

This step is of crucial importance in order to provide users with homogeneous datasets having the same minimal information content at any level.

New tools for geo-scientific data management in the framework of the ITINERIS project leveraging D4Science e-infrastructure capabilities

Gennaro S.*[1], Di Giuseppe P.[1], Perrone E.[1], Agostini S.[1], Trumpy E.[1], Assante M.[2], Candela L.[2], Pagano P.[2], Procaccini M.[1], Coro G.[2] & Provenzale A.[1]

[1] Istituto di Geoscienze e Georisorse, CNR, Pisa. [2] Istituto di Scienza e Tecnologie dell'Informazione, CNR, Pisa.

Corresponding author email: simona.gennaro@igg.cnr.it

Keywords: D4Science infrastructure, VREs, data sharing.

Open Science is a cultural movement based on transparency, inclusion, research integrity, collaboration, and cooperative work, promoting an enhancing approach to science. Benefits are expected from this approach, although doing open science can entail a contrast with several barriers, including: (i) cultural factors (e.g., the fear of the loss of control of the datasets); (ii) cost-base factors; and (iii) disincentive factors (Assante et al., 2019; 2023). The effectiveness of the Open Science approach of a project can be enhanced by using the D4Science infrastructure. This infrastructure promotes collaboration and cooperative work with Virtual Research Environments (VREs).

As part of the ITINERIS Project, a comprehensive Italian Research Infrastructures (RDIs) hub in the geo-scientific and environmental fields is under development, in which teams with a high level of trans-disciplinarity are working on the development of thematic VREs for topics that includes: (i) Critical Zone (CZ) VRE; (ii) Aquatic Biomass services (BIOMASS) VRE; (iii) Crops, Plants and Pests services (CPP VRE); (iv) Essential Variables (EV VRE); (v) Aerosol-biosphere (AERO VRE); (vi) Carbon Cycle services (CARBON VRE); (vii) Indicators and Impacts of Climate Change (CLIMA VRE); (viii) Downstream Effects of Environmental Change (DOWNSTREAM VRE); (ix) Isotope Database (ISOTOPE VRE). VREs are based on the D4Science infrastructure, and their development is based on the needs of the scientific communities and the specific stakeholders identified by the researcher.

VREs are new eScience facilities that address scientifically and socially relevant topics, especially through the sharing of information and data produced. Research data and results products following international standards are managed and shared with the members of the VREs.

In this context, these D4Science enabled VREs will become tools supporting the entire spectrum of the research lifecycle. Specifically, for data collection (i) the Collaborative Storage Framework promotes teamwork among users and offers a collaborative space to share digital objects. For data analytics, (ii) the Analytics Engine Framework equips VREs with Cloud Computing Platforms. For data publishing, (iii) the Publishing Framework facilitates the dissemination of research outcomes by means of the Metadata Catalogue and the Spatial Data Catalogue, which help organise and make research results available to the broader scientific community.

Moreover, VREs are planned with a modular structure with semantic services for data discovery, harmonization and interoperability, and will contribute to share workflows, procedures and analysis tools which could be applied to analyse new datasets by the members of the VRE. Data from multiple sources, analysis and modelling tools will be integrated into the VREs, allowing users to gain insights into the problems at hand and add their data and analysis methods to respond to the changing scientific and practical needs.

GeoSciences IR: a cloud research infrastructure for regional geological surveys

Guerrieri L.*[1], Battistoni P. [2], Cipolloni C.[1], Passaquieti R.[1], Rizzo M.[1] & Sebillo M.[2]

[1] Dipartimento per il Servizio Geologico d'Italia, ISPRA, Roma. [2] Dipartimento di Informatica, Università di Salerno.

Corresponding author email: luca.guerrieri@isprambiente.it

Keywords: geosciences, research infrastructure, data harmonization.

GeoSciences IR is a data research infrastructure in the geological domain supported by PNRR recovery funds (M4C2 line 3.1), under implementation by a large consortium composed by 13 Italian universities and 3 research institutes, coordinated by ISPRA, Geological Survey of Italy.

The infrastructure aims at supporting Regional Geological Surveys (RGS), i.e. the local technical offices having a specific mandate on geological topics at regional and local level.

Through the GeoSciences IR Cloud Research Infrastructure (CRI), it will be possible to access to about 50 datasets and services, developed in accordance with the FAIR principles and the INSPIRE Directive, which require fully open accessibility, interoperability, and reusability. Users will be able to access also to innovative tools based on specific algorithms available for cloud data processing. A specific section of GeoSciences IR will be dedicated to e-learning modules built to increase the transfer of knowledge from scientists to target users.

The priority topics of GeoSciences IR have been identified by RGS and encompass various geological topics, including 2D and 3D geological mapping, marine geology, geoheritage conservation, geohazard mapping and monitoring, sustainable mining, and land consumption.

The infrastructure architecture has been designed based on the Agile methodology by selecting the most innovative system architecture solutions fitting with the users' needs.

Several cloud computing components and tools are being deployed, including virtual machines, containers, virtual labs for scientific development and collaboration, geospatial databases, integrated machine learning development, servers for providing network services for spatial datasets, and metadata; as well as a framework for managing semantic resources and easy access to APIs.

The implementation of a pre-operational version of the infrastructure including a prototype of the management software will be followed by the final version of the CRI ready for testing and validation procedures.

The hybrid architecture will allow the provision of data access services and analysis functions in the various GeoSciencesIR topics, as well as the permanent availability of virtual laboratory rooms that will facilitate the collaboration among researchers. Furthermore, through the platform, it will be possible to build FAIR products (metadata, data, scientific vocabularies, software codes for tools, open access publications).

The infrastructure will open in 2025 and will be maintained for at least 10 years. In this long-term perspective, a dialogue with external stakeholders has already started with the aim of building a reference infrastructure for geological data in Italy. Meanwhile, a constant interaction has been established with other existing research infrastructures available at European (e.g. EPOS ERIC, EGDI), and national level (e.g. MEET) to ensure their complementarity and identify eventual gaps and overlaps.

Fostering the Open Science paradigm and strengthening the European volcanology community: contributions of the Volcano Observations Thematic Core Service to EPOS ERIC

Indovina E.*[1], Cacciola L.[1], Domínguez-Cerdeña I.[2], Geyer A.[3], Guehenneux Y.[4], Júlíusdóttir R.[5], Komorowski J-C. J.[6], Labazuy P.[4], Nave R.[7], Puglisi G.[1], Reitano D.[1], Saurel J-M.[6], Spampinato L.[1] & Vogfjörd K.[5]

Keywords: data management, EPOS research infrastructure, volcano community building.

The European Plate Observing System (EPOS) is a Research Infrastructure committed to enabling excellent science through the integration, accessibility, use and re-use of solid Earth science data, research products and services, as well as by promoting physical access to research facilities. EPOS represents a unique example of a federated approach to integrating scientific data and fostering FAIR data management in the European solid Earth sciences contributing to Open Science. High-quality data require an effective and sustainable management over the entire data lifecycle. With this perspective, EPOS has foreseen the Thematic Core Services (TCSs), of which the 'Volcano Observations' TCS (VOLC-TCS) is one of the ten formally established. The main objective of the VOLC-TCS is the implementation of a technical, financial, and legal framework compliant with EPOS, to strengthen the European volcanology community. A community including Volcano Observatories and Volcano Research Institutions providing virtual and physical access to data, data products and services from volcanoes in Europe and European overseas territories. Over time the VOLC-TCS has consolidated a wide number of multidisciplinary services and granted access to a diverse range of data, products, and services via the EPOS Data Portal. VOLC-TCS thus contributes to fostering the paradigm of Open Science and to promoting FAIR principles within the European volcanology community by providing tools and resources that facilitate access, integration, and analysis of geoscientific data. The intrinsic heterogeneity of volcanological data, which has represented the richness of the TCS's offer, has also been one of the main challenges in the management of the service provision. Since some of the services used in volcanology are in common with other communities, (e.g. seismology, GNSS, geomagnetic, geochemistry, geology, etc.) a huge work effort has been performed to harmonise the VOLC-TCS's services with those standardised by the other TCSs. An additional important task has consisted of implementing the VOLC-TCS Gateway. Unlike the EPOS Data Portal, the Gateway also enables access to services not fully compliant with EPOS, or services provided by institutions outside the EPOS boundaries. This initiative aims to ensure the visibility of these services within EPOS and to set the stage for potentially integrating the VOLC-TCS with global-scale data infrastructures, such as WOVOdat.

The new version of ITHACA Catalogue supported by GeoSciences IR and MEET projects

Maceroni D.*[1], Castorina G.[1], Blumetti A.M.[1], Bonadeo L.[2], Comerci V.[1], Di Manna P.[1], Guerrieri L.[1] & Congi M.P.[1]

Keywords: active and capable faults, paleosites, geopackage.

The ITaly HAzard from CApable faults (ITHACA) Catalogue gathers information on capable faults affecting Italian territory. Capable faults are active faults able to produce significant and permanent dislocation and deformation at or near the topographic surface during strong or moderate earthquakes (e.g., IAEA, 2015; 2022). The dislocation (i.e., surface faulting) and deformation of the ground surface represent a geological hazard to be taken into consideration at the local scale, particularly in the most densely populated and industrialized areas. Consequently, the knowledge and precise spatial location of capable faults are crucial issues for seismic risk mitigation. ITHACA implementation started in the nineties, taking advantage of the knowledge derived from siting studies of critical infrastructure (i.e., nuclear power plants, gas and oil pipelines, chemical plants, etc.). The first version of the ITHACA Catalogue was launched in 2000, representing the starting point for continuous updating and implementing up to the present-day version, accessible through the following link: https://sgi.isprambiente.it/ithaca/viewer/index.html.

The focus of this work is to present the new release of the ITHACA Catalogue, developed in the framework of the GeoSciencesIR and MEET projects, both aimed at contributing to the creation of research infrastructure on a national and European scale. Following the goals of the projects and in agreement with the INSPIRE Directive, the new version of ITHACA has been implemented to be more compliant with FAIR (Findability, Accessibility, Interoperability, and Reuse) principles. The structure of the ITHACA database has been revised and improved, with the introduction of new sections and layers and the implementation of new and more complete code lists based on the semantic standardization of attributes following standard vocabularies (e.g., INSPIRE, GeoSCiML). A specific section dedicated to paleoseismological studies (paleosites), crucial and already present in the Catalogue but poorly populated, has been invigorated and enhanced. Finally, interoperability and data sharing are ensured through the publication of OGC standard services (WMS, WFS, and OFAPI). To simplify resource reuse, the dataset is also made available in GeoPackage format with open license attribution (CC BY 4.0).

The EPOS research infrastructure and its FAIR data management approach

Paciello R.*[1], Bailo R.[1] & Freda C.[2]

[1] INGV, Roma. [2] EPOS ERIC, Roma.

Corresponding author email: rossana.paciello@ingv.it

Keywords: fair, research infrastructure, data management.

The European Plate Observing System (EPOS, https://www.epos-eu.org/) is a research infrastructure that harmonizes and integrates multidisciplinary solid Earth data acquired through diverse scientific systems across several disciplines in the solid Earth domain.

In 2018, EPOS obtained the legal status of ERIC (European Research Infrastructure Consortium) from the European Commission (https://www.epos-eu.org/epos-eric) and it is currently integrating around 300 national research organizations from 26 European countries into a single distributed Research Infrastructure.

The EPOS Platform (https://www.epos-eu.org/dataportal), officially launched in April 2023, provides access to high quality-controlled data and services from ten different disciplines: Seismology, Near-Fault Observatories, GNSS Data and Products, Volcano Observations, Satellite Data, Geomagnetic Observations, Anthropogenic Hazards, Geological Information and Modeling, Multi-Scale Laboratories, and Tsunami.

To date, the EPOS Platform was visited by over 20,000 users, showcasing its ability to cross geographical barriers and attract a diverse international audience. Researchers spanning the globe converge on this platform to access scientific data and products, thereby fostering collaboration and facilitating knowledge exchange on a global scale.

The Platform is the result of a collective work carried out with a co-development approach. Over the last decade, an international team of about 600 experts has worked in synergy on the integration and harmonization of over 60 types of metadata from the various solid Earth science disciplines, thus enabling interoperability.

The Platform was developed by following a FAIR data management approach and using a combination of open-source technologies and standards. Based on the EPOS experience, in this contribution we present that approach, which by defining a clear roadmap for compliance with the FAIR principles, produced several best practices and technical approaches for sharing multidisciplinary solid Earth data and products to foster research and innovation.

Geological data from submerged areas: a national standardised and harmonised database

Paolillo A.*, Orefice S. & Fiorentino A.

Dipartimento per il Servizio Geologico d'Italia, ISPRA, Roma.

Corresponding author email: annarita.paolillo@isprambiente.it

Keywords: submerged areas, PNRR, database.

Many Italian local administrations have among their main tasks the mitigation of impacts of natural events on the territory through land planning and management, such as: (1) land use, focusing on natural and environmental landscapes, (2) georesources, in particular sand and mineral deposits, and (3) coastal hazards, focusing on erosion and tsunami phenomena.

The main information relating to submerged areas requested by local administrations is morphobathymetric data, obtained through the acquisition, processing and interpretation of geophysical data concerning the seabed obtained from multibeam and side scan sonar surveys. Moreover, additional information can be obtained by seismic and gravimetric surveys, by samplings and well logging.

A database for submerged areas was created also according to the needs expressed by local administrations. It is structured as the set of investigations that might be carried out during an oceanographic campaign. The information acquired is represented by vector data and is organised in relation to the three geometric primitives to be visualised in a GIS environment: (1) punctual, for the collected samples, (2) linear, for the navigation lines, and (3) polygonal, for the areas investigated. Furthermore, one or more tables with selected attributes have been associated with each vector type to better describe and characterise all possible information.

The relational database was developed within the QGis software, where it is possible to set and report the information within a geopackage, also defining the relationships between the "parent" tables (those specific to the spatial characteristics of a GIS software) and the "child" tables.

The final product is a shared national database, standardised and harmonised, with the possibility to look for information through a single access point, avoiding long and expensive searches for each type of dataset, which will comply with FAIR principles as well as, above all, with the INSPIRE directive.

Instrumental enhancement to study Mt Etna ecosystem: Carbon dioxide measurements using Eddy Covariance and flux chambers (PON-GRINT project)

Pennisi M.*[1], Baneschi I.[1-2], Vivaldo G.[1-2], D'Incecco S.[1], Raco B.[1], Donato A.[3], Lelli M.[1-5], Berton A.[1], Pieracci D.[4], Puglisi G.[5] & Provenzale A.[1-2]

[1] Istituto di Geoscienze e Georisorse, CNR, Pisa. [2] National Biodiversity Future Center, Palermo. [3] Istituto di Geoscienze e Georisorse, CNR, URT Messina. [4] West Systems Srl, Pontedera. [5] INGV, Catania.

Corresponding author email: m.pennisi@igg.cnr.it

Keywords: CO_2 fluxes, soil-atmosphere interaction, Mt Etna.

The PON-GRINT project, led by INGV, is aimed at strengthening the Research Infrastructures and Italian facilities involved in the EPOS implementation plan and defining possible expansions of data, products and services. IGG-CNR was involved in the project with the goal to investigate CO_2 fluxes at the soil-vegetation-atmosphere interface in the Mt Etna environment and assess the balance between volcanic and biological CO_2. Two fixed stations for measuring CO_2 soil emission and an Eddy Covariance system for measuring net CO_2 exchange in the Mt Etna ecosystem have been installed since december 2021 and April 2022, respectively. These installations are located in the Valle del Bove (Piano Bello, Milo) at 1100 m above sea level in a relatively flat area. The main wind direction is W-E, and permanent outgassing occurs from the four summit craters that are upwind to the stations. The area is dominated by the endemic Genista aetenensis.

Fixed CO_2 accumulation chambers are dedicated to the measurements of ecosystem respiration and consist of opaque automatic chambers with a diffusion infrared Vaisala sensors for CO_2 measurement, a data-logger and a sensor for the measure of soil moisture and temperature. Data on CO_2 flux are acquired at an hourly sampling interval (length of a single measurement = 4 minutes).The Eddy Covariance station allows to measure the net ecosystem exchange, and includes an enclosed path gas analyzer for the measurements of CO_2, H_2O, latent and sensible heat, a sonic anemometer for the measurements of wind and turbulence parameters, sensors for both the total and photosintetically active radiance, a thermohygrometer, a set of probes for atmospheric pressure, soil humidity and temperature. All the Eddy Covariance sensors record raw data at a sampling rate of 10 Hz, while final eddy covariance turbulent fluxes are computed as 30 minutes averages. Data are trasmitted by West Systems to the IGG-CNR server. In addition, field campaigns performed at both sampling sites by a mobile accumulation chamber in light and dark configurations allow to measure both gross primary production and ecosystem respiration, thus integrating previous techniques measurements. Data acquired from the new stations allow high temporal and spatial resolution of CO_2, H_2O, latent and sensible heatfluxes at Piano Bello. Moreover, since few Eddy Covariance towers are reported in the literature for active volcanic contex due to the harshness of the environment (Werner et al., 2003; Lewicki et al., 2012), the new installation at Mt Etna will represent a new innovative challenge in the national panorama.

The data will be of interest to the international community dedicated to the study of natural CO_2 emissions at the soil-vegetation-atmosphere interface, and will be integrated in EPOS. Our long-term goal is an interdisciplinary study of volcanic, biological, ecological, biogeochemical, climatic, and biogeographic aspects, including anthropogenic impact on the environment. The new activities on Mt Etna benefit from collaboration the Etna Park Authority and the Regional Department of Rural and Territorial Development in Catania.

Keywords: isotope vre, database, stable isotopes.

Over time, isotopic data have gained increasing significance in Earth Sciences, and their numerous applications have proved valuable across diverse research areas, mainly in Geology, Environmental Science and other disciplines belonging to Earth System Sciences.

The importance of understanding natural processes using isotope ratios points out the need of data sharing. Consequently, the Italian Integrated Environmental Research Infrastructures System (ITINERIS) Project started to build the Italian Hub of Research Infrastructures (Ris) in the environmental scientific domain with the aim to facilitate access to data and services while aiding the nation in addressing current and future environmental challenges.

The Isotope Virtual Research Environment (ISOTOPE VRE) represents the first Italian VRE that aims filling the gap of a national database on environmental stable isotopes. The final scope is to build the first Italian isotope database, wherein isotopic data will be collected and harmonized to promote and facilitate data sharing within the scientific community. Moreover, the ISOTOPE VRE initiative will encompass tools for analysis, interpretation, and modelling services allowing researchers and environmental managers to interpreting and modelling biogeochemical processes in the area of Environmental Sciences.

At present, the national database on environmental stable isotopes is integrated into a web application deployed within a dedicated D4science VRE. The web application is accessible via any web browser. The software architecture under development is based on three main tiers: (i) a relational database, which is designed for heterogeneous data collection, supported by a dedicated access software; (ii) a web services API (Application Programming Interface) designed to allow automatic interactions with other applications in a “Service Oriented” perspective; (iii) a single page web application providing end-users with an intuitive, friendly, responsive, and robust interface allowing them to easily access the main functionalities of the application, such as, for instance, data retrieving and processing. The software architecture relies only on open source technologies, featuring PostgreSQL as relational database, Java 11 as language for developing data access and the REST APIs, and Angular 14.3.0 with Bootstrap as development platform for the web user interface.

Sharing data on seismogenic faulting in Europe: the EDSF platform

Vallone R.* & Basili R.

INGV, Roma.

Corresponding author email: roberto.vallone@ingv.it

Keywords: seismogenic faults, IT infrastructure, Europe.

The European Databases of Seismogenic Faults (EDSF; https://seismofaults.eu) provides a centralised platform, initially designed in 2016, for accessing and utilising datasets on European seismogenic faults proposed and elaborated by the scientific community in dedicated research projects. This platform contributes to improved earthquake hazard analyses across the Euro-Mediterranean region in the framework of the European Facilities for Earthquake Hazard and Risk (EFEHR), one of the three pillars of the Thematic Core Services (TCS) Seismology (Haslinger et al., 2022) within the European Plate Observing System (EPOS). The current data resource at the European scale is the European Fault-Source Model 2020 (EFSM20) (Basili et al., 2022), alongside its predecessor and regional-scale products.

The EDSF platform leverages a robust IT infrastructure - named SEISMOFAULTS.EU - for data storage, dissemination, and discovery (Vallone & Basili, 2023). Open Geospatial Consortium (OGC) compliant web services facilitate seamless integration with almost all Geographic Information Systems (GIS) software. In addition, EDSF adheres to FAIR data principles, while a Data Quality Assurance (DQA) procedure guarantees data accuracy and consistency. A comprehensive Data Management Plan (DMP) outlines the data lifecycle management practices at the level of the platform and of the individual datasets. Detailed metadata following international standards is stored in the official Open Data Portal of INGV (https://data.ingv.it), ensuring data discovery, retrieval, and understanding. Each dataset is assigned a unique Digital Object Identifier (DOI). Licenses, typically Creative Commons Attribution 4.0 International, govern data use.

The SEISMOFAULTS.EU infrastructure also guarantees that the EDSF datasets are distributed through the EPOS multi-disciplinary Data Portal (Bailo et al., 2023), fostering interoperability and integrated access to solid Earth science datasets. At the Italian level, EDSF is integrated with and supported by the EPOS Italia Joint Research Unit.

Overall, EDSF is vital for researchers, engineers, and policymakers working on earthquake hazard analyses. The platform's maturity acquired over the years, commitment to FAIR data principles, capabilities of a robust IT infrastructure, and integration with EPOS promote the further integration of additional datasets stemming from current (e.g., MEET) and future projects.

Integrating geophysical models and numerical simulations to study the dynamics of the active geothermal system of Vulcano island (Italy)

Califano C.*[1], Salone R.[2], Troiano A.[2], Di Giuseppe M.G.[2], Isaia R.[2] & Di Maio R.[1]

Keywords: geothermal degassing systems, geophysical models, numerical simulations.

The island of Vulcano (Italy) is the exposed summit of an active composite volcano in the southernmost sector of the Aeolian archipelago. It has experienced many eruptions in historical times, including at least three phreatic events. Since the last eruption between 1888 and 1890 AD, Vulcano has been characterized by periodic episodes of unrest. In September 2021, significant variations in geochemical and geophysical parameters, routinely monitored by the INGV, indicated an increased influx of magmatic fluids into the shallow geothermal system. These changes included variations in the chemical and isotopic composition of gases, rising temperatures in fumaroles and increased soil gas emissions in the La Fossa crater area, as well as associated ground deformation and micro-seismicity (Federico et al., 2023). Consequently, the alert level for Vulcano was raised to yellow.

This study aims to elucidate the fluid dynamics and the mechanisms driving Vulcano's active geothermal system. To achieve this goal, we propose integrating geophysical models with geological and geochemical constraints to construct an accurate three-dimensional petrophysical model of the study area. Specifically, a 2.5 km depth magnetotelluric tomography (MT) carried out in 2022 (Di Giuseppe et al., 2023) provided us with the fundamental information regarding the main volcano-tectonic structures of the caldera and the circulation of the geothermal fluid. By adopting a conceptual model of the island derived from the MT results, integrated with geochemical and geological data, we reconstructed the thermodynamic steady state of the system through the use of the TOUGH2 numerical code (Pruess et al., 1999), highlighting the physical processes occurring in the system and their temporal evolution. This approach allowed for estimating fluid distribution in terms of pressure, temperature, and vapour phase saturation, describing the volcano's current state.

Vegetation cover dynamics in the Mediterranean region: a spectral-based assessment of the riparian vegetation patterns

Castronuovo R.*, Borghetti M., Ferrara A.M.S., Spatola M.F. & Nolè A.

Dipartimento di Scienze, Università della Basilicata, Potenza.

Corresponding author email: rossella.castronuovo@unibas.it

Keywords: Riparian vegetation, ecological dynamics, environmental changes.

Riparian areas worldwide are valuable ecosystems whose dynamics are strongly related to socioeconomic context. Riparian vegetation represents an extremely important ecosystem component, which ensure water supply, erosion prevention, riverbank strengthening and ensuring biodiversity protection and restoration (Dufour et al., 2019). In the last decades, climate changes and extreme drought events have particularly affected Mediterranean regions, inducing marked alterations in wetlands and threatening their functioning. The multitemporal analysis of riparian vegetation patterns provides a better understanding of riparian ecosystem resistance or vulnerability (Mahdianpari et al., 2020). We assess the spatio-temporal evolutionary trends in riparian vegetation cover in the Mediterranean Bioregion using 20 years of Landsat based Normalized Difference Vegetation Index (NDVI), analysed in Google Earth Engine (GEE). Non-parametric Mann-Kendall and Theil Sen tests were performed to assess statistically significant NDVI trends. Results showed a constant and significant increase in NDVI values over time on 57% of the study area (@ 900.000 ha). Growth trends, evenly distributed throughout the study area, could be driven by several factors including: reduction in river flow and flooding; local land management practices and policies (dams, water extraction facilities for agriculture or humans uses); establishment of biodiversity reserves and increased environmental protection measures; post-fire recolonization; socio-economic changes and land abandonment of marginal areas and demographic decline. Almost 700.000 ha shown non-significant changes, represented by riparian zones with full vegetation cover falling in narrow areas and high slope classes, interfaces zone subject to flood, artificial embankments, or areas that underwent urbanization during the period covered by the analysis. Here positive or negative trends detected are not significant over time. Decreasing trends were detected in area characterised by deviations or slight displacements of the river course, near anthropic activities linked to riverbed mining or to new management practices related to agriculture (greenhouses, farming installations) or to river management (bridges, dams, new riverbanks). Climate change is certainly one of the driving factors of increasing NDVI trends; the widespread increase in temperatures and drought conditions, contributes to changes in hydrological regimes and decreases in water surface availability and thus generating favourable conditions for vegetation expansion and colonization. Riparian vegetation cover patterns represent an interesting example of ecological feedback to environmental and socio-economic drivers within a climate changing scenario. More in depth analysis will investigate the impacts of hydrographic, climatic, topographic and socio-economic variables affecting riparian vegetation patterns and ecosystem resilience.

Probabilistic hazard modelling of the non-volcanic gas emissions of Mefite d'Ansanto, Southern Italy

Dioguardi F.*[1], Chiodini G.[2] & Costa A.[3]

[1] Dipartimento di Scienze della Terra e Geoambientali, Università di Bari "Aldo Moro". [2] The Lyell Centre, British Geological Survey. [3] Istituto Nazionale di Geofisica e Vulcanologia, Sezione di Bologna.

Corresponding author email: fabio.dioguardi@uniba.it

Keywords: probabilistic hazard modelling, atmospheric gas dispersion, natural gas emission.

The emission of gas species dangerous for human health and life is a widespread source of hazard in various natural contexts. These mainly include volcanic areas but also non-volcanic geological contexts. One of the most notable examples of non-volcanic gas emissions is the Mefite d'Ansanto area in the Southern Apennines in Italy. Here, significant emissions of carbon dioxide (CO_2) occur at rates that make this the largest non-volcanic CO_2 gas emission in Italy and probably of the Earth. Given the morphology of the area, in low-wind conditions a cold gas stream forms and spreads in the valleys surrounding the emission zone. This process proved to be potentially lethal for humans and animals in the past. In this study we present a gas hazard modelling study that considers the main specie, that is CO_2, and the potential effect of the most dangerous one, which is hydrogen sulphide (H_2S). For these purposes we used VIGIL, a tool that manages the workflow of gas dispersion simulations specifically optimised for probabilistic hazard applications. We produced maps of CO_2 and H_2S concentration and persistence at various exceedance probabilities considering the gas emission rates, their possible range of variation defined in previous studies and the seasonal control.

Enhancing the assessment of underground cave stability through machine learning-driven mechanically-based methods

Fazio N.L.*[1,2], Sollecito F.[1,5], Lollino P.[3] & Fazio V.[4]

[1] Geotechnical Engineer formerly CNR-IRPI, Bari. [2] Istituto di Ricerca per la Protezione Idrogeologica, CNR, Bari. In the recent years, sinkhole hazard related to man-made underground caves has increased in the Italian territory, with important consequences in terms of human lives as well as damages to the anthropogenic environment. Such man-made caves have been generally dug within very soft porous rock formations, as for example the calcarenite deposits, even at shallow depths, and later on abandoned. The low values of the mechanical strength of such rocks, along with their susceptibility to weathering and consequent strength degradation, make these rock masses prone to the sinkhole development. In order to develop a speditive but mechanically-based method to assess the stability of man-made caves based on the cave geometrical features and rock mechanical properties, an enhanced formulation of the abaci initially proposed by Perrotti et al. (2018) has been recently proposed by Mevoli et al. (2024), which introduces the feature to evaluate also the range of the cave safety factor. In this perspective, the application of the abaci can be used as a quantitative tool to assess sinkhole hazard in a preliminary way, to be used in analyses at wide scale, and, eventually, followed by detailed and advanced studies at the local scale.

Based on this newly-developed version of the abaci, a data-driven approach was employed to compare and discuss the results obtained from the direct application of the abaci. The selected method, proposed by Giustolisi & Savic (2006), and known as 'Evolutionary Polynomial Regression', is based on the paradigm of genetic programming and returns simple functional relationships, namely polynomials of elementary functions, among the considered physical parameters. In particular, it generates a Pareto front of expressions that considers simplicity and accuracy. This allows the results of the data modelling approach to be interpreted, thereby maintaining focus on the physics of the phenomenon under investigation, as outlined by Fazio et al. (2024). The results will also show how these machine learning techniques can be used to provide mathematical formulations that can be easily used in the field by experts involved in assessing the stability of underground cavities.

3D limit equilibrium analyses for landslide susceptibility analyses at the urban area scale

Fazio N.L.*[1,4], Lollino P.[2], Mevoli F.[3], de Lucia D.[4] & Ugenti A.[4]

[1] Geotechnical Engineer. [2] Dipartimento di Scienze della Terra e Geoambientali, Università di Bari "Aldo Moro".
[3] Istituto di Ricerca per la Protezione Idrogeologica, CNR, Perugia.
[4] Istituto di Ricerca per la Protezione Idrogeologica, CNR, Bari.

Corresponding author email: nunziolucianofazio@hotmail.it

Keywords: urban scale landslide susceptibility, slope stability, 3D limit equilibrium method.

As detailed in the 2021 Report on Hydrogeological Instability in Italy (Trigila et al., 2021), a significant proportion of Italian municipalities are vulnerable to natural hazards such as landslides, floods and coastal erosion. In particular, the region of Puglia in south-east Italy, and in particular the north-western sector of the Daunia Apennines, faces various geohydrological threats, with landslides being a prominent concern. This widespread risk highlights the need for the development of reliable quantitative methods for the assessment of landslide hazard at different scales, in order to allow the establishment of effective land use planning and risk mitigation strategies.

This study presents a physically based method for assessing landslide susceptibility at the urban area scale, taking into account both shallow and deep instability processes that affect almost all urban areas in the Daunia Apennines. The approach was tested in the municipality of Carlantino (FG), where geological and geomorphological maps, together with soil physical and mechanical data, were used to construct a comprehensive three-dimensional geotechnical model. This model, covering an area of 2.5 km², includes both the urban area of Carlantino and the surrounding slopes.

A subsequent three-dimensional limit equilibrium analysis considered equilibrium conditions in both slip and transverse directions, leading to the production of a map showing safety factors for the area. By analysing three different scenarios based on different assumed groundwater table depths, the study identified zones of increased landslide risk, characterised by lower safety factors.

The results, validated by comparisons with field and remote sensing data, demonstrate the effectiveness of this methodology in supporting landslide hazard assessments. This technique not only facilitates immediate and informed land use decisions, but is also adaptable to similar geological settings, increasing its applicability to broader regional planning.

Comparative soil-to-plant fractionation of Rare Earth Elements in chlorophyll-deficient wheat mutants

Ferroni L.*[1], Tassinari R.[2], Martina A.[1] & Marrocchino E.[1]

[1] Dipartimento di Scienze dell'Ambiente e della Prevenzione, Università di Ferrara.
[2] Dipartimento di Fisica e Scienze della Terra, Università di Ferrara.

Corresponding author email: mrrlne@unife.it

Keywords: REEs, soil to plant, ICP-MS.

The concentrations of Rare Earth Elements (REEs) in soils reflect those of the geological substrate of origin, and their bioavailability depends on soil pH, organic matter and weathering conditions, as well as on relatively low mobility of REEs as compared to other elements. Although some beneficial effects of REEs have been reported in plants, the REEs do not play any known specific role (Gonçalves Egler et al., 2022). Accordingly, plants do not have specific root absorption systems for lanthanides, which are absorbed approximately proportional to their concentration in the soil, likely using calcium channels (Tao et al., 2022). With the exception of Eu, for which plants tend to show a low affinity, it is generally assumed that the different REEs do not undergo element-specific fractionations from soil to leaves, but all merely decrease in concentration. Consequently, the relative proportion of REEs in leaves is expected to be almost the same as in the soil, i.e., the leaf/soil concentration ratio should be very similar for each REE. In this work, the REEs concentrations have been analysed in a soil parcel of the Botanical Garden of Ferrara and compared with that in leaves of a minipanel of four bread and four durum wheat lines, each comprising the wild-type cultivar and three chlorophyll-deficient mutants (Colpo et al., 2023). The mutation affects with variable severity the absorption of Mg, which is promoted in the mutants, the element being required for the chlorophyll synthesis. Analysis was conducted by inductively-coupled triple-quadrupole plasma-mass spectrometry (QQQ-ICP-MS) with special reference to REEs. As expected, it was found that in the soil samples the lanthanides with even atomic numbers were more represented than the adjacent odd atomic numbers, and the overall concentrations decreased according to increasing atomic numbers. In wild-type leaves, the same general trends were also found, but with two noticeable anomalies: selective absorption of Eu and selective exclusion of Tm. In general, the mutants tended to accumulate more REEs in relation to the severity of chlorophyll depletion. Concerning Eu, there were no consistent changes in the mutants, while the selective exclusion of Tm was instead completely lost. At the extreme, the most severe mutant absorbed REEs without any selectivity. These results indicate that the common assumption about the absence of element-specific fractionation of REEs during plant absorption and translocation cannot always be met, and therefore should be verified case by case.

Keywords: sustainability, mining industry, research infrastructure.

European policies such as the Green Deal, Agenda 2030, and Next Generation EU mark the transition of European countries towards a new economy based on fostering growth according to sustainability, circularity, and energy transition criteria. In this context, the mining industry, which significantly alters the landscape, can be considered sustainable if the concept of transforming to enhance initial conditions is integrated. Since the modern technological industries require several raw materials that are difficult to recover through recycling, Mining activity plays a role in energy transition. A series of tools and certifications have been proposed for supporting the sustainability of industrial processes, for monitoring the social and economic impact of product life cycles and to guarantee consumers regarding greenwashing practices. The mining industry has also embraced this trend and create a Sustainable Development Goals systems and research projects for the enhancement of convenient and eco-friendly solutions (such as Smart Exploration, PACIFIC, and NEXT, etc.).

The problem of the sustainability of the mining industry focuses on the implementation of mining plans. The sustainability challenge of the mining industry focuses on the implementation of mining plans that which concern deposits covering a very large areal extension and are framed in specific Mining Activity Plans managed at regional level. These plans are designed based on urban planning criteria committed to restoration, change of land use, and preservation of the landscape context. However, if planning is aligned with the directives of the Green Deal, which introduces the concept of "acting to improve," the extractive activity plan must be able to assess the correct balance between transforming the territory for national or international economic purposes, within the framework of actual interactions with the industrial production fabric, the pre-operational level regarding environmental, social, and economic degradation of the territory. Giasone is a multiparametric method integrated within a GIS environment with which it is possible, using overlay mapping systems, to propose a series of scenarios to asses the sustainability degree of a project as indicated by the Green Deal directives. It was born as an ideal practical application within the GEOSCIENCES IR research infrastructure. The evaluation is based on a quantitative analysis of the geological, naturalistic, and environmental characteristics of the territory, determining the "naturalness" status of places. Based on this premise, territorial planning will be designed, at the scale of the Extractive Activity Plan, to mitigate degradation and achieve improvement in the context of the broader area, in terms of environmental recovery and/or socio-economic conditions. The use of the GIS system as a multidisciplinary analysis tool, based on geographical and socio-economic data, allows for a dynamic approach in identifying the intricate relationships of selected themes, modeling the territorial reality with the aim of proposing multiple scenarios to evaluate, distribute, and evenly mitigate the benefits and negative impacts on the entire territory. The "sustainability" index obtained by applying the Giasone method will utilize the following data categories, the initials of which form the acronym of the name: G (geology, geography, hydraulics, hydrogeology...), I (mining industry data), SO (socio-demographic data), N (Nature, environment, agricultural and forestry resources), E (economic data). For each territorial segment derived from the comparison of indicators, a "sustainability" index - the GIASONE index - is calculated by summing the indices related to each indicator, multiplied by the weights associated with their respective categories.

Shallow subsurface stratigraphy of the Mirandola Area (central Po Plain) reconstructed through combined sedimentological and geotechnical analysis

Keywords: subsurface stratigraphy, quaternary, geotechnical analysis.

Reconstructing the geometry of shallowly buried late Quaternary alluvial successions can be carried out through the integration of facies analysis and geotechnical investigations, including drill cores, piezocone penetration tests (CPTU) and groundwater wells. Under the realization of CARG Sheet 184, we present a high-resolution reconstruction of the Middle Pleistocene to Holocene subsurface stratigraphy of the Mirandola Area (central Po Plain, Italy). Based on the sedimentological analysis of 16 new continuous cores, interpretation of 100 new piezocone penetration tests (CPTU), and stratigraphic correlation of 16313 available data, we demonstrate that CPTU tests, a tool that is commonly used in engineering geology, following calibration with core data may play a key role in subsurface stratigraphic analysis, as they can provide crucial information about the sedimentary facies. Furthermore, CPTU tests enable the identification of prominent stratigraphic markers in the geological record, such as peat layers and paleosols; these latter represent key markers of basin-wide extent that are typically neglected in conventional stratigraphic descriptions. Using eight stratigraphic cross-sections (four with N-S orientation and four running W-E), we identified a series of laterally extensive, fluvial channel-belt sand-bodies and performed high-resolution correlations with their genetically related paleosols. From proximal to distal locations, the Quaternary succession was divided in two distinct portions: i) a mud-dominated sector, close to the Apennines foothills, characterized by floodplain deposits, with laterally continuous paleosols and ribbon-shaped sand bodies; ii) a sand-dominated part, beneath and south of the modern Po River, with thick, vertically amalgamated channel belts that can be mapped individually. In this study, we point out how the combination of multiple data sources into stratigraphic analysis enhances the reliability and effectiveness of subsurface mapping efforts.

Multiparameter markers of territoriality: geochemical-isotopic and fluorometric analysis for asparagus characterization

Keywords: isotope, soil, geochemistry.

The coastal environment of the Eastern area of the Emilia-Romagna Region is characterized by sandy soils, typically dry and exposed to salinization phenomena. These challenging conditions, usually critical for plant life, are worsening due to climate change, making it a priority to strengthen territorial resilience by characterizing and enhancing local crops that ensure a better response to saline and drought stress. The "Asparagus of Altedo PGI" demonstrates remarkable adaptability to the local soils making it a cornerstone product of this region, important for both economic valorization and territorial uniqueness and heritage. Sandy-based terrains offer ideal conditions for the emergence of asparagus turions; however, notable variations spanning from sandy-clayey loam soils to lean sandy soils delineate a gradient from inland to coast.

By conducting the multi-parametric analyses of the soil-plant system, we unveil the intrinsic connection between agricultural products and their native terroir. Leveraging geochemical-isotopic techniques alongside advanced plant phenotyping methods it is possible to discern opportunities to detect potential asparagus diversification driven by soil and environmental characteristics.

Soil samples were subjected to XRF analysis for major elements; soil and plant samples underwent ICP-MS-QQQ compositional analysis down to ultra-trace elements and EA-IRMS analysis (Marrocchino et al., 2023). The stable isotopes of light elements present in crops, such as carbon ($\delta^{13}C$) and nitrogen ($\delta^{15}N$), offer a unique form of 'isotopic signature' reflective of both the geochemical conditions of the soil (D'Archivio et al., 2014) and the metabolic specificity of the plants, including processes such as photosynthesis and nitrogen assimilation. PCA analysis revealed a remarkable differentiation of soils based on geochemical factors achieving resolution even at scales of just a few tens of kilometres. Notably, the abundance of Na2O effectively delineated the coastal fields from the inland ones, while soil samples from the close-to-town Malborghetto field exhibited distinctiveness through elevated concentrations of specific heavy metals (Cr, Ni, Pb), setting them apart from their counterparts. In addition, the turions were subjected to fluorometric analysis by fast chlorophyll *a* fluorescence induction (OJIP) (Ferroni et al., 2022), a non-destructive near-instantaneous method for physiological plant assessment. An interesting correlation emerged between soil diversity and chlorophyll fluorometric parameters. Despite the uniformly excellent photosynthetic functionality of the plants observed across all fields, it was possible to distinguish the asparagus samples based on their geographical origin.

Work is still in progress to achieve a comprehensive understanding of the seamless continuity between soil and plant dynamics in correlation with the environmental attributes of the surveyed fields.

Keywords: eddy diffusion coefficient, volcanic gas dispersion, numerical modelling.

The development of efficient methods to monitor gas concentrations in volcanic areas and to evaluate the related hazard is pivotal for developing strategies for risk mitigation. Numerical models are commonly used nowadays together with gas concentration measurements in order to quantify local emission sources. However, large uncertainties can derive from approximations associated with the physics and formulation used to reproduce the natural phenomena. In this study, we present the validation of a passive gas transport atmospheric model using local CO_2 concentration and wind measurements acquired at La Solfatara crater (Campi Flegrei Italy), during an ad hoc campaign from 4 to 10 May 2023. We simulated gas dispersion using the DIGAS v.2.5.1 model and calibrated it against the observations. Our results indicate that in order to avoid systematic overestimations of the gas concentrations during stable atmospheric conditions, a minimum value of the eddy diffusivity coefficient has to be set at 1.5 m2 s-1. Such a correction drastically improved the agreement between model results and observations. The performance of the corrected model allows us to use it in an integrated way with the periodic measurements in order to retrieve the gas source conditions.

Eroding edges: exploring the tectonic forcing on submarine canyon evolution

Keywords: submarine landscape evolution, machine learning in geoscience, coastal hazards.

High rates of tectonic driven differential vertical movements along coastal areas, act as both time-independent predisposing conditions and time-dependent preparatory factors for submarine gravitational processes, leading to the retreat of submarine canyon heads. This retrogressive erosion is a significant driver of submarine landscape evolution in outer shelf and slope areas and may represent the source of major coastal natural hazards due to its tsunamigenic potential and the associated risk of coastal erosion and subsidence. Although the link between the retrogressive erosion of canyon heads and active tectonics has been explored through individual case studies, a comprehensive study addressing a statistically significant number of cases has yet to be conducted. This research aims to fill this knowledge gap by employing a machine learning approach that utilizes clustering and regression analyses to investigate correlations between active deformation and the retreat rates of canyon heads, thereby enhancing our understanding of active crustal deformation as a non-climatic driver of such offshore natural ground instabilities.

For this purpose, we have developed a new dataset comprising over 2700 canyon heads along almost the entire Italian offshore using the freely available MaGIC bathymetric data (https://github.com/pcm-dpc/MaGIC, Chiocci et al., 2009). This dataset is enriched and compared with literature-derived information on uplift rates, instrumental seismicity, bathymetry, coastline distance, and a newly computed GNSS velocity field across the peninsula (DISS Working Group, 2021; Ferranti et al., 2006; Rovida et al., 2021). The expected outcomes of this study will improve our understanding of the connection between the landward migration of canyon heads and active tectonic deformation at different spatial scales. A primary goal is to determine the numerical relationship between the parameters defining these phenomena.

Based on this dataset, we aim to develop the first Italian canyon retreat hazard map for the immediate offshore regions. By elucidating the impact of differential vertical movements on the retrogressive erosion of submarine canyon heads, this study will provide essential information for risk management strategies and action plans, aiding in mitigating potential natural hazards related to tsunamis and rapid coastal subsidence that could affect coastal infrastructures.

Keywords: Yellowstone Volcanic Complex (YVC), 3D thermo-rheological model, magnetic Curie depth.

The Yellowstone Volcanic Complex (YVC) in Yellowstone National Park (Wyoming, USA) attracts intense geological interest, as it ranks as one of the largest active continental silicic volcanic fields worldwide. Despite extensive research on the region's high heat flow and abundant geothermal features, a detailed quantitative analysis of the brittle-ductile transition has been lacking. Such analysis is essential for investigating the volcanic plumbing system, advancing geothermal exploration, and improving the assessment of volcanic hazards. This study aims to deepen understanding of the subsurface geological and geophysical properties of the Yellowstone area, with a specific focus on obtaining an optimized lithospheric thermal profile, which is fundamental for reliable rheology and lithospheric strength analysis. Initially, extensive mapping of the Curie isothermal surface depth was performed using high-resolution aeromagnetic data and innovative spectral analysis techniques. This mapping revealed a notably shallow Curie isothermal surface, ranging from 1 km to 5 km deep beneath the YVC. Subsequently, a three-dimensional thermal model of the Yellowstone lithosphere was developed using COMSOL Multiphysics software to simulate heat transfer in a purely conductive regime. A comprehensive rheological model was also conducted to delineate the distribution of the brittle-ductile transition within the analyzed lithospheric volume. The results highlight a brittle region in good agreement with the distribution of earthquake epicenters, and reveal a non-homogeneous structure in ductile zones, supporting the "sandwich hypothesis" for the local lithospheric structure. We conclude that our approach contributes to a better understanding of the YVC subsurface dynamics, providing insights into its complex geodynamic processes and offering methodologies applicable to similar studies in volcanic and geothermally active regions with large calderas.

3D stratigraphic architecture of the late Quaternary Pescara paleovalley and seismic site characterization

Purri F.*, Di Martino A. & Amorosi A.

Dipartimento di Scienze Biologiche, Geologiche e Ambientali, Università di Bologna.

Corresponding author email: federico.purri@studio.unibo.it

Keywords: late quaternary paleovalley, 3d modelling, site characterization.

Late Quaternary Paleovalley systems have been extensively documented worldwide in the geological record. These shallow subsurface incisions were formed in response to the post MIS 3 sea-level fall and subsequently filled with new sediment during the Last Glacial Maximum and post-glacial sea-level rise. Due to the sharp contrast between the soft valley fill and the over-consolidated substrate, these sediment bodies can amplify earthquake ground motions; however, the influence of buried geometries and stratigraphic architecture on seismic amplifications still needs to be investigated. In this study, we carried out the detail subsurface reconstruction and seismic characterization of the Pescara Paleovalley System, located in a highly urbanized area undergoing rapid infrastructure development. To reconstruct the 3D stratigraphic architecture, we built five cross-sections: four running transversal and one perpendicular to the main paleovalley axis. These cross-sections were built using 60 stratigraphic descriptions and one continuous core. The stratigraphic cross-sections highlight a prominent valley geometry; in the depocentral area, a 52 m-thick succession includes fluvial gravel, overlain by organic-rich clay, 30 m thick, capped by 9 m of fluvial sand. Using 85 microtremor-based horizontal to vertical spectral ratio curves (mHVSR), we produced a resonance frequency map, highlighting low resonance frequencies (0.9 Hz) in the depocentral area and high resonance frequencies (4 Hz) close to the valley margin. Following a calibration of 20 mHVSR curves with the stratigraphy, we built a Frequency-Depth model and obtained a 3D paleovalley map. To perform a reliable 2D ground motion analysis, it is crucial to build an accurate subsurface model, however the complexity of facies architecture poses a challenge. To this purpose, we derived five simplified cross-sections and according to geometric and geophysical criteria we identified six seismic layers. Relying on six Down Hole test we assigned a Vs value to each layer, building a robust subsurface model that reflects the stratigraphic complexity. In addition, highlighting the differences between the high-resolution stratigraphic cross-section and the simplified reconstruction we point out the possible sources of error. In this work, we show that detailed information about facies architecture, sediment body geometries and resonance frequencies can be used for ground motion analysis.

Analysis of possible failure mechanisms of a coastal rocky cliff by means of a three-dimensional discrete element model

Roseto R.*[1], Lollino P.[1], Parise M.[1], Spalluto L.[1], Festa V.[1] & Fazio L.[2]

[1] Dipartimento di Scienze della Terra e Geoambientali, Università di Bari "Aldo Moro".

Keywords: discrete element model, failure mechanisms, 3DEC.

The analysis of the possible instability mechanisms of a rock cliff characterized by a large number of discontinuity sets, which assigns a marked anisotropic behavior to the rock mass, turns out to be a fairly complex operation, which can be pursued only through the use of numerical calculation codes. In recent years, the availability of increasingly powerful computational tools has favored the application of such codes to the analysis of complex case studies, which is justified since they allow to define failure mechanisms of the rock mass that are more reliable than the traditional two-dimensional softwares. This is certainly the case of the distinct element method, which has experienced a new acceleration in the application to the study of fractured rock masses after the introduction of the three-dimensional version, which is more accurate and reliable in simulating the real discontinuous rock mass behaviour. This contribution proposes a three-dimensional application of the discrete element method, which has been carried out with 3DEC software (Itasca Consulting Group, 2023), to the study of the failure susceptibility of the fractured limestone coastal cliff located at the rear of the Vignanotica beach, in the territory of Vieste (Southern Italy). The numerical study was aimed at identifying the possible instability mechanisms that can be generated in the cliff as a result of the evolution of the factors controlling the cliff stability. Therefore, the contribution presents the procedure adopted for the construction of the three-dimensional geometric model within the software environment starting from the point cloud obtained from laser scanner survey, the choice of the main computational assumptions adopted and the numerical results that have been obtained. In particular, the contribution discusses the effects of the choice of the value of the joint shear strength angle on the stability conditions and the associated failure mechanisms of the cliff.

Itasca Consulting Group, Inc. (2023) - 3DEC — Three-Dimensional Distinct Element Code, Ver. 7.0. Minneapolis: Itasca.

A new insight into the dynamics of the Pisciarelli hydrothermal system (Campi Flegrei, Southern Italy) based on the integration of geophysical and numerical modelling

Salone R.*[1-2], Troiano A.[1], Di Giuseppe M.G.[1], Isaia R.[1] & Di Maio R.[2]

Keywords: thermo-fluid dynamic numerical modelling, Pisciarelli Fumarole Field, Phlegraean volcanism.

The Pisciarelli fumarole field (Campi Flegrei caldera, Italy) has exhibited progressive activation since 2011. This area, located along the eastern outer flank of the Solfatara volcano, has become the main degassing area of the caldera, with a main fumarole currently releasing more than 600 tons/day of CO_2 (Tamburello et al., 2019). Sudden morphological changes, the opening of new fumaroles, variations in the water level of the local spring, and mud emission have also characterized the evolution of Pisciarelli. These phenomena have been accompanied by a significant increase in seismicity, which currently represents a significant fraction of the entire caldera.

Here, we attempt to develop a thermo-fluid dynamic numerical modelling applied to the Pisciarelli fumarole field in order to understand the main processes driving the increasing activity and the role of the main geological features present in the area. Specifically, our work aims to provide a more accurate and comprehensive understanding of the hydrothermal processes occurring in the shallow feeding system of the Pisciarelli area, following an integrated approach based on multi-method geophysical prospecting (i.e., electrical resistivity and time-domain induced polarization tomographies, and self-potential mapping) and numerical modelling to achieve this goal.

Previous 3D resistivity and chargeability models (Isaia et al., 2021; Troiano et al., 2021) identified a highly fractured area that acts as a conduit for shallow hydrothermal fluids to generate a water/gas plume covered by a clay-cap formation. At the same time, a structural survey and a self-potential mapping identified the main fault systems present in the area. Based on these geophysical evidences, a conceptual model of Pisciarelli has been developed and imposed during the numerical simulation of fluid flow dynamics in the fracture system, also integrated with recent and accurate volcanological and geochemical analyses available in the literature.

The results of the numerical modelling, performed using the Tough2 numerical code, have confirmed the role of the main fault system, which acts as a permeability barrier parting the hydrothermal circulation into two separate sectors. A clear characterization of the state of the fluids rising into the permeable conduit was also obtained in terms of water and CO_2 pressures, as well as temperature and saturation of the gaseous fraction. This reconstruction of the present state of Pisciarelli gives an original insight into the main and still unresolved questions about this fumarolic field, in particular concerning the compatibility of its physical conditions with the possibility of sudden explosive events of a hydrothermal nature.

Keywords: geostatistics, geochemistry, aquifer.

A comprehensive dataset from over 3600 wells is created by integrating, correcting, and standardizing groundwater data collected across the Padana Plain (Lombardy, Piedmont, Emilia-Romagna, Veneto, and Friuli-Venezia Giulia regions) by various Environmental Protection Agencies in 2018. The dataset is initially used to classify groundwater of unconfined and confined aquifers into hydrochemical facies and assess the main geochemical processes, providing a complete overview of the natural and anthropic processes characterizing the entire Po plain. Then, the database is used to spatially simulate the depth-averaged As concentration of the wide and complex aquifer systems. Utilizing in-depth geostatistical analysis and Monte Carlo simulations, the research aims to elucidate the variability of As concentrations and provide a probabilistic perspective on contamination, quantifying the probability of local concentrations exceeding national regulatory limits. Results highlight the most probable As contaminated zones in confined aquifers in the proximity of the mountainous areas and in the phreatic aquifers of the lowland territories. By integrating hydrogeological, geological, and geochemical information, the study identifies the sources and mechanisms of As release, with reductive dissolution of Fe and Mn oxyhydroxides and organic matter mineralization identified as major drivers. Vulnerable areas, such as the Po, Adige, and Brenta river basins, are identified, along with localized high As values in the Friuli-Venezia-Giulia region. The study underscores the importance of monitoring and management strategies to mitigate contamination in groundwater resources, offering insights to aid local and national authorities in sustainable resource management.

Past and recent evolution of the submerged beach, shoreline, and dune-beach morphology as baseline to monitor a nature-based reef solution for coastal protection and marine biodiversity enhancement

Corresponding author email: sonia.silvestri5@unibo.it

Keywords: nature-based solutions, coastal dynamics.

In a context of sea level rise and the intensification of extreme wind events and storm surges, low coastal areas and sandy beaches experience intensified damages and erosion processes. Engineered hard solutions are often necessary to protect inhabitants and ports; however, a soft approach is desirable for natural coastal systems and beaches. The LIFE NatuReef project implements a solution based on the exploitation of the work of species that can be considered ecosystem engineers, as they are able to build reefs on sand beds along the coast, thereby protecting the shore and mitigating erosion. The construction of a limestone artificial reef near the Bevano outlet (Ravenna, Italy) will serve as the substrate for the development of populations of oysters (*Ostrea edulis*) and sabellariid worms (*Sabellaria spinulosa*), which are native species capable of building three-dimensional structures atop and around the original artificial reef. These structures retain sediments and dissipate wave energy, thereby counteracting coastal erosion.

In this work, we present the activities and preliminary results of continuous monitoring conducted on the submerged beach and the dune-beach system. The activities aim to establish a baseline that, through a reconstruction of past and recent morphological evolution, defines the current state of the system. This provides qualitative and quantitative elements for assessing fundamental morphological features as well as for describing habitats of key importance as for example embryo-dune, foredune, and back-dune habitats. Integrating Global Navigation Satellite Systems (GNSS) observations and digital photogrammetry obtained from UAVs (Unmanned Aerial Vehicles), we created a detailed model of the dune-beach system. This information was corroborated with the distribution of vegetation species. The morphology of the submerged beach was retrieved using OpenSWAP vehicles equipped with multibeam, sub-bottom profiler, side-scan sonar and single-beam echosounder. The combination of results obtained from different methodologies provided a comprehensive picture of the morphology of the entire submerged-emerged beach and dune system at extremely high spatial resolution.

Continuous monitoring of the system state through periodic surveys will yield quantitative results on the variations caused by the constructed reef in front of the beach, including detailed analyses of shoreline dynamics resulting from the surveys.

Geophysical and geochemical data integration for agricultural soil monitoring and prevention of the effects of salinity, organic matter, and climate change in the Province of Ferrara (Northern Italy)

Keywords: soil, geophysics and geochemistry, salinity.

Agricultural soil monitoring plays a crucial role in ensuring sustainable agricultural practices and environmental conservation, particularly in areas like the Ferrara plain in the Po Valley, known for its rich agricultural potential. Nowadays, this area is threatened by climate change effects, including frequent and prolonged droughts, which are responsible for the decrease of field yields and the increase of greenhouse emissions from soil. Unfortunately, traditional soil monitoring techniques often fall short in providing comprehensive insights into soil properties and dynamics, hampering farmers to develop more efficient and sustainable agricultural practices to preserve soil from degradation. Therefore, in recent years, there has been a growing interest in integrating geophysical methods with geochemical analyses to enhance soil characterization and monitoring at field-scale (van der Kruk et al., 2018; Ratshiedana et al., 2023). In line with this, we integrated both geophysical and geochemical data to characterize the soil properties in particular agricultural areas of Mezzano Valley (Ferrara province), a recently reclaimed lowland with peaty soils located near the Adriatic Sea coasts and therefore affected by salinity issue. For this study, geoelectrical and electromagnetic methods, such as electrical resistivity tomography (ERT), electromagnetic induction (EMI) and ground-penetrating radar (GPR) offered non-invasive means for in-situ investigation of soil properties, such as moisture content, porosity and soil texture or structure, to delineate soil horizons up to 200 cm in depth. Meanwhile, in laboratory, geochemical analyses of soil collected at different horizons (0-15 cm; 15-30 cm; ...) provided valuable information on variations in salinity, pH, and major, and trace element compositions, including concentration of contaminants, along depth. In addition, for each horizon were measured total (TC) and organic carbon (OC) contents and relative isotopic ratios to reconstruct the soil organic matter dynamics. This synergic approach furnished insights into the extent of organic matter depletion, saline contamination, fertility levels, and the degree of overexploitation resulting from unsustainable agricultural practices in the investigated area. Therefore, the correlation of geophysical 2D and 3D soil mapping and monitoring over time with geochemical signatures represents a valid method to infer spatial variations in soil properties and identify critical areas for targeted interventions, including precision agriculture practices or remediations efforts in contaminated sites. This is useful for better-informed decision-making in agricultural management practices, in areas facing the effects of climate change, such as droughts which leads to salinization issues, soil organic matter degradation and decrease of fertility.

Keywords: pockmarks, seismic attributes, machine learning.

Pockmark are seafloor depressions which offer valuable insights into subsurface fluid migration and geological processes, representing a significant forcing on the offshore landscape evolution. This study adopt a novel approach based on the integration of 2D seismic reflection profiles and multibeam bathymetric data in order to investigate the pockmark distribution on submerged area (i.e. Adventura Bank), closed to South-Western Sicily.

The primary goal is to discriminate actively degassing pockmarks and to examine their relationship with geological structures favourably oriented with respect to the current crustal stress field.

Secondly, employing attribute assisted machine learning technique to identify subsurface fluid migration pathways from a grid of high-resolution seismic reflection profiles (Singh et al., 2016; Srivastava, 2018; Kumar et al., 2021). Subsequently we implemented a workflow for the extraction of pockmarks from bathymetric datasets using morphometric wavelength analysis.

Finally, we explored the correlation between the extracted datasets, a newly produced structural map, geodetic and seismological datasets. This investigation aims to assess the potential of actively degassing pockmarks as proxies for blind and tectonically active faults.

Modeling the priming mechanism of phreatic and geothermal eruptions: physical model and preliminary integration results

Stocchi M.*[1-2], Houzeaux G.[2], Costa A.[3], Folch A.[4], Massaro S.[1-3] & Sulpizio R.[1]

[1] Dipartimento di Scienze della Terra e Geoambientali, Università di Bari "Aldo Moro". [2] Barcelona Supercomputing Center BSC-CNS, CASE, Barcelona, Spain. [3] Istituto Nazionale di Geofisica e Vulcanologia, Bologna. [4] Geosciences Barcelona, GEO3BCN-CSIC, Barcelona, Spain.

Corresponding author email: manuel.stocchi@uniba.it

Keywords: phreatic eruptions, hydrothermal eruptions, numerical modeling.

Phreatic and hydrothermal eruptions are physical processes consisting in an explosive expansion of groundwater, due to the input of hot fluids and heat of magmatic origin for the former, or without the direct input of magmatic origin for the latter (Montanaro et al., 2022). To the present date, the research for precursory signals for these eruptions is still in progress, and no phreatic or hydrothermal eruption has been successfully forecasted. This is in part due to the fact that we lack a clear and accepted quantitative model for these eruptions.

Here we propose a physical model for phreatic and hydrothermal eruptions composed of a set of differential equations for the conservation of the (total and chemical component) mass, momentum and energy based on the multiphase mixture theory. The goal of such a model is to understand what are the conditions that lead the system into building up an overpressure that would eventually prime a phreatic or hydrothermal eruption.

Due to the complexity of the model, numerical integration is a key tool for solving the problem. A numerical model built with the multiphysics engine ALYA, developed in Barcelona Supercomputing Center, is currently under development and we will show some preliminary results.

The development of such a model is a key step in understanding phreatic and hydrothermal eruptions and will eventually help, in future, forecasting these events.

Keywords: geochemistry, mineralogy, winemaking.

In recent years, wine has experienced exponential growth, thanks to the increasing interest by consumers, in the world market leading the scientific community to deepen various aspects related to the wine production process. Some specific geological concerns emerged as central topics into this research once the importance of vineyard soils was assessed. Actually, soils, further than influencing the growth of the vine and grapes, can provide completely different organoleptic characteristics to the wine depending on the type of soil on which the vineyards are established. In this regard, a geochemical fingerprint that reflects the geological features of the vineyard soils and their bedrock is the $^{87}Sr/^{86}Sr$ isotope ratio. This operational approach aims at finding a direct link between the final product and the territory, thus including also wine in the concept of food traceability and, at the same time, limit possible fraud and adulteration. In this work, some vineyards of the Cantina di Solopaca winery were investigated by means of a multidisciplinary approach in order to understand the relationships among geology, soil composition and wine quality. A purely geochemical approach, accounting for the determination of the $^{87}Sr/^{86}Sr$ isotope ratio on different matrices (soil, grapes, microvinifications and wine samples), was flanked by a mineralogical characterization of the soils which included thermal analysis, X-ray powder diffraction (XRPD), and Fourier-transform infrared spectroscopy (FT-IR). A joint work between various experts in different fields such as geology, soil science, and winemaking, was crucial in enhancing the results of the present research shedding a new light necessary for a comprehensive understanding of how geology, viticulture, and wine-making techniques all interact. This collaborative method not only provided valuable scientific novelties but also led to the development of creative solutions in the wine industry.

Holocene sedimentary and geomorphological evolution of the Po Plain between Po, Secchia and Panaro rivers, reconstructed through a morpho-stratigraphic approach

Watanabe D.*[1], Bruno L.[1] & Amorosi A.[2]

Keywords: fluvial mapping, alluvial plain geomorphology, Po Plain.

The Po Plain is the widest and most populated alluvial plain in Italy. The Po River, flowing from west to east, receives several tributaries from the Southern Alps and from the Apennines. The Po Plain geomorphology reflects the evolution of these rivers, including episodes of flooding, crevasses and avulsions. In this study, part of the Geological Mapping of Italy at the scale of 1:50.000 (CARG sheet 184), we reconstructed the evolution of the fluvial network between Po, Secchia and Panaro rivers in the last 4ka**.** Within a Geographic Information System (GIS) environment, different types of data and methods were integrated to characterize morpho-stratigraphic features associated to fluvial landforms. Ancient paleochannels were mapped using texture and reflectance features in satellite imagery and orthorectified aerial photographs, whereas digital elevation models were used to identify fluvial ridges. Fluvial-channel deposits were mapped in the subsurface using core data and cone penetration tests. Archeological data and radiocarbon dating were used to constrain chronologically the mapped fluvial landforms. The integration of surface and subsurface data led to the identification of a set of morpho-stratigraphic units reflecting the activity of Po, Secchia, Panaro and Reno rivers. Following CARG nomenclature, we mapped two stratigraphic units: AES8, including Roman and pre-Roman Holocene deposits and AES8a, including post-Roman deposits. In AES8, we also identified: (i) two meandering systems of the Po River that were active during the Bronze and Iron ages; (ii) a fan-shaped system which activated during the late Iron Age in the upper Po delta plain, and (iii) a WE-flowing Apennine paleochannel that was active during the Roman age. AES8a includes (i) two inner delta systems developed in the south during the Early Middle Age from the Secchia and Reno rivers, (ii) a Late Middle-Age Secchia river system to the northwest, and (iii) the Panaro riverbed, active since the Renaissance. This study portrayed a highly dynamic fluvial network during the Holocene. The methodology used in this work, based on the integration of various data types, proved to be effective in mapping the evolution of rivers systems and is potentially applicable to other alluvial settings.

Corresponding author email: monica.pondrelli@unich.it

Keywords: equal opportunities.

Article 21 of the EU Charter of Fundamental Rights (https://fra.europa.eu/en/eu-charter) prohibits discrimination for any reason and specifically stresses that equality between women and men is a fundamental value of the European Union. Although the gender issue nowadays is present in the political debate much more than in the past, and this has produced significant progress in favor of women, the inequality in the division of labor between men and women remains evident. Social and organizational psychology research suggests that organizations – like universities – are mainly driven by masculine defaults, that is, "a form of bias in which characteristics and behaviors associated with the male gender role are valued, rewarded, or regarded as standard, normal, neutral, or necessary aspects of a given cultural context" (Cheryan & Markus, 2020). As a consequence, the chances to get a top-managerial position for women are fewer than for men, because organizational values, norms, practices, interaction styles, and beliefs, disadvantage women within organizational contexts.

Among their different responsibilities, the scholars at universities have a pivotal role in the development of the 'cultural elite' of a country, so they must be aware of the stereotypes that form the foundation of this problem and develop good practices to overcome them starting from the daily life in the classrooms as well as outside them .

The University d'Annunzio is increasingly active in this direction and within this framework the Department of Engineering and Geology (InGeo) established a formal working group on equal opportunities with the goals to: 1. picture the present situation of the department and the trend since its foundation in 2012; 2. reveal which gender stereotypes (if any) are present and how they can undermine women full participation to the Department life in its broader meaning and ultimately affect their career perspectives; 3. promote good practices to help everybody to consciously overcome gender-role beliefs, share an inclusive language and finally inclusive behaviors; 4. promote the organization of scientific events (e.g. workshops, special sessions or study days) which focus on the role of the women in the STEM (science, technology, engineering, maths) subjects.

Hence, moments of guided reflection (e.g., on gender belief, inclusive language and behavior, objectification) and social studies under a scientific supervision are going to be performed among the Academic and the Technical staff together with PhD students and fellows which form the Departmental population of STEM-educated people. Such a preliminary research project has the main objective to identify the cultural obstacles to the gender equality that hide behind the awareness of transgender value and respect.

Cheryan S. & Markus H.R. (2020) - Masculine defaults: Identifying and mitigating hidden cultural biases. Psychol. Rev., 127, 1022-1052, https://doi.org/10.1037/rev0000209.

Gender equality plan (GEP) of Earth Science Department in the framework of the Science Faculty and Sapienza University

Bozzano F., Antonielli B., Bigi S.*, Calzolari L., Della Seta M., Coltellacci D., Medeghini L., Pacella A., Piacentini D., Sannino A., Scuderi M., Tinti E., Tullio C., Scacchia E., Ruspandini T. & Vergari F.

Dipartimento di Scienze della Terra, Sapienza Università di Roma.

Corresponding author email: sabina.bigi@uniroma1.it

Keywords: women, science, future.

The Departmental Gender Equality Plan (GEP) Commission of the Earth Science Dep. of Sapienza was born in February 2024, coordinating with similar commissions established in other departments belonging to the Faculty of Mathematical, Physical, and Natural Sciences. The objective of this commission is to promote actions aimed at balancing the so-called gender gap in the university Community and, in our department. The Gender Equality Plan includes several different aspects that the commission will explore, starting with the culture of respect in the language and behaviour, to the exploration of mechanisms and reason that control the anomalous distribution of women in scientific academic careers.

Several initiatives have been undertaken during 2023 and 2024 years, to support the described actions. Sapienza is the biggest University in Europe and represents a large community where the gender gap is yearly monitored from 2016. The most recent report of 2022 (https://www.uniroma1.it/sites/default/files/field_file_allegati/bilancio_di_genere_2022.pdf) indicates the majority of the female component for students and technical-administrative staff, and a persistence of the majority of the male component in the academic staff. This obviously results in fewer opportunities for women to attain prestigious and responsible positions which consequently limit their economic status.

But gender gap and discrimination include even more personal involvement of girls and women, passing through language, personal behaviour, gender-based violence, and sexual harassment. Even for these aspects, it was important to be aware of the problem and to create a place where welcome the victims. For this reason, the Science Faculty hosts the Safe Zone project to prevent gender-based violence in all faculties of Sapienza. It is based on targeted training directed at personnel and students on topics related to gender, sexual orientations, gender identities, factors that contribute to reducing discrimination and increasing the sense of safety and well-being.

More complex, (and in some way connected with the previous ones?) is the issue of gender balance in the top grades of academic carriers, which still shows big gaps and disparities in most of the faculties and departments. Our commission has wondered if this noticeable gap is perceived as such by the scientific community or if instead even the presence of a small number of women in leadership positions is already considered sufficient (for example, in Italy there are 61 public Universities and only 13 rectors are women, only the 15%).

Fossils, drawings and letters. Women's contribution to the development of early 19th century geosciences

Cofano A.* & De Ceglie R.

Dipartimento di Ricerca e Innovazione Umanistica, Università di Bari "Aldo Moro".

Corresponding author email: cofanotonia099@gmail.com

Keywords: women in geosciences, drawings, letters.

The early 19th century was a decisive moment in the definition and development of earth sciences. Traditionally, the narrative of this period has featured male scientists as protagonists; however, a more composite and varied picture is slowly emerging in which women, who in different ways and as they were able, participated in the development of geology and palaeontology. This was a particularly lively and dynamic period in Britain where, between the cliffs and the hinterland, a large group of women actively collaborated in scientific research and helped unravel the secrets of the Earth's past (Burek & Higgs, 2007). These were scholars who, neglected by scientific institutions and academies, were able to make their own contribution to the development of geosciences. Mary Anning (1799-1847), Charlotte Murchinson (1788-1869), Elizabeth Philpot (1779-1857) and Mary Buckland (1797-1857) were thus great protagonists of the early 19th century and, thanks to their activities, they succeeded in bringing their husbands closer to the nascent disciplines, they enabled the dissemination and genesis of theories that are still crucial today for understanding the evolution of the Earth, they produced illustrations of great scientific and historical value, they curated collections and they continued their husbands' studies even after their deaths (Emling, 2009). Their numerous letters not only reveal the relationships that united their husbands with other scientists, but also show us the relationships and collaborations they had with each other in the process of research. In particular, a female network of researchers and illustrators began to build up around the figure of Mary Anning who, amidst discouragement, fears and apprehensions, created a united and passionate group of scholars who were able to contribute in a relevant and fruitful way to the development of geology and palaeontology. Multifaceted and independent, the protagonists of this historical period made their voices heard. They were able to approach and infiltrate a predominantly male environment, and they were able to influence the evolution of earth sciences by working alongside and on a par with men. (Turner et al., 2010).

The frontiers of the space and the sea: the records of Dr. Kathryn Sullivan

Colacicco R.*

Dipartimento di Scienze della Terra e Geoambientali, Università di Bari "Aldo Moro".

Corresponding author email: rosa.colacicco@uniba.it

Keywords: exploration, space, records.

Throughout her career, Dr Kathryn Sullivan has been a pathbreaker in both scientific exploration and space endeavours. Indeed, she is the only person to have walked in space and reached the deepest point in the ocean.

Born in 1951, Kathryn Sullivan received a degree in Earth Sciences from the University of California, Santa Cruz, in 1973, followed by a PhD in Geology from Dalhousie University (Halifax, Nova Scotia) in 1978 (https://www.nasa.gov/former-astronaut-kathryn-d-sullivan/). Her path as a pioneering figure began when she was selected by NASA in 1978 as one of the first six female astronauts in its history. In 1984, Sullivan achieved a historic milestone as the first American woman to conduct a spacewalk during the Space Shuttle Challenger mission. With three space shuttle missions accomplished, she has accumulated over 532 hours in space. In addition, Dr Sullivan was the first woman to wear the Shuttle-era spacesuit, a ready-to-wear suit, not custom-made, with interchangeable arms, legs, and torso units in different sizes (225-pound Extravehicular Mobility Unit) (https://airandspace.si.edu/).

Following her tenure at NASA, Sullivan assumed leadership roles, notably serving as the Under Secretary of Commerce for Oceans and Atmosphere and later as the Administrator of the National Oceanic and Atmospheric Administration (NOAA). In 2020, she made history once again by becoming the first woman to visit the Challenger Deep in the Mariana Trench, the deepest spot in the world's oceans (http://kathysullivanastronaut.com/).

Beyond her pioneering achievements in space and ocean exploration, Sullivan's contribution to the STEM fields has been profound, inspiring countless future scientists and astronauts. Her commitment to environmental awareness and conservation has further strengthened her impact, earning her recognitions and awards that go far beyond her achievements in space exploration.

Anna Fiori and the balance between teaching and research in the years between the Second World War

Contessi M.*

Sistema Museale di Ateneo, Università di Bologna.

Corresponding author email: michela.contessi@unibo.it

Keywords: teaching, palaeontology, women.

Anna Fiori was born in Formigine (Modena) in 1902, she studied at the Bologna University and she earned a B.Sc. in Natural Sciences in 1927, with a top racking score, discussing a thesis in Entomology with professor Ghigi. Short after graduation she began to work as curator (formerly daily technician) in the geological and paleontological museum "Regio Museo Giovanni Capellini" under the guide of his director of the time, Professor Michele Gortani.

In 1932, she upgraded to the role of "technician", and from 1930-31 she replaced Gortani in teaching palaeontology. From 1935 she officially held the Palaeontology course at the Bologna University, without ever gaining the title of "Professor". She taught palaeontology, and especially vertebrate palaeontology until 1953, when she was moved to the teaching of physical geography, as the palaeontology course was reformed: vertebrate palaeontology was abandoned, in favour of micropalaeontology, more useful in the emerging oil and gas industry. Fiori was also one of the people responsible of the safeguard of the museum collections during the WW2 bombing, when most of the museum specimens were packed and moved in the cellars, and consequently moved back upstairs at the end of the conflict.

Little is known about this woman, one of the first to teach palaeontology in an Italian university, but of particular interest is the transcript of her "last lesson", a sort of scientific testament that underline the difficulties in following a career in research and conjugate it with the teaching at the university level, a matter that is still faced nowadays, to account her words: "on the teaching point of view I've reached discrete levels, on the scientific point of view, not; I have missed […]. When young I have done better, but gradually I have folded my wings, I have run instead of flying, then walked instead of running."

Here is thus presented a woman, and a scientist, who has devoted her life to the teaching of palaeontology and tried her best to inspire the minds of future scientists.

Engaging Women in Science: harnessing social media for STEM and Geoscience outreach

De Lucia M.*[1], Cafarella L.[2] & Pignone M.[3]

Keywords: gender stereotypes, social media channels, gender statystics.

Gender stereotypes still influence women's access to scientific careers and recognition of their merits. These stereotypes are deeply ingrained in Italian society, often manifested through distinctions between culture and science, such geoscience, as difficult or uninteresting subjects for girls. Furthermore, societal expectations, even in a subtle way, perpetuate these stereotypes.

Despite these challenges, gender stereotypes can be overcome. Anyway, while there has been progress in women's participation in science, they remain underrepresented, particularly in leadership roles. Women should take an increasing more active role with an increased investment in research and education.

Geosciences offer opportunities to Increase the involvement of women because such research can bring diverse perspectives and approaches, enriching scientific efforts.

To encourage young women to pursue their passions in science, sharing attractive scientific content via social media can be one tool. To develop a communication plan whose objectives are encouraging young women to follow a scientific career, it is necessary to start from knowledge of what may interest them.

The National Institute of Geophysics and Volcanology manages a large number of social media channels. Among these, particularly those that convey scientific information are the channels managed by the three communication groups related to the three departments: Earthquakes, Volcanoes, and Environment. Thus, we have three Facebook pages, two Instagram pages, three institutional X/Twitter accounts, three YouTube channels, in addition to three blogs.

It is possible to obtain statistics regarding the gender and age of participants only for the Facebook, YouTube and Instagram pages. Therefore, our analysis will focus specifically on these social media platforms.

30 years of Women in Science in Italy through the lens of the Major Risks Commission

Di Bucci D.*, Franceschetti C. & Postiglione T.

Dipartimento della Protezione Civile, Presidenza del Consiglio dei Ministri.

Corresponding author email: daniela.dibucci@protezionecivile.it

Keywords: major risks commission, gender balance, civil protection.

In Italy, the National Commission for the forecasting and prevention of the Major Risks is a technical-scientific advisory body of the Civil Protection Department (Legislative Decree 1, 2018). Often referred to simply as the Major Risks Commission, it provides technical-scientific opinions on questions and topics posed by the Head of the Civil Protection Department in relation to the various types and potential risk situations, imminent or ongoing, or even proposals to update or improve assessment, forecasting and prevention skills with respect to civil protection risks. Its contributions are fundamental for implementing the strategies for forecasting and preventing civil protection risks and for the management, from a technical-scientific point of view, of emergencies (Dolce et al., 2020).

The long tradition of interaction between the Italian civil protection and the scientific community dates back to the 1976 Friuli earthquake, according to the intuition and vision of Giovanni Zamberletti, the founder of modern civil protection.

Steps to set up a Major Risks Commission were taken during the 1980s, but its formal establishment came with law no. 225, enacted in 1992 (Law 225, 1992). Since then, the Commission has operated until today, albeit with organization and internal composition that have varied over time.

The Commission has always been made up of high-level experts in various scientific disciplines related to the different risks faced by Civil Protection. Therefore, it can be considered a kind of indicator of the gender balance of the represented scientific community for over 30 years.

In this work, we analysed the number, expertise and gender distribution of the Commission's members since its establishment. We retrieved the official Prime Minister's Decrees appointing the members of the Commission, to investigate the absolute number, percentage and role played by women scientists over the considered period. For the last decade, we compared our results with the most recent gender analysis for the Academia and Research Institutes, conducted by the National Agency for the Evaluation of the University and Research System (ANVUR, 2023).

Our results show that the percentage of women in the Major Risk Commission is rather low, but almost in line with the percentages observed at the highest levels of the Academy. A general increase can be observed over time, but the growth is still slight.

Some considerations can be made to understand the reasons for this limited presence of women. For instance, the members of the Commission are generally selected from among Full Professors and Research Managers, or from high hierarchical level of State Technical Agencies. These positions, in turn, are occupied in high percentage by men. Moreover, the technical skills required by the Major Risk Commission over the years are largely represented by STEM disciplines (science, technology, engineering and mathematics), which still have a low percentage of women.

Promoting the Geosciences among the young women: an example in the framework of the PLS program

Donato P.* & Lucà F.

Dipartimento di Biologia, Ecologia e Scienze della Terra, Università della Calabria, Rende.

Corresponding author email: paola.donato@unical.it

Keywords: gender balance, piano lauree scientifiche.

The underrepresentation of women in the field of Earth Science persists as a significant challenge within the broader context of gender inequality in STEM (Science, Technology, Engineering and Mathematics) disciplines. Additionally, the limited emphasis placed on Earth Sciences within the Italian secondary education system, contributes to the disproportionately low enrollment of girls in Geological Sciences courses. Promising strategies and interventions aimed at promoting the gender balance in these disciplines have been developed within the PLS (Piano Lauree Scientifiche), an institutional program aimed at the diffusion of STEM disciplines among the students of the upper school. With the aim of fostering gender diversity and inclusion in STEM disciplines, the Women's Studies Center "Milly Villa", together with the different scientific courses of the University of Calabria, promoted in 2023/2024 a training focused on "Environmental Sustainability", entirely dedicated to young women from six different high schools. The program featured a preliminary seminar intended for all participants and titled "Science and Gender Issues", which highlighted the barriers faced by women scientists at various stages of their careers (from recruitment to advancement and leadership opportunities), notwithstanding their important role in the scientific development. Subsequently, the young women followed theoretical lectures and practical activities on a specific environmental topic, different for each school. One of the sessions was dedicated to soil protection, with a focus on the key factors influencing the erosion and resulting landforms, as well as techniques for estimating soil loss. By using satellite images and Q-GIS, the young women gained practical skills in assessing annual soil erosion in a study area close their school and residences. Afterwards, the girls independently developed experimental plans to further investigate soil erosion dynamics, followed by delivering a comprehensive presentation. The results gained by each school were presented during an event held at the University of Calabria on 14th February, coinciding with the International Day of Women and Girls in Science. This event, which welcomed students from other upper and intermediate schools, provided a platform for the young women to present their research outcomes and experimental findings, thus becoming "scientists for one day". A survey to assess participants' satisfaction and to monitor the students' opinions was conducted among all the participants.itrevealed that most of girls found the initiative both interesting and stimulating, particularly appreciating the hands-on aspects and collaborative opportunities.

Participation of women in engineering geology and hydrogeology research in Italy

Ducci D.*

Corresponding author email: daniela@unina.it

Keywords: women, engineering geology, hydrogeology.

The aim of this study is to present relevant concepts and open questions stimulating the discussion on women and research in Engineering Geology and Hydrogeology in Italy (GEO05 discipline), starting from historical data and proposing points of reflection for the future. In research, and particularly in the field of geology, women face problems mainly related to: i) discrimination in access to employment; ii) discrimination during their working career. It is believed that women's performance is less relevant than that of men, partly because women are considered less suitable for field work. During their working career, women sometimes receive «attention» at different levels from male colleagues, facilitated by field trips and summer schools, which often include overnight stays.

Moreover, there are prejudices linked to motherhood, linked both to the absence of young women researchers in the workplace and to their lower participation in research. Often the male colleagues, instead of supporting them in this delicate moment of their working life, take the opportunity to get ahead of them in the career. In the GEO05 discipline, all these aspects related to geological careers are exacerbated by the fact that engineering disciplines are considered even more as a male discipline, not suitable for women.

My research between gender and engineering geology and hydrogeology, conducted with the substantial contribution of the female colleagues of the GEO05 disciplinary sector, concerns the representation of gender, barriers, and experiences. Statistics on the trend of the sector show a strong gender inequality: in particular, in 2001 there were 148 GEO05 scientists and only 18 female scientists, among whom no one was a full professor; after 22 years, at the end of 2023: the numbers were 46 women and 118 men, but only 6 female full professors, despite the bibliometric indices being similar (H-index around 20-22 for full professors and around 15-17 for associate professors). The small number of women in top positions is an issue that deserves much attention in the future. The gender gap confirms that women's roles are poorly valued, almost always kept in the shade, marginalized or even unacknowledged. To overcome this gap, it is necessary to highlight the benefits that women have brought and carry in the field of engineering geology and hydrogeology.

Learning from the pioneer women in Geosciences

Fregola R.A., Maiorano P., Micheletti F., Sabato L. & Zucchi M.*

Dipartimento di Scienze della Terra e Geoambientali, Università di Bari "Aldo Moro".

Corresponding author email: martina.zucchi@uniba.it

Keywords: women geoscientists, dissemination, education.

From the beginning of the 19th century, when geology was firmly established as a modern science, many women geoscientists made significant contributions to the advancement of the geoscience's knowledge, although many universities were still closed to women. A recent review of the existing literature on the role of women in the history of earth sciences (Vincent, 2020) indicate that at least 210 women geoscientists were active before the 1950, a number which undoubtedly exceeds what we would imagine. In fact, they are not sufficiently well known in the scientific community, to the public and accordingly within young students. As part of the group "Women in Geosciences" of the University of Bari, we have started a dissemination activity, mainly involving young students, bringing together the individual histories of female earth scientists from the 17th to the 20th century. They were active in various fields of geoscience such as mineralogy, paleontology, petrography, marine geology, stratigraphy, geological mapping, exploring mines, mountains and oceans, while collecting and studying minerals, fossils and rocks. In many cases, their activity resulted in economic and cultural improvement of which little groups, at first, and entire communities, later, got benefit. The lesson from the past tells us that most of them have faced numerous obstacles and huge prejudices over time due to persevering of unequal gender balance in Earth Sciences. Some of them remained invisible because their scientific goals were mainly attributed to well-known men (the Matilda effect of Rossiter, 1993), and some others only received recognition later. All of them are a great source of inspiration for their perseverance and their contribution to the development of geology as a science. Learning from the pioneering women geologists should encourage more young women into geosciences and help all of us to understand which prejudices we have overcome and what we still have to achieve.

Keywords: gender gap, representation of women, STEM.

Numerous studies across Europe, including Italy, have illuminated the gender disparities prevalent in academic positions across various disciplines. Within STEM fields, notorious for historical gender imbalances, the underrepresentation of women persists, notably within geosciences, which is going to be the focal point of this inquiry. While there has been significant progress, evidenced by near gender parity among doctoral graduates in geosciences by 2018, the journey to higher academic echelons remains fraught with challenges for women.

The phenomenon of the "glass ceiling" is palpable, particularly in leadership roles and decision-making spheres, with ramifications extending beyond individual careers to the quality and diversity of research outcomes. Recent research by Agnini et al. (2020) underscores this complexity, revealing a diverse landscape in the representation of women in Italy across geoscience fields, whereby some areas show low levels of female representation more than others.

The "glass ceiling" phenomenon is particularly evident in leadership and decision-making positions, with implications beyond individual careers for the quality and diversity of research outputs. This disparity indeed exacerbates financial inequalities, reinforcing the gender pay gap, since STEM disciplines are usually the ones that offer the most remunerated career paths with the most stability. Furthermore, Agnini et al. (2020) shed light on the underrepresentation of women in leadership roles within various geoscientific fields in Italy, emphasizing their concentration in specific disciplinary sectors (SSD), thus highlighting a heterogeneous distribution across the spectrum of leadership positions.

In light of these findings and the imperative to gain deeper insights into this phenomenon, we aim to investigate contrasts and parallels of this trend within the private sector of the same domain. Drawing from a feminist framework (Harding, 2004), our research endeavors to critically examine and disrupt the prevailing paradigm that sustains gendered biases and discriminations within the geosciences. By challenging assumptions regarding women in geosciences, our aim is to illuminate collective solutions and develop effective tools for dissemination, education, and design. Ultimately, we aspire to cultivate an environment where the pursuit of a career in geosciences is not exceptional but rather encouraged and accessible to future generations.

Keywords: geoscience careers, women geologist.

To celebrate the 30th years of the Geology degree at Univ. d'Annunzio (Chieti-Pescara) a series of webinars with ex-students (https://udascienza.unich.it/?p=573) have been organized to show the potentiality of a degree in geological sciences as professional career to undergraduate students. All speakers have described their own working experiences after graduation, highlighting failures and successes to inspire students.

The aim of this abstract is to enlighten the professional careers of women geologists as aspirational paths for young women and suggest the various options in the geoscience field.

Adele Garzarella works as biostratigrapher at Geological Survey of Italy, ISPRA, for the CARG Project (Geological Map of Italy). She described with passion and competence the importance of geology for the social and economic development of the territory, resembling the UNESCO guidelines. She was strongly involved in the application process of the Maiella UNESCO Global Geopark and also reported the impact of geology in the II World War strategy in Abruzzo, a strategic point of the Gustav Line for the German Army.

Valeria La Torre, R&D specialist at the Centro Ceramico (Sassuolo), completed her scientific training with a master's degree in Ceramic Business and Technology. Her journey tells the importance of geology in raw materials study for the ceramic tile manufacturing industry, from the productive process up to the technical-performing parameters of the finished product. Her scientific background allowed a transversal application of her skills in the field of ceramic tiles ranging from the execution of laboratory tests, to the coordination of regional/European projects or training of technicians.

Vittoria Morena Salerno, Environmental Compliance Officer aboard Princess Cruise Line ships, told us how she built her expertise on the strong leverages provided by the systemic and holistic approach acquired during her studies in Structural Geology and her PhD in Computational Geodynamics which helped to interpret complex sets of data and information of various kinds. This mindset has been pivotal in quickly mastering environmental compliance and effectively applying it in the maritime sector, to achieve sustainability and circular economy goals.

Edisa Shahini, is part of the Oil Field service and Equipment (OFSE) organization. During her speech, she has passionately summarized her career path in Structural Geology and Geodynamics and her professional career at Baker Hughes. She started as Field Operator in Pescara and moved through different management position in operations and product management in Europe. Exposing herself into different working positions aimed to reduce carbon footprint for more sustainable solutions for human and planet such as the role for Clean Power Solution as Program Manager, and more recently as Remote Operations Manager for all OFSE product lines.

Is there still a price to pay for being a woman geoscientist? Perspectives and lessons learnt

Keywords: women, gender equality, geoscience.

Women geoscientists in the 21st century challenge the traditional norms and, with their pioneering science, produce remarkable achievements in STEM and pave the way for future generations with dedication and passion. Yet, gender bias, stereotypes, underrepresentation, and discrimination negatively influence their working environments, affect their career choices and hinder their advancement in academic science. Despite some progress made to mitigate gender equality in STEM over the past two decades, recognizing, addressing and taking action to overcome these barriers is crucial for creating a more inclusive and equitable environment where science can thrive. In this contribution, we collectively revisit available data from the literature and compare with recent data and our personal perspectives and lessons learned thus far. We provide preliminary questionnaire results which give valuable insights on how and to what extent women geoscientists face disparity and underrepresentation in academia. We report some of the pivotal challenges that women geoscientists face and highlight the opportunities that arise from those challenges. We propose strategies for reshaping the equality and diversity agenda, promoting women geoscientists to serve as role models for inspiring future generations. To reach this goal, collective actions and commitment from individuals, institutions, and academia should be put into practice. We recommend a working environment where counselling services are available to employees and students in conjunction with effective support strategies at the institutional level. Such actions will allow women geoscientists to access support networks for families, brighten their scientific and professional achievements, and find empowerment in their roles in the academic community.

The Gender Equality Plan @ UniTo

Montomoli C.*

Dipartimento di Scienze della Terra, Università di Torino.

Corresponding author email: chiara.montomoli@unito.it

Keywords: gender gap, motherhood penalty, glass ceiling

Following the European Commission guidelines in the frame of an European Project (MINDtheGEPs: Modifying Institutions by Developing Gender Equality Plan, Horizon 2020, ccordinator Prof. C. Slera and with the contribution of CIRSDe -Centro Interdisciplinare di Ricerche e Studi delle Donne e di Genere and CUG- Centro Unico di Garanzia) the University of Torino approved the new "Gender Equality Plan" (GEP) (https://www.unito.it/sites/default/files/gender_equality_plan_unito_2023.pdf) last July 2023.

The GEP focuses on reducing the gender gap that till now is very wide in the University.

After a carefull revisions of the state of the art in the Departments of the University in terms of gender equality in different academic roles, the GEP takes into account different actions, both cultural and structural (i.e. supported by funds) to reduce this gap.

Even if the number of women is higher during the university studies and most of the PhD students are females in the following academic carrier men override women in the stable positions, starting from the lower level, i. e. researcher. The difference in academic roles grows enourmously in the case of associate and full professors.

The main structural actions approved to try to reach a gender balance are particularly focused on the so call "motherhood penalty" and to break the "door and glass ceiling" to allow women to reach not only apical positions but also a stable position.

In particular to try to reduce the "motherhood penalty" main actions will regard funds dedicated to cover baby-sitters expenses and additional research funds will be dedicated to the new mothers. In addition Departments that enrole women in stable and apical positions will be granted.

In addition cultural action will be active (i.e. short online courses regarding unconscious gender prejudices and transformative mentoring dedicated to young women in academic carrier).

The role of women in the Geosciences: the case of INGV in preparing and managing the emergencies

Moretti M.*[1], Bianco F.[2], Castello B.[1], Cocina O.[3], Cultrera G.[4], Graziani L.[1], Latorre D.[1], Margheriti L.[1], Montone P.[4], Nostro C.[1], Pastori M.[1], Pondrelli S.[5], Scognamiglio L.[1] & Valoroso L.[1]

[5] Istituto Nazionale di Geofisica e Vulcanologia, Sezione di Bologna, Bologna.

Corresponding author email: milena.moretti@ingv.it

Keywords: preparing and managing the emergencies, INGV women.

It is well known that in the geosciences (as in all STEM disciplines), the percentage of women in top positions decreases in favor of men, despite comparable academic careers and, sometimes, even better results for women.

The authors of this contribution hold managerial roles in preparing and managing seismic and tsunami emergencies at INGV (Istituto Nazionale di Geofisica e Vulcanologia). It has been a long journey, but it is now a positive reality. But it has sometimes been different!

Since its establishment in 1999, the INGV has undergone significant growth and transformation. De Lucia et al. in 2021 analyzed gender diversity within the organization, revealing that the workforce comprised 38% female and 62% male. While these proportions have remained relatively stable over subsequent years, nuances emerge when examining gender distribution with higher representation of women in administrative roles and men in technical positions. What is slowly changing in recent years is the presence of women in research and managerial leadership positions.

Notably, between 2016-2020, a woman served as General manager and, since 2017, one of the three Department Directors (Environment, Earthquakes and Volcanoes) is a woman. Currently, 4 out of the 10 Directors of the INGV Offices are women, reflecting a positive trend towards gender parity in leadership roles. Additionally, both the recently elected INGV members of the Scientific Council are women, underscoring the growing influence of female voices in shaping scientific discourse and decision-making. In the present day, an increasing number of women fulfill pivotal roles across research, technical, and administrative realms, actively contributing to coordination and leadership. Notable instances include women actively engaged in the preparation and execution of seismic, volcanic and tsunami emergency protocols. Their responsibilities encompass crucial tasks and providing support services for emergency response teams (including operational rooms for seismic, volcanic, and tsunami surveillance, network monitoring infrastructures, or emergency response teams).

In this contribution, the authors recount their experiences.

De Lucia et al. (2021) - Le persone dell'Istituto Nazionale di Geofisica e Vulcanologia a venti anni dalla sua istituzione. Quad. Geofis., 173, 192, https://doi.org/10.13127/qdg/173.

Women at the Geological Survey of Italy: where we were, where we are, where we are going

Radeff G.*, Tomassetti L., Garzarella A., D'Ambrogi C. & Lettieri M.

Dipartimento per il Servizio Geologico d'Italia, ISPRA, Roma.

Corresponding author email: giuditta.radeff@isprambiente.it

Keywords: gender equality, mentoring, geological field survey.

At the Geological Survey of Italy, women in research or technical roles are 34%, a number confirmed by women geologists applying for new positions: 41% for general geologist positions and 33% for field geologist positions. The percentages: i) reflect the situation of female graduates in earth sciences in Italy (36%, ALMALAUREA 2017-2022, https://www2.almalaurea.it/cgi-asp/classi/Scheda.aspx?codiceAggr=10016&tipoCorso=L&lang=it; https://www2.almalaurea.it/cgi-asp/classi/Scheda.aspx?codiceAggr=11086&tipoCorso=LS&lang=it); ii) are comparable with those of other national "geoscientific" institutes (INGV: 29%, INGV 2021; OGS: 40%, OGS, 2023) and iii) are considerably higher than other working realities (e.g. companies or universities).

The higher number of women geologists present in public institutes may be due to a less biased recruitment system, where competition is also based on tests and less affected by personal career.

The lower number of women applying for field geologist positions compared to those applying for other geologist positions might be instead associated with the perception that being a field-geologist is an demanding job in terms of physical energy or the long time required by fieldwork; women tend to apply for jobs requiring less in-person time to attend the "care-work" at home which are culturally induced to.

Nevertheless, in the last years, at the office responsible for the geological field survey and mapping activities of the Department of the Geological Survey of Italy, many of the roles of responsibility have been covered by women. This peculiar situation, enforced by the hiring of some women at the office, has created the conditions for mentoring the younger employees; moreover, set the basis for a more receptive environment, where emerging upcoming needs have encountered privileged spokeswomen, capable of finding flexible solutions.

In addition to encouraging attendance at training courses organized as part of the Institute's Three-Year Plan of Positive Actions (PTAP), some strategies have been positively adopted.

These include simple actions, like welcoming small children on video calls or at dinner during field campaigns, but also more complex and codified procedures that aim to take family priorities into account. The possibility of smart-working with no-fixed days or hybrid solutions, like the alternation of smart-working and parental leave, are all arrangements helping women (and men) willing to have a job but, in the meantime, busy with care work at home.

When the needs of the employees are met and the organization's performance goals are achieved, it is a win-win situation. This might also induce male colleagues to take their "family time".

We believe that these best practices, implementing the rules and actions defined by ISPRA in the PTAP and in the "Gender Equality Plan" (GEP), are a positive step into the gender-equality direction, and might be a step further. Detection and satisfaction of employees' needs don't deal only with women: it might be a virtuous model aimed at creating a better working environment for everyone.

INGV (2021) - Piano di eguaglianza di genere.
ISPRA (2022) - Bilancio di Genere ISPRA 2022.
OGS (2023) - Piano di uguaglianza di genere 2022-2024.

Stubbornly holistic: Zonia Baber and her groundbreaking work in the field of Geosciences education

Rosati A.*, Sabato L. & Tropeano M.

Dipartimento di Scienze della Terra e Geoambientali, Università di Bari "Aldo Moro".

Corresponding author email: annachiara.rosati@uniba.it

Keywords: interdisciplinary education, experiential learning, historical gender bias.

There are many uncredited women in Science's past whose tales may never be uncovered, and even though the chances were stacked against them, they yet made significant contributions that endowed the development of some breakthroughs and discoveries which, apart from anything, have historically been associated with males. To honour one of these trailblazing ladies who enabled the current level of understanding in Earth Science, this paper seeks to shed light on Zonia Baber's life and her pioneering contributions to the Geosciences in terms of communication and education.

The Geosciences continued to serve as preparation for war, conquest, and exploitation of natural resources during the turn of the 19th and 20th centuries, when the United States' mostly informal imperialism sought to merge with Great Britain's global hegemony. Nonetheless, throughout her multifaceted career as a professor of geography and geology, an activist against racism and imperialism, an environmentalist, a pacifist, and a feminist, Zonia Baber (1862-1956) stressed the value of a young-age holistic, interdisciplinary education and emphasised the importance of experimentation and field work as tools of experiential learning, showing how geography and geology should be used to unite rather than divide humanity (Baber, 1904). She put forth a dynamic, flexible, and constantly evolving educational approach (Baber, 1901a; 1901b; 1901c) in which the Earth and environment are explored as keepers of diversity, which ought to be praised as a source of enrichment rather than seen as a cause of conflict.

Zonia Baber had a strong commitment to all of the delicate issues of her era. And she managed to bring them all together in her educational mission: indeed, among the other things, she served as the chair of the Race Relations Committee of the Chicago Women's Club and as a member of the National Association for the Advancement of Coloured People's (NAACP) of Chicago's executive committee; she served as president of the Women's International League for Peace and Freedom (WILPF); in addition, she continues to be greatly valued for her assistance throughout the unforgettable Puerto Rican women's voting rights campaign. All of this occurred while she co-founded the Geographic Society of Chicago in 1898 and was appointed to lead the Geology, Geography, and Palaeontology departments at the University of Chicago from 1901 to 1921 — she was the only female professor there.

In Baber's view, geosciences education was a means to improve the world since all things were interconnected, part of a comprehensive view of the total — a belief that holds true to this day.

A contribute to the PLS Project from "Women in Geosciences" of Bari University

Sabato L.[1], Zucchi M.[1] & Tropeano M.*[1-2]

[1] Dipartimento di Scienze della Terra e Geoambientali, Università di Bari "Aldo Moro".
[2] Responsabile PLS Scienze Geologiche, Università di Bari "Aldo Moro".

Corresponding author email: marcello.tropeano@uniba.it

Keywords: women in geosciences, PLS scienze geologiche, Bari university.

The "Women in Geosciences" Group ("Donne nelle Geoscienze", in italian) was born in the "Dipartimento di Scienze della Terra e Geoambientali" of the Aldo Moro Bari University, at the beginning of 2021, as an "appendage" of the "Diversity, Equity, Inclusion – PanGEA" Division of the Italian Geological Society, which includes women geologists from all over Italy. The objective of the "Women in Geosciences" group is to encourage secondary school girls to undertake scientific studies, to break down the prejudice according to which girls are less capable than boys in STEM subjects (Science, Technology, Engineering, Mathematics).

The group formed thanks to the idea of Luisa Sabato (LS) and Martina Zucchi on 11 February 2021, on the occasion of the 7th "International Day of Women and Girls in Science". Currently, the group is made up of around 60 women, including PhD students, postdocs, researchers, and professors. Their activity falls within the themes of the PLS ("Progetto Lauree Scientifiche", i.e., Scientific Degrees Project) aimed at the University orientation of students in the final years of high school, in this case with a particular focus on girls.

The group work consists of creating a series of very short videos, with light tones, to also tell personal experiences in the field of geological sciences, and to demonstrate that girls can also undertake paths that some continue to consider exclusively male. Some videos follow the style of double interviews, others show through comics or stories the various types of activities that a geologist can carry out, still others are dedicated to the pioneers of Geosciences, women who get a notable contribution in the past (even very recent) to the development of the discipline of Geosciences, but remained "invisible", obliterated by the often-cumbersome male-presence.

The group also organized numerous days on February 11, hosting many high school classes, and even during the lockdown due to the COVID pandemic many classes connected for these meetings, even outside the regional perimeter. The group also played an important role in spreading the concept of geodiversity, organizing a series of seminars on October 6th (International Geodiversity Day), also playing on terms geodiversity and geo-diversity, and further highlighting the role of women in the scientific disciplines.

This contribution aims to present an overview of the activities carried out by the group and to share our experience. http://www.scienzegeologiche.uniba.it/2-non-categorizzato/1082-donne-in-geo.html.

The valorisation of Cultural Heritage and the archaeometric studies as effective tools for disseminating scientific culture: the experience of the ADELE-RS project

Alberghina M.F.*, Ricca M., Ruffolo S.A. & La Russa M.F.

Dipartimento di Biologia, Ecologia e Scienze della Terra, Università della Calabria, Rende.

Corresponding author email: francesca.alberghina@gmail.com

Keywords: valorization, heritage science, innovative museum.

The Adele-RS Project, funded by the Erasmus+ Programme (measure VETKA2020; https://erasmus-plus.ec.europa.eu), started at the begin of 2022, has been promoted by the Association "Arte e Fede" of Gerace (RC) and its general aim is developing an innovative e-Learning and Smart-Working system (D'Angelo, 2007) in the fields of Heritage Science.

The partners involved in European working group are: University of Calabria, Italy; Distretto ad Alta Tecnologia per i Beni Culturali S.C. a R.L., Naples, Italy; University of Malta, Msida; Fondazzjoni Belt Victoria - Heart of Gozo Museum and Cultural Centre, Malta; Universidade de Evora, Portugal; Museu Nacional de Arte Antiga, Lisbon, Portugal; Universitatea Politehnica din Bucuresti, Romania.

The general purpose of the ADELE-RS Project (https://www.adele-rs.org/) includes the design, development and implementation of specialization training courses aimed at graduates in disciplines in the Cultural Heritage field. Among these, in particular, the Partnership, developed a peculiar profile of specialization devoted to the scientific communication for valorisation of Cultural Heritage and dissemination of scientific culture aimed at involving the general public (Ponterio et al.,2019).

The tasks of this profile, named "Expert in Advanced Valorisation of Cultural Heritage", has been individuate in: to accepts the requests for new solutions for CH communication and dissemination, identifies resources and recognizes possible areas of development; to identify the starting technological and economic characteristics; to assess the costs and strategies of the project idea in terms of feasibility and competitiveness; to recognize the requirements for the realization of new valorisation tools, services and strategies and analyses their effects and impact in terms of economic, social and cultural development and sustainability improvement, also through the involvement of the communities of reference.

The Expert develops valorisation solutions for Cultural Heritage in different contexts and for different target groups and knows in depth the complex sector of innovative technologies for communication and information including those on based on the use of innovative Information and Communication Technologies (ICT) and Internet of Things (Casillo et al., 2022). The Expert also knows the use of social media and virtual communities applied to the context of Cultural Heritage communication and he/she is also able to develop technological solutions for the virtual reconstruction of sites, works and finds and to solve problems and themes of the communication for Cultural Heritage in complex and specialized contexts and for different audiences, finding solutions also aimed at dissemination of the Cultural Heritage.

This professional profile finds solutions, in particular, to improve the "traditional" communication, learning methods and in general the fruition of Cultural Heritage, designing innovative strategies for training and educational purposes based on scientific knowledge.

An educational escape room experience for teaching younger generations about seismic risk

Amoroso O.*, Gargiulo M.V., Napolitano F., Russo R. & Capuano P.

Dipartimento di Fisica "E.R. Caianiello", Università di Salerno, Fisciano (SA).

Corresponding author email: oamoroso@unisa.it

Keywords: escape room, seismic risk communication.

Effective science communication is crucial for ensuring the societal impact of research. In today's digital age, the abundance of information circulating significantly influences public perceptions of science. However, the effectiveness of risk mitigation relies not only on the scientific community but also on society's readiness and understanding of risks. Educating local populations is essential for enhancing disaster preparedness and societal resilience. Seismic risk communication has evolved from one-sided, top-down approaches to prioritizing individual involvement (Musacchio et al., 2023). Italy, with its history of earthquakes, faces challenges in public perception, particularly among youth (Crescimbene et al., 2018). To address this, interactive experiences like Serious Games can effectively engage youth and convey the importance of seismic risk preparedness (Solarino et al., 2021; Musacchio et al., 2016). Several Serious Games have been utilized in Italy for seismic risk education, typically as part of extensive awareness campaigns and projects.

The didactic experience developed in this work represents a one-time endeavor, making it more accessible for testing and replication. Its primary aim is to stimulate students' interest in the topic rather than establish enduring knowledge. Amid the COVID-19 pandemic during the 2020/21 academic year, there was a need to adapt orientation and engagement activities with schools to virtual platforms approved by the schools. A novel educational approach was employed: an escape room experience designed to educate high school students about seismic risk. The escape room experience begins with a brief frontal lecture to introduce basic concepts. Students are then immersed in an interactive world where they grapple with challenges and decisions related to seismic risk. It offers a compelling narrative, puzzles, and scenarios mimicking real-life situations. Through this experiential learning approach, students are placed at the center of activities, observing how the gained knowledge can be applied in seismic events to estimate earthquake location and magnitude estimation. To personalize the experience a regional case study near the student's residences was chosen.

The impact of the experience was assessed through tests. Results demonstrated an improvement in pupils' interest in the topic. The 'one-time endeavor' protocol in seismic risk communication emphasizes a concentrated educational experience over continuous programs. It aims to stimulate interest and awareness effectively. While ongoing initiatives are common, this approach offers a fresh perspective, suggesting that a singular, intensive experience can be more replicable and impactful. Although international examples are limited, the interactive nature of disaster communication supports the idea that focused experiences can engage individuals and communities in preparing for seismic risks.

The world in 2D: Alfonso Di Pasquale, between paintings and geological maps

Argentieri A.*[1-2] & Tortonesi E.[3]

[1] Dip. IV Servizio 2 "Geologico, difesa del suolo- Risorse agroforestali. Rischi territoriali", Città metropolitana di Roma Capitale. [2] Società Geologica Italiana, Sezione di Storia delle Geoscienze.

Keywords: Alfonso Di Pasquale, figurative painting, geological maps.

Geological maps, bidimensional representation of the complexity of structures forming the outer layer of our planet, are definitely art works. From the dawn of their presence on Earth, early humans had the urge to depict with lines, symbols and colors their perception of reality. Basically, history of art follows the path of human ingenuity towards an increasingly refinement of such capacity. Since 19th century, modern geology found a tool for representing, on the two dimensions of a paper sheet, the 4D vision of our dynamic Earth: geological mapping, a "screenshot" of a system continuously changing in space and time.

This contribution focuses on a particular character, worth a mention having been an excellent 'supporting actor' in the history of 20th century Italian geology: Alfonso Di Pasquale (1899-1987), painter and draughtsman from Apulia (Masi, 2013). He served for more than 40 years in the Italian Geological Survey, becoming a real artist of geological mapping (Argentieri, 2021). This notwithstanding, he cultivated concurrently the lifelong passion for realist painting, actually the downside of his ordinary job. After the reconstruction of Di Pasquale's human, professional and pictorial path, our storytelling ends with an unexpected finding. A postcard, drawn by Alfonso in 1917 and suddenly lost, reappeared after a journey across the Alps lasted more than a century, revealing a peculiar and touching story (Tortonesi, 2024): a further evidence of Alfonso's personal contribution to the art of Geosciences communication.

Science in the Riviera dei Fiori: 'traces elements' of geology in Italo Calvino's literary output

Argentieri A.[1-5], De Caterini G.[2-5], De Ritis R.*[3-5], Romano M.[4-5] & Rotella G.[1-5]

[1] Città metropolitana di Roma Capitale, Dip. IV Servizio "Geologico, difesa del suolo- Risorse agroforestali- Rischi territoriali". [2] ISPRA, Roma. [3] INGV, Roma. Corresponding author email: riccardo.deritis@ingv.it

Keywords: Floriano Calvino, Italo Calvino.

The literary output of Italo Calvino (1923-1985) reveals a solid scientific culture, derived from his family tradition, education and youth reading about astronomy and natural sciences. As known, he grew up in the Flowers Riviera of Liguria, in a family environment strongly permeated of scientific culture (Scarpa, 2013). The father Mario, born in Sanremo, was agronomist, republican and Freemason. The mother Giuliana Eva Mameli, mathematician, botanist and naturalist, was the first Italian woman to hold a chair of botany, at the University of Cagliari in 1926. Moreover, the maternal uncle Efisio Mameli was professor of organic chemistry in Pavia. In 1909, Mario Calvino emigrated to U.SA. and then to Mexico, participating to the revolution of Pancho Villa and becoming afterwards deputy director of the Escuela Nacional de Agricultura. In 1917, he moved to Cuba to head the Experimental Station of Floriculture of Santiago de las Vegas, where Italo was born six years later. In 1925, the family returned to Italy, and Mario became director of the "Orazio Raimondo" Experimental Station of Floriculture in his hometown. Thus, the Calvino- Mameli couple gave impetus to the floricultural activity which has made Sanremo world-famous. In 1936, Mario was appointed as a professor of tropical and sub-tropical agriculture in the Torino University and joined the Fascist Party. The second son of Mario and Eva, Floriano, was born in Sanremo in 1927. The two kids studied at the local Lyceum, entitled to Gian Domenico Cassini, the astronomer born in Perinaldo, on the Ligurian Alps: this is another subtle connection to scientific culture for Italo and Floriano. In autumn 1944 the Calvino brothers, to avoid conscription to the Italian Social Republic army, escaped on the Maritime Alps and joined the Resistance. After the war Italo obtained a degree in literature at the University of Turin (1947), having quitted the initial and unrewarding course of study in agronomy; Floriano, on the other hand, graduated in mining engineering from the Polytechnic University of Turin, and went on to become an appreciated geologist, later professor at the Genoa University. The enchanting scenario of the "Riviera di Ponente" stimulated in the past the interest for natural environment and scientific studies (Barale & Bicknell, 2024). In these terms, Sanremo and the Calvino- Mameli familiar framework represent the breeding ground for the seeds of a hybrid culture, between Humanities and Science. Following recent celebrations of the writer's birth centenary, we thus propose, starting from Floriano's research output, a virtual journey through Italo's literature, seeking for 'traces elements' of geology (Argentieri, 2023).

From bones to bulk: a 3D volumetric approach to estimating theropod dinosaur body mass

Bindellini G.*[1], Manucci F.[2] & Romano M.[1]

[1] Dipartimento di Scienze della Terra, Sapienza Università di Roma.
[2] Associazione Paleontologica e Paleoartistica Italiana APPI.

Corresponding author email: g.bindellini@gmail.com

Keywords: theropods, body mass, 3D reconstruction.

Body size estimation of theropod dinosaurs remains a challenging yet crucial aspect of paleontological research, offering insights into their ecology, behavior, and evolutionary dynamics (e.g., Campione & Evans, 2012; Brassey, 2016; Romano et al., 2021; 2023). Traditional approaches relying on regression formulas derived from extant taxa often yield wide and potentially misleading ranges of values. In this study, we propose a methodological framework centered on 3D volumetric reconstructions and density analysis as a more precise alternative for estimating body size and mass in theropods dinosaurs. Drawing from recent investigations, we try to demonstrate the efficacy of this approach in generating accurate estimations while overcoming limitations associated with conventional methods. By employing high-resolution digital scans of real specimens and casts, we reconstruct detailed 3D models of dinosaur skeletons, therefore allowing for precise body volumes reconstruction. Through the application of literature-derived tissue density ranges, we refine weight estimates to provide narrower and more reliable ranges of body mass. Our results underscore the importance of methodological rigor, particularly in reconstructing flesh and bones of extinct organisms with unique anatomical features or very large sizes. This approach not only enhances our understanding of dinosaur paleobiology but also serves as a valuable tool for elucidating broader questions regarding the evolutionary dynamics and ecological roles of non-avian theropod dinosaurs. Moreover, a precise in-vivo reconstruction of these extinct animals, that rules out any speculation and instead is based on peer-reviewed published data, would either enhance the quality of the results dissemination and establish a major reference for future works and for the understanding of a wider public.

"Scotland For Ever!". This was the battle cry of the Grey Scots during the cavalry charge at Waterloo in 1815. The picture capturing this moment, perhaps the most famous and evocative image of the event, was painted by Lady Butler (also known as Elisabeth Thompson) in 1881, nearly 70 years later.

As a woman, Lady Butler never participated in any battles. Instead, she immersed herself in the stories of those who had experienced them, observed the uniforms of the time, and meticulously studied the anatomy and behaviour of galloping horses. From this wealth of knowledge, she immortalised an extraordinarily dramatic scene from an unusual perspective, capturing the motion and intensity of the moment.

This captivating painting and the story behind its creation serve as an excellent example of the work involved in reconstructing Deep Time, and thus, of Palaeoart. Palaeoartists follow a similar process, tasked with representing the lost world of prehistory through extensive research and the study of fossils.

But what exactly is Paleoart? It is the branch of art, whether through sculpture or illustration, that focuses on representing and reconstructing prehistoric environments and organisms based on artifacts found in the field. While allowing for some artistic interpretation, palaeoart primarily operates within the confines of scientific evidence and is subject to the meticulous oversight of scientists. Their role is to convey their research and conclusions through the work of the artist.

The reconstruction of prehistoric organisms or environments is a collaborative effort involving various professionals. Geologists and paleontologists excavate and unearth fossils, preparators in museums extract them from their matrix, and together they assemble the skeletons. Illustrators and sculptors then use these skeletons to imagine the appearance of these extinct organisms in life.

It's a lengthy and intricate process, demanding considerable effort and attention to detail, sometimes bordering on obsession. Yet, it's also incredibly rewarding and, undoubtedly, at times, immensely enjoyable.

GeoSciences IR: 'Thematic geological content dissemination' web system to support users

Campo V.*, Antonietti D., Attanasio A., Coiro A. & Congi M.P.

ISPRA, Roma.

Corresponding author email: valentina.campo@isprambiente.it

Keywords: geosciences, dissemination, e-learning.

The project GeoSciences IR aims at creating a new research infrastructure for the Italian Geological Surveys Network (namely "Rete Italiana dei Servizi Geologici" RISG), a coordination network among ISPRA, Geological Survey of Italy and "Regional Geological Surveys" (RGSs), i.e. technical offices within Regions, Autonomous Provinces and Regional Environmental Agencies with a specific mandate in the geological domain at regional level. GeoSciences will provide to ISPRA and RGSs the technical and scientific skills to carry out their duties concerning responsibilities at national (ISPRA) and regional (RGSs) level in specific geological matters themes identified by RGSs as a priority. This target will be achieved through several actions aiming to transfer scientific and technical knowledge implemented by Universities and Research Institutes on priority themes. Through a highly technological cloud infrastructure, GeoSciences will provide access to a huge amount of data, services, tools, specifically implemented by project partners, made available to target users to fulfil with their institutional mandate. Within the new research infrastructure also a web system and e-learning platform will be available in order to make available all data to a wider audience of users, and to disseminate and give greater visibility to the results and deliverables produced by the project activities. For the training phase, e-learning modules will be available for users' technical and scientific updates. These products cover several issues: geological and geothematic mapping and modeling, landslides, sinkholes, hydrogeological risk mitigation, satellite and in-situ monitoring, active and capable faults, sustainable mining, and land use and consumption. E-learning certainly contributes to create shared knowledge about specific topics involving different skills and it is a valuable driver for the achievement of concrete technology-level goals. Technical offices of the Italian Geological Surveys Network (RISG), which are the main target users of the research infrastructure, will thus have the opportunity to learn about the methods, technology trends and innovative solutions produced for GeoSciences IR. Training starts from data visualization to procedures for complex analyses. Training materials will be developed to meet the needs and requirements of technical personnel of different skill levels. Users will benefit from specific softwares, tools for cloud processing and e-learning modules aimed at increasing technical and scientific skills in the geological domain. All materials created for training and made available in the web system and e-learning platform will be maintained and updated for the next 10 years after the end of the GeoSciences IR project.

Challenges and strategies in geothermal communication

Cannone E.*, Manzella A., Galione M.R. & Criscuolo L.

Istituto di Geoscienze e Georisorse, CNR, Pisa.

Corresponding author email: elisa.cannone@igg.cnr.it

Keywords: geothermal energy, communication, popularization.

Geoscience communication plays a key role in promoting the transition to a more sustainable future for society and the planet. The complex challenge of a sustainable transition is particularly so for geothermal energy, which integrates various technologies into the invisible nature of underground processes. It is, therefore, difficult to envision the energy resource and associate its strengths and weaknesses with the different technologies.

The initial phase of any activity involves identifying the audience and the message to be conveyed: "What do they already know about geothermal energy?" "What is their perception?". Most importantly, "Why should they care about our message: what topics will we use to connect our research to their values and daily life experiences?" (Turnsek & Nibbs, 2023). Here we describe our experience in communication geothermal knowledge, that necessarily entails translating the complexity of research into understandable language and involves choosing the most effective communication modes to reach the recipients of the message. In the frame of a Research Night organised at the CNR Campus of Pisa we created a miniTED (Technology, Entertainment and Design) to raise awareness of geothermal energy in Tuscany: "Do Tuscans know it?". In an ironic and friendly tone, we narrated in just 8 minutes the various geothermal applications and products to be found trivially in a kitchen, completing the picture with a graphical representation of the energy input that Tuscany provides nationally and globally. For the celebration of the Centennial of the CNR, a day was dedicated in Padua to new forms of energy for energy efficiency and sustainability for the future of the planet. It was another opportunity to popularise the diverse geothermal applications, from the best known, such as spas, to the lesser known, e.g., vegetable drying. We created and explained a 2-meter roll-up entitled "Geothermal Energy for Decarbonization", depicting a thermometer embedded in a section of soil to show the increasing temperature with depth and the correspondence of temperature with different applications. We focused on the peculiarities of the Euganean Hills to inform citizens about the geological and geothermal characteristics of the Padua subsoil. In addition to traditional communication channels, websites, social channels, and newsletters, we are implementing a set of graphic drawings to represent geothermal technologies in a simple, understandable, and catchy way for a Horizon Europe project (DeepU, G.A. 101046937) and a European Cost Action, DHC Geothermal.

In conclusion, the variety of approaches and solution tested proved effective in engaging the public and in making complex messages understandable appears effective. We will continue to explore communication activities to promote the dissemination of this important renewable energy source in a strategic and informative way.

Turnsek M. & Nibbs W. (2023) - Communication skills in geothermal energy. Geothermal DHC, https://www.geothermal-dhc.eu/News/Details?id=234.

The National Antarctic Museum-Section of Trieste: integrated educational approaches for understanding environmental and climate changes

Colizza E.*[1-2], Geniram A.[1], Protopsalti I.[2] & Salvi G.[1-2]

[1] Dipartimento di Matematica, Informatica e Geoscienze, Università di Trieste.
[2] Museo Nazionale dell'Antartide, Sezione di Trieste.

Keywords: scientific museum, geosciences communication, climate change education.

The experience of the National Antarctic Museum – Section of Trieste highlights the crucial role of scientific museums as places of informal learning.

The National Antarctic Museum has adopted various participatory pedagogical methods to actively engage students in learning. The Socratic method, based on questioning and dialogue, stimulates critical thinking and creative problem-solving. Peer education promotes knowledge sharing among students, creating a collaborative and inclusive learning environment. Collaborative learning, through group projects and practical activities, encourages the development of problem-solving skills and interdisciplinary collaboration.

The integration of these pedagogical methodologies in a museum context offers a unique opportunity to engage students in authentic and meaningful learning. Scientific museums provide a space where students can interactively explore complex concepts and connect acquired knowledge with real-life experiences. Interactive exhibits, simulations, and practical laboratories allow students to experience scientific concepts firsthand and develop a deeper understanding of environmental and climatic issues.

In conclusion, the National Antarctic Museum – Trieste Section offers an example of how collaboration between educational institutions and other actors can enrich students' learning experience and promote an interdisciplinary and participatory approach to scientific knowledge. The integration of innovative pedagogical methodologies in a museum context offers a unique opportunity to engage students in authentic and meaningful learning, preparing them to become informed and active citizens in the future society.

Satellites, or the Big Eye at the time of the Anthropocene: remote sensing for capturing landscape changes

Coluzzi R.*, Imbrenda V. & Fanti L.

Istituto di Metodologie per l'Analisi Ambientale, CNR, Tito Scalo (PZ).

Corresponding author email: rosa.coluzzi@cnr.it

Keywords: Earth observation, Copernicus data, land change.

For some time now, remote sensing, i.e., the technique of observing and analyzing objects from a distance without being in direct contact with them, has captured both media attention and practical applications, revealing its enormous potential in various disciplinary contexts (meteorology, engineering, agronomy, archaeology, etc.). The synoptic view of large areas (using various platforms: satellites, aircraft, helicopters, drones) and the privilege of being able to go back in time make remote sensing unique in estimating the human footprint on landscapes, which are to be intended as the dynamic and complex expression of natural and human factors and also as an economic asset. Human development needs have led to a deep transformation of natural ecosystems, with agriculture and urban areas significantly increasing their ecological footprint in the last century, resulting in a reduction/degradation of ecosystems' ability to provide goods and services. Considering the extensive nature of the subject, an educational initiative was developed specifically for high-school students. It aims to enhance their capacity to interpret dynamic landscapes using remote sensing tools and techniques. The goal is to grasp the scale, duration, and extent of human impact on Earth.

The proposed activity consists of three distinct phases. The first phase has been theoretical, focusing on the scientific introduction to remote sensing and its potential applications across various disciplines (ecology, zoology, forestry, climatology, urban planning, etc.), demonstrating how human influence has deeply affected landscapes configuration and health. The second phase has been predominantly a training activity: through the Copernicus Data Space Ecosystem platform (https://dataspace.copernicus.eu/) that provides a large amounts of open and free Earth observation data mainly included those derived by the Copernicus Sentinels Missions, students have been guided to explore and engage with satellite imagery, using the user-friendly and intuitive browser. The main purpose has been to recognize the impact of human actions and natural events on land surface. The third step has been focused on an independent student work carrying out analyses on selected pilot areas concerning adverse phenomena affecting the Italian peninsula (fires, floods, etc.). Finally, students have showcased their conclusive findings through presentations showing excellent ability in engaging with a new tool, expressing a keen interest in further exploring the platform independently with the aim of becoming sustainability practitioners in a rapidly changing world.

"The Fountain of the Four Rivers" (Rome, Piazza Navona) as a representation of the sense of wonder in Baroque art and science

De Caterini G.*[1-5], Argentieri A.[2], Delfini C.[1], Galetto G.[3] & Monaco V.[4]

[1] ISPRA, Roma. [2] Città metropolitana di Roma Capitale, Dip. IV Servizio 2 "Geologico, difesa del suolo- Risorse agroforestali. Rischi territoriali". [3] Storico dell'Arte. [4] Dipartimento di Fisica, Università di Torino.

Corresponding author email: giovanni.decaterini@gmail.com

Keywords: baroque art, complexity, horror vacui.

The Europe of the 16th and 17th centuries underwent a series of profound transformations, characterized by both tumultuous upheavals and moments of jubilation. The contrast between the Protestant Reformation and the Counter-Reformation ignited violent religious conflicts, coinciding with famines, plagues, and pandemics exacerbated by the Little Ice Age. Simultaneously, the discovery of new continents revealed a vastly diverse, exotic, and enigmatic world, catalyzing a shift in scientific and artistic discourse from the structured medieval worldview to the chaotic natural world dominated by tumult. In the Baroque era, nature was perceived as both awe-inspiring and terrifying, prompting humanity to seek harmony through theatrical, emphatic, and emotionally charged yet scientifically rigorous representations. God was viewed as the necessary and perfect origin and cause of the universe.

Exploring this worldview through the lens of art, science, and mathematics, we turn to one of the Roman Baroque's most iconic symbols: Bernini's "Fountain of the Four Rivers" in Piazza Navona. This masterpiece is interpreted through the scientific thought of two exceptional polymaths of the period: Athanasius Kircher (1602-1680) and Gottfried Wilhelm Leibniz (1646-1716). Kircher, a central figure in the intellectual culture of his time, inspired the allegory of the fountain.

The lower portion of the fountain features the four rivers—the Nile, Danube, Ganges, and Rio de la Plata—symbolizing the intricate nature of the known continents. This diversity evokes both awe and terror in humans, confronting the metaphysical void, indeterminacy, and complexity.

In stark contrast, the upper portion of the monument exhibits straight lines and ascends towards the sky with an Egyptian obelisk, embodying the ordered linear structure ordained by the Catholic Church. A top this structure transcends a bronze dove, symbolizing spirituality and the divine will. During Leibniz's stay in Rome from 1675 to 1676, it is intriguing to ponder his reaction to the grandeur of Roman palaces and Bernini's work. For the German philosopher, the fountain's plasticity, dominated by its folds, constituted a compelling manifestation of the will of God. Leibniz conceptualized reality as an infinite series of spiritual entities known as monads, each encapsulating the entire universe within itself. In his quest to understand and interpret nature, Leibniz developed infinitesimal calculus. The mathematical derivative, in its essence, signifies the interconnectedness and interdependence of variables. Thus, the derivative of one of the folds of the Fountain of the Four Rivers metaphorically represents the interconnectedness between different facets of the universe or folds of human experience.

Science and Art in the dissemination of volcanic risk

De Novellis V.*[1], Ascione V.[2], Somma R.[3] & Zoccola M.[4]

[1] IREA, CNR, Napoli. [2] Video artist, VJ, Sound Designer, Napoli.
[3] Musician, Napoli. [4] Musician, Musical Technologies at the State High School, Campobasso.

Corresponding author email: denovellis.v@irea.cnr.it

Keywords: Mt. Vesuvius, phlegraean fields, theater.

In scientific research, art plays a crucial role in making complex natural phenomena understandable and accessible. This role is especially significant when an artist, with a musical background, approaches scientific research with a unique perspective. Similarly, researchers may use artistic expression, such as musical performances, to disseminate scientific knowledge about impactful events like volcanic eruptions and earthquakes. Through a combination of musical, visual, and narrative elements, we aim to convey scientific knowledge in an engaging way, encouraging greater awareness and understanding of natural risks. This work explores the role of art in facilitating scientific dissemination and promoting broader dialogue on safety and preparedness in the face of catastrophic events. We create two theatrical representations focused on the famous volcanic areas of Phlegraean Fields and Mt. Vesuvius.

The first show, titled "Dottò, ma quando scoppia il Vesuvio – il Nuovo Grand Tour" is a journey through time, blending images, videos, and music to immerse the audience in Vesuvius's eruptive history (De Novellis & Somma, 2024). The narrative, animated by tailored video and live musical performances, goes beyond describing eruptions, revisiting the cultural growth in the vesuvian area from the Grand Tour era to modern technological discoveries. An innovative vision is proposed for addressing volcanic risk, highlighting how Vesuvius can drive economic growth and development, promoting a "new" Grand Tour that balances ancient and modern elements.

The second show, titled "Phlegraean Fields: Mankind, Fear, and New Sibyl - The Challenge of New AI" is a multimedia work blending the expertise of a volcanologist, a musician, and a VJ creating AI-generated visual content (Zoccola et al., 2024). The project represents human fear of bradyseism in the Phlegraean Fields, where the myth of the Cumaean Sibyl once provided oracular insights. Today, humanity seeks answers from AI, the "New Sibyl" while confronting fears about AI itself. This interdisciplinary approach creatively harnesses technology, generating scores, sounds, and images through traditional and innovative processes, promising a memorable experience.

These shows offer a unique platform to explore the intersection of art and science, combining musical, visual, and narrative elements to convey scientific knowledge in an engaging way. They aim to educate the public about volcanic dangers, promote awareness of natural risks, and encourage critical reflection on our relationship with the natural world. These theatrical representations provide an overview of the history of volcanology, highlighting pioneers, key discoveries, and the discipline's evolution. They illustrate geological processes, emphasize preserving historical volcanic sites, introduce modern volcanic monitoring tools, and stimulate curiosity and interest, fostering a deeper connection with our planet.

In the last two years, an interdisciplinary research project (sosteam.org) has been carried out in the University of Bari Aldo Moro, aimed at bridging scientific knowledge with musical language (and viceversa) by emphasizing the shared principles of symmetries and proportions.

Educational research is trying to gain knowledge on what actually works in the classroom. The fast spread of evidence-based education relates to the need of providing functional data that can be used for taking informed decisions. Such approach leads to introducing novel teaching strategies supported by scientifically based research and connecting different disciplines within a unifying framework.

Our project introduces an innovative educational strategy utilizing interactive sonification, transforming phase diagrams into graphic scores to be played by students under the guidance of a conductor (teacher).

Although graphic scores are attested as early as in the Renaissance, starting from the 1950s several composers (e.g. Cage, Brown, Ligeti, Wolf, Feldman, Stockhausen, Bussotti, Braxton) adopted this form of representation of music with visual symbols sometimes combined with traditional musical notation. The visual language adopted to convey musical information is sometimes extremely precise, sometimes deliberately aleatory to involve the performers in the creation of the music.

Phase diagrams, depicting thermodynamic phases in equilibrium systems as a function of pressure and temperature, offer a parallel visual language which can transmit compositional intentions as well as phase stabilities based on empirical data.

The pedagogical reason for employing musical interpretation of phase diagrams derives from the analogy between musicians interpreting scores and students decoding chemical and physical properties of the materials: musicians need to know the score and the poetics of the composer in order to interpret it properly; students interpreting musically a phase diagram have to learn its chemical and physical aspects in order to decode it. By means of sonification, phase diagrams of substances such as H_2O, $CaCO_3$ and SiO_2 become musical exercises, where the conductor guides the performers through different states of matter using vocal motifs and body percussion for a dynamic and engaging representation of molecules, phases, temperature, and pressure. Each performer plays as a single molecule in a given phase, and concurs in determining the state of the system. Mastery of thermodynamic principles is essential for accurate musical interpretation, promoting the understanding of scientific concepts and social inclusion through unconventional musical stimuli.

This innovative approach not only enriches STEAM (Science, Technology, Engineering, Arts, Mathematics) education but also underscores the potential of interdisciplinary collaboration in fostering creative learning environments.

Gem Session: aural logos of gemstones by sonification

Eramo G., Monno A., Tempesta G., Mesto E. & De Tullio M.*

Dipartimento di Scienze della Terra e Geoambientali, Universita di Bari "Aldo Moro".

Corresponding author email: mario.detullio@uniba.it

Keywords: music, gemstones, sonification.

Gemstones can vary widely in terms of their characteristics, but there are several key attributes that are commonly used to describe them, such as color, clarity, carat weight, luster, hardness and cut. These characteristics, among others, contribute to the beauty, value, and uniqueness of gemstones, and are recorded on the grading card associated with each gem.

This contribution proposes an acoustic representation of the mineralogical data and the gemological features which define a cut gemstone by means of a specific sonification algorithm. The result is a musical logo unique for each gem, which makes the object even more fascinating and evocative.

The musical texture of the sonification is homophonic, with the melody based on the sonification algorithm to sonify the mineral species adopted in the project "Aural Structures". The algorithm encodes the stoichiometry and the group symmetry which characterize any mineral into an aural model where rhythm, pitch, dynamics and timbre are organized accordingly. The accompaniment of the melody is obtained by sonification of the clarity, carat weight, color and cut, associated to instrument family, dynamics and attack, type of trichords, number of trichords and bass tones, respectively.

A selection of simulations made starting from gems of different nature (diamond, emerald and quartz) and quality aimed at showing sound differences related to different gemological characteristics. The result constitutes an additional sonification-based fingerprint for each specific gemstone and a new perceptual modality, which could open new perspectives in the field of gemology.

Geoscience communication through videos

Erba E.*[1], Mariani L.[2] & Poli S.[1]

Effectively communicating geoscience concepts to non-expert audiences and inspiring students to pursue graduate programs in the field demand a unique set of skills that researchers may not naturally possess or know how to develop. This necessitates collaboration between geoscientists and communication professionals to strike the delicate balance between scientific rigor and engaging communication methods.

The successful partnership between geoscientists and communication experts has proven pivotal in bridging this gap. By leveraging their respective expertise, they can craft compelling narratives and interactive experiences that make complex geological concepts accessible and captivating to broader audiences.

Drawing from our collective experience, we have collaborated within the Italian Geological Society in conjunction with SIMP (Società Italiana di Mineralogia e Petrologia) and SPI (Società Paleontologica Italiana) to create the initiative “ON THE ROCKS.” This innovative project utilizes multimedia platforms, including videos, to creatively depict the intricate processes preserved within rocks. Through the art of storytelling and fiction, these videos illuminate some of the geological wonders of our world, making them not only educational but also entertaining.

By harnessing the power of storytelling and visual media, we can effectively convey the beauty and significance of geoscience to diverse audiences, inspiring curiosity and fostering a deeper appreciation for our planet’s rich geological history. Through continued collaboration and innovation in science communication, we aim at cultivating a new generation of geoscientists and empower them to communicate their research effectively to the wider world.

The Italian Paleoart Award

Facchino E.[1], Mazzei S.[2], Locchi L.[1] & Giamborino A.*[2]

[1] Museo Paleontologico dell'Accademia Valdarnese del Poggio, Montevarchi (AR). [2] APPI, Parma.

Corresponding author email: direzione@accademiadelpoggio.it

Keywords: paleoart, communication, outreach.

The Italian Award for Paleoart is an annual international artistic competition, organised and promoted by the Accademia Valdarnese del Poggio and the Paleontological Museum of Montevarchi since 2021.

Among the objectives pursued by the organisers is the desire to spread knowledge of Paleoart (understood as the representation of prehistoric life through various artistic techniques) and consequently to offer a showcase to professional and aspiring paleoartists who wish to promote their creations, as well as to create works that have a great impact in the field of communication of geo-paleontological themes.

The First Edition of the Italian Award for Paleoart already collected more than 120 works by 75 artists from all over the world, as it did in the following years.

The Italian Award for Paleoart, conceived by Sante Mazzei, has been supported since its first edition by the Italian Paleontological and Paleoartistic Association APPI, the Italian Geological Society and the Italian Association of Scientific Museums.

Over the years, the organisation has become more structured and since 2024 the Award has been divided into two categories: illustrations and projects.

Illustrations may depict, either in graphic or sculptural form, any kind of prehistoric animal and plant life form, a particular environment, biotic community and prehistoric ecosystem; works must be original and unpublished, not published in any other context.

Projects may include original proposals dedicated to paleoart and more generally to communication in the field of geo-palaeontology through images such as books, comics, articles, short films, animated shorts, collections of original sculptures, augmented reality experiences, applications for mobile devices, etc., and which must be narrated through the creation of a poster.

Every year, great attention is paid to the selection of the jury, composed of influential figures from the Italian and international geological, palaeontological and artistic scene. Each edition features a different jury, so that the works are judged as objectively as possible and to allow each aspect of the reconstructions to be highlighted by experts from various fields.

Originality, complexity, scientific rigour and technical ability are the aspects that the Italian Award for Paleoart intends to valorise; in fact, all the works are equally evaluated both for their scientific component and from the point of view of artistic technique.

Finally, we would like to point out the enhancement of the authors included in the "budding artists" category (under 18), for the illustrations section.

In order to further emphasise the contribution of all those who participate in the Italian Award for Paleoart each year, the Palaeontological Museum of Montevarchi organises an exhibition of all the entries submitted during the current year's event in its spaces. Every year, the exhibition attracts many visitors and schools and remains open to the public for about a month.

The Time Machine Project - A travel into Deep Time

Giamborino A.*[1-2], Petti F.M.[3], Innamorati G.[4] & Zuccari A.[3]

[1] Dipartimento di Scienze Biologiche, Geologiche e Ambientali, Università di Bologna. [2] Associazione Paleontologica Paleoartistica Italiana APPI aps. [3] Società Geologica Italiana ETS.
[4] Dipartimento di Scienze della Terra, Sapienza Università di Roma.

Corresponding author email: agiamborino@gmail.com

Keywords: deeptime, comunicazione, sensibilizzazione.

The concept of Time is very complex and not innate in man. We have always attempted to define and quantify it, but only relatively recently have we managed to determine it absolutely thanks to Patterson's isotopic studies.

The difficulties that man has always had in defining the concept of Time are linked to its nature, to the way in which it is perceived and above all to the discipline with or for which it is attempted to be defined. Not least the difficulty of having a very limited point of view, especially if we relate it to our daily life and our empirical experience. As we commonly understand it, Time is relative, therefore determined by the simple succession of events: by the life of a single man, by a certain historical period, by the development of a civilization.

In geology, it is defined according to a fundamental event: the formation of planet Earth.

One of the main purposes of Earth Sciences is to reconstruct the chronological succession of the biological and geological events that have characterized the history of our planet and to help us measure the immensity of the Deep Time that has passed through it.

But if the age of our Planet, over 4.5 billion years, is a value that researchers and those involved in Earth Sciences are now accustomed to managing, the same cannot be said for all those who are approaching these disciplines for the first time or have a different educational background.

Thinking in terms of billions, millions or sometimes even just thousands of years means having to process too large values that often cannot be fully understood. For this reason, especially if you are dealing with children, students in their first years of schooling or with a general public, it is necessary to adopt, in communication and dissemination activities concerning Earth Sciences issues, a language that is understandable to everyone and try to use tools that allow us to communicate clearly and effectively. First of all, the use of simple but at the same time immediately communicative images, such as paleoartistic reconstructions. For this reason, "The Time Machine Project - a travel into Deep Time" aims to be a useful and effective means in addressing issues concerning time and the geological history of our Planet, offering a relative reading of time, therefore presented as a succession of events, but in the same way try to give value to the dimensions of the various periods and above all highlight their differences.

A complete way to present the dynamics and impact of events that have shaped the Earth, the catastrophes, appearances and extinctions of life forms that have determined the geological past of our planet, to better understand diversity and the environments that still characterize it today. A fundamental knowledge to better understand the world we live in, our role as living beings and useful to us in our relationship with the environment around us.

Land degradation: an unconventional tale

Giampaolo V.*[1], Calamita G.[1], Corbo D.[2], Fanti L.[1] & Imbrenda V.[1]

[1] Istituto di Metodologie per l'Analisi Ambientale, CNR, Tito (PZ). [2] Theatre educator, Potenza.

Corresponding author email: valeria.giampaolo@cnr.it

Keywords: geoscience communication, narrative formats, engagement.

Land degradation is a complex issue that involves the degradation of natural resources across various dimensions, including soil, vegetation, water, and biodiversity. Its profound impact extends to billions of people worldwide resulting in significant socio-economic and ecological consequences. Furthermore, it is recognized that the depletion and degradation of these assets often exceed the capacity for recovery within a single human lifespan.

Given the broad scope of the topic, an educational activity was conceived for high-school students, focusing on the narrative dissemination of land degradation in one of its many facets. Science, like other aspects of human experience, benefits from storytelling - a fundamental aspect of human communication, serving both our innate curiosity about the world and our need to share experiences. Communication of science encompasses two of humanity's fundamental needs: to know and understand one's surroundings and to tell stories.

The workshop unfolded in three phases: an introduction to the theme, independent group work, and presentation of the work. Initially, participants were introduced to the topic through visually rich slides, eschewing excessive text in favor of evocative imagery. The discussion emphasized the interdisciplinary nature of the issue, touching upon its intersections with fields such as humanities, global economics, and social sciences. Using an interactive approach based on debate and involvement, students were encouraged to explore the local ramifications of land degradation, making the topic more relatable to their everyday experiences.

Following, students were instructed to form groups (of about 10 people each) and guided in the construction of their narratives. They were prompted to consider various elements, such as the choice of communication medium, target audience, stylistic approach, thematic focus, and narrative structure. This exercise aimed to foster creativity and critical thinking while encouraging students to engage with the topic on a personal level. After an hour of collaborative work, each group presented their narratives, while their peers evaluated them based on creativity, clarity of content, and engagement. Evaluation was facilitated through software, allowing students to provide feedback directly from their smartphones.

The students' response to this approach was enthusiastic. From their efficient self-organization into groups to their creative choices of communication tools, the students readily embraced their role as science communicators for one day. The resulting works showcased a diverse array of communication methods, ranging from contemporary podcasts to traditional artistic mediums, as well as innovative approaches facilitated by artificial intelligence. Some narratives even drew inspiration from literary figures such as Giacomo Leopardi, T.S. Eliot, Giuseppe Parini, and Primo Levi, demonstrating the students' depth of engagement with both the scientific and cultural dimensions of the topic.

"Can You Sea?": an aerial and acrobatic performance to involve people in marine bio-geoscience researches

Lupi C.*[1], Marchini A.[1], Brioschi S.A.[2], Crenca E.[2], Gazzola F.[1] & Innocenti Malini G.[3]

[1] Dipartimento di Scienze della Terra e dell'Ambiente, Università di Pavia. [2] ASD Kirkes, Piccola Scuola di Arti Acrobatiche, Cava Manara (PV). [3] Dipartimento di Studi Umanistici, Università di Pavia.

Keywords: performing art, bio-geosciences, climate change.

The ocean is a key element of the Earth system and is an archive and source of information and resources for humanity. Today, this precious piece of the planet's well-being is increasingly threatened by climate change and anthropic activity with tangible losses and degradation of habitat and biodiversity. Unfortunately, the social perception of this situation is disproportionately low, because the affected systems are hidden and not adequately presented by media. To ensure the effective implementation of science-based solutions to restore marine ecosystems and safeguard this critical resource in global policies, society's relationship with the ocean must change, and this requires the adoption of new educational tools and communication processes.

Here, we present the impact of a physical/acrobatic theater performance aimed at raising awareness of the main threats to the ocean. A performance titled "Can You Sea?" was co-created by choreographers, researchers in marine ecology, biology and geology around the themes: marine pollution (including nutrients, plastic, noise), overfishing, bioinvasions and climate change. The physical performances are accompanied by audio recordings, video scenography and short readings, written and performed by scientists, with the supervision of a community theater researcher. Scientists are on stage with thirteen teenage athletes.

The show benefited from three performances in very different cultural contexts: the WeWorld Festival of Milan in May 2023, the Blue Festival of La Spezia in July 2023 and the European Researchers' Night 2023 in Pavia in September 2023.

During the second and third reruns, before/after performance surveys were submitted to the public, in order to measure the performance impact and the level of audience engagement. The surveys were completed by approximately one hundred and thirty spectators. Participants stated that they learned new topics and that what they already knew was presented in an original and particularly clear way. In the free comments collected through the post- performance survey, the spectators proved to be enthusiastic about the approach and particularly emotionally involved. These findings document how the performing arts can represent innovative approaches to communicating complex issues and achieving social change, creating an emotional connection that conveys new values and insights.

Echoes of extinction: how an exhibition can unveil the lost world of dinosaurs through science and art

Maganuco S.*[1-2-3], Ambrogi L.[2], Capuccella E.[2], Figus C.[2] & Gambini I.[2]

[1] Sezione di Paleontologia, Museo di Storia Naturale di Milano. [2] Mostra Extinction - Prima e dopo la scomparsa dei Dinosauri, Gubbio. [3] Associazione Paleontologica Paleoartistica Italiana, Parma.

"Dinosaurs in the Flesh: Science and Art bring the Rulers of a Lost World Back to Life" is an educational project made in Italy, managed by Geomodel. Since 2011, it has aimed to create a stable and lasting bridge between the academic community and the general audience. Being initially conceived as a travelling exhibition, each new instalment is designed to fully enhance the host venue and the geopalaeontological heritage of the region, allowing the public to learn about natural treasures previously largely unknown to laypersons (Romano et al., 2016).

In this regard, in 2017, "Dinosaurs in the Flesh*"* journeyed to Gubbio (Umbria, Italy) to bring to life the exhibition "Extinction. Before and after the disappearance of dinosaurs", in collaboration with the Municipality and the Department of Physics and Geology of the University of Perugia. Here, the rock strata of the Gola del Bottaccione are highly significant from a geological, biostratigraphic, and palaeomagnetic perspective, but have become famous primarily as the first evidence of the events underlying the fifth mass extinction, the most famous among those that have marked geological time: 66.0 million years ago, an asteroid the size of a mountain struck the Earth, triggering a series of catastrophic events that annihilated 75% of life forms, including the gigantic non-avian dinosaurs that had dominated the Mesozoic era (Alvarez et al., 1980).

The "Extinction" exhibition tells the story of life on Earth through the traumatic events that have marked it, the major mass extinctions, offering the opportunity to delve into a topic of burning relevance in scientific debate. Spectacular life-size sculptures, fossils, and casts are displayed in the evocative "Ex Monastero di San Benedetto", the ideal setting for a unique exhibition. Panels and multimedia content - such as Paco Lanciano's Quadrisphere - guide visitors through a fascinating journey. Ample space is dedicated to research conducted in Italy and behind the scenes: the work of the palaeontologist and palaeoartist to bring back to life the rulers of a Lost World, amidst old bones and new technologies. At the end of the journey, there is a section on the timeless allure of dinosaurs and Ice Age mammals, icons of the collective imagination and absolute protagonists of Pop Culture.

The exhibition offers a rich educational project aimed at schools of all levels: guided tours, excursions in the area, and workshops tailored to various age/schooling groups. Every weekend, there are events, activities, and workshops for the public.

The primary objectives for the coming years include: 1) the complete redevelopment of the adjacent public park (Orto San Benedetto), 2) the integration of multimedia content accessible via smartphones, 3) improving accessibility with a path for visually impaired visitors, 4) the creation of a diorama representing the last day of the Mesozoic Era, and 5) the complete transformation of the exhibition into a fully-fledged permanent museum.

How do comics help to learn about Marine Geology?

Mazzini I.*[1-2] & CNR ECORD-IODP and ICDP Commission[2]

[1] Istituto Di Geologia Ambientale e Geoingegneria, CNR, Montelibretti (RM).
[2] Dipartimento Scienze del Sistema Terra e Tecnologie per l'Ambiente, CNR, Roma.

Corresponding author email: ilaria.mazzini@igag.cnr.it

Keywords: science communication, comics, research dissemination.

Illustrations are a good way to visualize what is not readily seen and to express ideas and concepts with images. Telling stories in pictures, comics have been proven particularly effective in science communication. Comics can serve as a valuable tool for understanding the geological exploration of oceans by providing a visual medium to depict what may not be easily observable (Farinella, 2018). Through vivid illustrations and storytelling, comics can bring to life the intricate processes and discoveries involved in exploring the depths of the ocean. They enable readers not only to visualize the geology of the ocean and scientific instruments used in exploration efforts, but also to better understand the life of scientists on board. By presenting complex concepts in a visually engaging format (Lin et al., 2015), comics make it easier to grasp the challenges and advancements in marine geology, fostering a deeper understanding of this fascinating field. Due to their sequential nature, comics strips make it easy for readers to follow a story and comprehend the concepts that are covered (Robin et al., 2021). The limited text in each panel can also help those where reading is a challenge or for those who become nervous and/or discouraged with long text passages. The illustrations also add visual clues that can aid in understanding the concepts being laid out.

Drawing inspiration from the IODP "EXP 402: Tyrrhenian Continent-Ocean transition" that took place from 09 February 2024 to 08 April 2024, the CNR ECORD-IODP and ICDP Commission has decided to use comics to engage reading for young and old alike. The "Ocean exploration issue" is aimed at primary and middle school students to spark their interest in Earth Sciences. The issue has been created by Comics&Science, a series by CNR Edizioni, as a special edition ("off-series"). The interaction with the comic book artist Alessio Spataro has helped to develop a contemporary pedagogical approach, rending science concepts such as deep-sea drilling engaging and accessible to students. The issue also includes brief texts about the history and the future of IODP, the ICDP project and the IODP-ICDP land-to-sea proposals. The issue's goal is to create a bridge between science and entertainment, both of which are relevant for individual and societal growth.

Earth Sciences in the Divine Comedy: a hidden story

Monno A.*, Iurilli V. & Eramo G.

Dipartimento di Scienze della Terra e Geoambientali, Università di Bari "Aldo Moro".

Corresponding author email: alessandro.monno@uniba.it

Keywords: Divine Comedy, geology, mineralogy.

Since Antiquity, Literature has numerous examples of writings that show the close and inseparable relation with Natural Sciences. Both classical authors and modern ones, have produced scientifically important works in the field of Natural Sciences, about plants, rocks, fossils, metals, minerals, etc. Goethe, for example, wrote the Theory of Colors in 1810, which demonstrates how a man of letters can be re-membered as a scientist at the same time. On this theme, the Museum of Earth Sciences of the University of Bari set up a temporary exhibition in 2015 showing fascinating and imaginative connections between the two aspects of knowledge. Although science and poetry may be considered two distinct domains in common opinion, a thin thread connects them. The examples proposed in this note start from Dante Alighieri, the famous author and man of letters endowed with great curiosity and widest knowledge, who lived in an era in which there was no clear division within knowledge. To emphasize the fascinating narratives of his great poem, the Divine Comedy (14th century), he inserted quotations of minerals inspired by Albertus Magnus' treatise De Mineralibus (13th century). Paradise and Purgatory, mention above all gemstones, including diamond, topaz, emerald and sapphire, while in Hell, in addition to helitrope (a form of chalcedony), we find precious minerals such as gold and common ones as ice, which is the glassy-looking component of the infernal lake Cocytus. In this regard, we also propose a video, which combines the sequence of the silent movie L'Inferno (Milano Films, 1911) related to the 9th circle (Hell, Canto XXXII), with the melodies obtained from the sonification of the crystalline structure of ice (I_h) according to the methodology of the project Aural Structures (Eramo et al., 2018; Candela et al., 2023). It represents an effective combination between the vintage images of the movie and the tense mood expressed by the symmetry of ice (I_h) transformed into music. Furthermore, this contribution highlights the morphological analogies between the artistic and imaginative representations of Dorè (1861), Zuccari (1586-88) and Britto (1544), and real karst environments culturally connected to Dante's travels during his exile, such as the Covolo of Camposilvano (Velo Veronese), the Tolmin Cave (Zadlaška Jama) and the Veja Bridge (Lessinia Regional Nature Park). It is said that Dante Alighieri was so fascinated by the latter that he was inspired by the description of the Malebolge, i.e. the 8th circle of Hell in which fraudsters are punished.

Furthermore, current photographic-geographical research makes it possible to draw parallels between the karst environments and the artistic representation of the artists already mentioned. This contribution also includes storytelling that blends some verses of the Poem with real images and eloquent drawings by the greatest illustrator artists of the Divine Comedy.

SIGN ME IN - accessibility and usability of MUST (University Museum of Earth Sciences) explanatory panels for deaf visitors: an analysis

Pioggia M.* & Sardella R.

Dipartimento di Scienze della Terra, Sapienza Università di Roma.

Corresponding author email: marta.pioggia@uniroma1.it

Keywords: MUST, accessibility, cultural democracy.

The art of Geoscience communication is also the art of choosing the right words for the public you want to engage. This is particularly true when considering publics with special needs. In order to promote in everyone the basic knowledge and understanding of the principles of Earth Sciences crucial to make conscious choices about environmental sustainability, climate change and the exploitation of energy resources, any obstacle preventing the widest participation in science education, especially in non-formal and informal settings, must be removed. To foster public engagement, active citizenship and cultural democracy, and in compliance with objectives 4, 10 and 11 of the Agenda 2030, any action towards accessibility of scientific contents must be taken with the involvement of the interested parties.

SIGN ME IN is a Sapienza Earth Science PhD project in Environment and cultural Heritage that aims to:

improve deaf people visiting experience of the MUST (Museo Universitario di scienze della Terra) by adapting and translating into LIS (Lingua dei Segni Italiana - Italian Sign Language) the texts of some of the explanatory panels;

make the museum's cultural offering more available also to people with low education levels and/or a low literacy in the italian language, according to the principles of UDL (Universal Design for Learning).

This project investigates the challenges deaf people may face in understanding scientific communication inside the MUST and tries multiple strategies to adapt the existing texts to suit the needs of different audiences with the involvement of a group of deaf (and hearing) students from ISISS Magarotto in Rome and a group of deaf adults. A two-year PCTO (Path for transversal skills and career counseling) involving 3 classes of senior students was carried out to work on the adaptation of 7 of the panels' texts and a LIS translation of a panel chosen by the students. This project will act as a guideline for the design and implementation of the MUST, that's currently under renovation, and for the activities that the museum will promote in its spaces.

Through the pages of the ages: conveying the unfathomable depth of time in an illustrated book

Troco E.[1], Manucci F.[2], Maganuco S.*[2-3] & Ambasciano L.[4]

[1] Atelier Troco, Cividale del Friuli. [2] Associazione Paleontologica Paleoartistica Italiana, Parma.

Keywords: deep time, palaeoart, books.

*"*Tempo Profondo. La storia della vita sulla Terra*"* ("Deep Times: The History of Life on Earth"; Troco et al., 2024) is an innovative, multidisciplinary attempt at tracing the evolution of nature in all its forms, from the origin of the cosmos to the history of humanity. One of the goals of the volume is to communicate the richness of modern scientific discoveries to as wide an audience as possible, through engaging and immersing artistic and storytelling techniques. The use of oil paintings featuring novel and unexpected compositions, combined with a lively yet authoritative popularizing approach, allows readers to transport themselves into the most evocative, and almost alien, scenes of the deep past. The presence of easy-to-follow brief text sections, carefully designed as expanded captions to accompany each painting, allows for a piecemeal understanding of the multidisciplinary contents and improves the consolidation of memory retention. The book also offers an enticing large-scale perspective approach rarely before seen in similar publications, in which the entire range of historical and natural sciences is included to supply a most comprehensive history of life, i.e., cosmology, the geological and palaeogeographical history of planet Earth, the interactions between organisms and their environment, palaeoanthropology, and human history. Furthermore, this sweeping narrative extends to the development of scientific thought and addresses the challenges of modern society, from pressing ecological problems to the currently undermined legitimacy of scientific research, reconnecting the topics previously addressed in the book with modernity and the state of our planet. The readers, upon reaching the end of this expansive narrative, will perceive the events featured in the early pages as unfathomably distant, but will also acquire a strong sense of historical continuity between the deep past and the present day, and will understand the strong links that tie together all earthly ecosystems past and present. This universal worldview allows readers to embark on a journey through the ages and make sense of the vastness of the Deep Time.

From 'Gerusalemme Liberata' to Dante's Divina Commedia: the seismogenic hypothesis of earthquakes linked to underground winds

Zuccari C.*[1], Artegiani F.[2], Fagioli G.[3], Tancredi S.[4] & Romano M.[4]

[1] Dipartimento di Scienze Biologiche, Geologiche e Ambientali, Università di Bologna. [2] Dipartimento di Scienze, Università di Roma Tre. [3] Istituto Di Geologia Ambientale E Geoingegneria, CNR, Roma.
[4] Dipartimento Scienze della Terra, Sapienza Università di Roma.

Corresponding author email: costantino.zuccari2@unibo.it

Keywords: history of geology, Dante Alighieri, seismogenic theories.

Earthquakes and seismic phenomena in general have always attracted the interest and awe of human civilizations, especially in connection with the emotional impact that such energetic events could evoke following great destruction and loss of human lives. In this contribution, we analyze the earliest seismogenic theories dating back to the Middle Ages, essentially inherited from the new translations available at the time of fundamental texts including Aristotle's "Meteorologica". According to the knowledge of the time, earthquakes were connected and believed to be caused by the thrust of underground vapors and winds, with varying intensity based on the ease or difficulty these air masses encountered in traversing the "veins" of the Earth. After Aristotle, the theory that saw underground winds and vapors as the cause of earthquakes and the birth of mountain ranges is extensively found in the work of the Arab physician Avicenna Ibn Sina (980-1037), who essentially reworked the theories presented in the "Meteorologica" with his vision. Furthermore, echoes of this theory, or system of theories, can also be traced in Albertus Magnus and Ovid. In the work of Ristoro d'Arezzo published in the 1200s, the Italian cosmographer curiously compares earthquakes caused by the movement of underground vapors to gases produced and expelled from the bodies of animals (Romano, 2023). Similarly, the same comparison is found in the Commentary on Aristotle's "Meteorology" by Nicolò Vito di Gozze, this time using flatulence in the human body as an analogous phenomenon. In addition to treatises, including those of Brunetto Latini (Romano, 2020), in this contribution we show how this theory also found space in the verses of various poetic works, starting from Dante's immortal work in the Divine Comedy (Romano, 2016), but also in later works such as Cecco D'Ascoli's "L'Acerba" and Torquato Tasso's "Gerusalemme Liberata". The theory was initially embraced by the genius of Leonardo da Vinci and shortly thereafter by Bernardino Telesio (1509-1588), an Italian philosopher and naturalist who can be considered the true initiator of the new Renaissance philosophy of nature and from whom thinkers such as Descartes, Giordano Bruno, Tommaso Campanella, and Francis Bacon drew inspiration.

The dissemination of Marine Geosciences in schools as a contribution to the Ocean Literacy process: from teachers' training to hands-on activities

Alvisi F.*[1], Cheimonopoulou M.[2], Koulouri P.[3], Mogias A.[4] & Mokos M.[5]

Keywords: ocean literacy, marine geosciences, scientific approach.

Widespread environmental education is essential to meet the challenges of an increasingly interconnected planet whose future is at stake. Since we have just entered the UNESCO Decade dedicated to Ocean Sciences for Sustainable Development, Ocean Literacy (OL) is a way to link marine science with education for sustainability through the promotion of behavioural change and the adoption of a systems approach to marine environmental issues. The role of schools is therefore crucial in acquiring and strengthening environmental knowledge, skills, and competences, educating the citizens of the present (teachers) and those of the future (pupils). However, teachers' involvement is necessary to achieve the goal of bringing OL into the European school system in the short and long run. Therefore, to engage teachers and keep them engaged on this topic in the coming years, there is a need to combine traditional and innovative teaching methods and educational tools in integrating the content knowledge (CK) on ocean science issues, mainly lacking in the primary school, with the pedagogical one (PCK), often not considered in the secondary school. During the last 4 years, several EU projects and initiatives were dedicated to bringing OL to school (e.g., BlueS_MED, BlueNIGHTs, BlueMinds4Teachers, EMSEA, EU Blue School Network). Thanks to this, a permanent multidisciplinary working group where scientists, teachers, and young ocean ambassadors can fruitfully and continuously interact was formed. Long-lasting educational communities (Mokos et al., 2022), as well as quality, modern, and innovative educational materials and tools (Alvisi et al., 2022; Cheimonopoulou et al., 2022; Koulouri et al., 2022), were built and consolidated, giving birth to innovative teachers' training and school activities. Some of the best practices developed will be presented and discussed, including:

1. the open-access online course and digital toolkit developed as part of the BlueMinds4Teachers project () that provide teachers and educators with materials and tools, relevant references, resources, and links;
2. the practical seascape activity entitled "How deep is the sea? Discovering the underwater territory". The aim is to familiarise oneself with the 'land beneath the water' by building 3D models of sea and ocean basins using simple techniques and low-cost materials;
3. the hands-on activity on the water cycle "Water Pathways". Its aim is to: a) discover the link between water and climate and the elements needed to build the water cycle in different climatic contexts, b) explore the physical processes that transport water across continents to the sea and c) find the "water numbers" through the dedicated "Water Quiz";
4. the hands-on activity + guided tour "There's wall and wall! " to discover the link between the building materials of our historical centres, often of marine origin, and the geology of the surrounding areas.

The sea: life's source

Barbarito L., Lillo A.*, Marzolla M., Menga H. & Ricco G.

High School "G. Galilei - M. Curie", Monopoli (BA).

Corresponding author email: ariannalillo@pololicealemonopoli.edu.it

Keywords: sea, pollution, protection of ecosystem.

This work comes from a Social Studies Project developed during 2023-2024 school year including the disciplines of Natural Sciences, Mathematics and Physics with the support of the teachers of the Polo Liceale in Monopoli, Lillo Arianna and Lucia Barbarito.

The III B of the Liceo Scientifico, composed of 22 students, has been subdivided into 7 groups who faced making original works on the theme of the sea, scientifically suitable (poems, podcasts, newspaper articles, stories, posters, photos). At the end of the creation of the various works, the most appreciated one that obtained the highest consensus and approval, has been chosen by the students themselves, through a process of self-evaluation, with the teachers' support.

The group who made the selected work, is composed of the students Heden Menga, Matteo Marzolla and Giacomo Ricco. Initially, they consulted a series of bibliographical scientific sources with the aim of studying the sea in its various aspects (resources, legality, ecosystems protection, sustainable transport via the sea and the life in the coastal community). Later, the group translated the acquired knowledge and its relationships in a PP presentation and in a drawing made by the technique of pastel colours (a synthesis of the content of the PP slides). Moreover, the drawing has been commented by a description - shown below- that explains in a poetical form the profound sense of the problems connected with the sea, according to the students of the group.

'Under a veiled sky, grey of smoke, the sea cries tears of oil. In the obscure abysses, the silence is interrupted by the noise of ships that discharge venoms and the corals, once shining, suffer their obscure destiny in a gloomy procession. Man, with his carelessness, has dishonoured the sea, maternal lap and cradle of life. Hope is renewed in the wave crashing against the cliffs of human indifference and in the hands of those who tear the sorrowful painting to colour a new source of life'.

The work made by Heden Menga has received the first prize at the National Competition "The citizenship of the Sea", announced by the Department of Education and the Department of Transport and Infrastructures. Giuseppe Valditara, Minister of Education and the Deputy Commander General Admiral Inspector Sergio Liardo awarded the student during a ceremony held in Reggio Calabria on 11th April 2024, during "The Sea Day and the maritime heritage".

Science Nights at the High School Complex in Monopoli (BA)

Barletta M.L., Benedetto S., Genchi L., Ippolito M.P., Lillo A.*, Longano D., Ratti L. & Valletta S.

High School "G. Galilei - M. Curie", Monopoli (BA)

Corresponding author email: ariannalillo@pololicealemonopoli.edu.it

Keywords: celebration of scientific culture, dissemination activities, workshop activities.

During the 2023/2024 school year the "G. Galilei - M. Curie" High School in Monopoli (BA) hosted the sixth edition of "La Notte delle Scienze" (The Night of Sciences), an event aimed at promoting scientific culture. The event stems from the teamwork of teachers from the Departments of Natural Sciences, Mathematics and Physics, Sports Sciences, with the collaboration of Art History and Philosophy teachers, and students from all high school addresses, with the aim of opening the doors of the Institute to the community through scientific dissemination activities (conferences with nationally and internationally renowned speakers) and workshop activities (carried out in various Biology, Chemistry, Earth Sciences, Physics, and Computer Science laboratories). The students were the undisputed protagonists, lively and brilliant, and they were able to positively infect guests and all attendees with their enthusiasm.

Throughout this year, experts, researchers engaged in internationally resonant projects, such as Dr. Massimiliano Morelli, Prof. Domenico Mavilio, and Prof. Francesco Colucci, presented on topics related to the fascinating field of Biotechnology, accompanied by students who acted as moderators, presenters, and animators.

In all editions, we aimed to draw the attention of young people, and beyond, to the importance of scientific culture in our society to better understand the world we live in. Scientifically relevant topics were addressed in various sectors such as moon landing, complexity of biological systems, fake news in the scientific field, and climate change. Among the laboratory activities, there were in-depth studies on rocks, karst phenomena, and numerous experiments conducted by students. Seminars by qualified experts were particularly stimulating, such as Telmo Pievani's "The virus of fake news: what vaccine," Piergiorgio Odifreddi's "The two cultures: humanism against Science," Donato Boscia's "Xylella in Puglia: an annoying truth," and Mario Tozzi's "Science, misinformation, and fact checking." In the first edition, guests included Colonel Vitantonio Laricchia, who spoke about "Climate change," the IPSP-CNR Research Group and DiSSPA University of Bari, with "The case of annoying Xylella," Prof. Domenico Di Bari with a seminar titled "How is the Universe made? The physicist's story," Dr. Ciola Gianfranco, with the seminar "Coastal environments between nature and tourism," and Dr. Alessio Perniola, with the theatrical workshop "Magical Science: theater, magic, and science." These are just a few of the speakers and disseminators who participated in various editions. Over the years, this event continues to represent for the entire school community and the citizens of Monopoli and neighbouring towns, an opportunity for growth, discussion, and celebration of scientific culture.

An experimental approach to improving the teaching-learning process in the geosciences

Barone A.*[1], Madonia G.[1-2] & Rotigliano E.[1]

[1] Dipartimento di Scienze della Terra e del Mare, Università di Palermo.
[2] National Biodiversity Future Center NBFC, Palermo.

Keywords: geosciences literacy, inquiry-based learning, instructional model.

How can the teaching-learning process in the field of Geosciences be made more effective? Geosciences are difficult disciplines, because of their complexity and articulation, and this makes the teaching – learning process challenging. In order to implement an effective didactic approach teachers should have a solid geological background that allows them to structure effective activities characterised by inductive approach, innovation and engagement. Furthemore, most teachers don't dedicate the right amount of time to the Geosciences, and the deductive approach to teaching scientific disciplines is widely used. In order to overcome these difficulties we have designed an instructional model based on the literature data (Hoffman & Ritchie, 1998; Bybee, 2014; Ambrose et al., 2017) on how we learn, that can be used with different inductive methodologies and for all type of topics. The model has been applied in the framework of the PLS/PNRR project in two different high schools in Sicily and has been proposed to the Lyceum students from the third to the fifth year. In this context the pathway aims to guide students towards discovery by investigating the causes, evidences and effects of Climate Change. As detectives, the students collect "clues" through real data, observations, tools and use investigative techniques that allow them to piece together the current complex climatic process in its general aspects. The objectives are to develop knowledge, skills and competences in the Geosciences and the way Geoscientists study the Earth. This is important to acquire Geosciences Literacy and to educate citizens who make conscientious and sustainable decisions for our planet. The path consists of four activities building on inquiry-based learning, each addressing an aspect of the Global Climate Change. For each activity a different methodology which place the student at the centre of the didactic action in order to promote the construction of learning has been used. Each activity is included in the instructional model that is developed in 3 phases: preparation, construction and evaluation. In order to explain this framework, we will present one of the four activities, according to the DGBL methodology, regarding the main cause of Global Climate Change. The students are guided step by step in the learning process, and they are given a "Pre-Test", a "Post-Test" and a metacognition survey. The Pre-Post Tests are designed to evaluated the success of the activity and its effectiveness in developing the Geosciences Literacy, while the metacognition questionnaire is structured to assess the students' satisfaction with the activity and to make them aware of their cognitive path, and preconceptions and misconceptions. The data obtained shows that there has been an improvement in skills and knowledge acquisition. Furthemore, an improvement of competences development in Geosciences Literacy and consciousness of what it means to be a Geoscientist has been recorded.

Caving and hiking activities for promoting knowledge and landscape preservation

Benedetto S., Genchi L. & Valletta S.*

High School "G. Galilei - M. Curie", Monopoli (BA)

Corresponding author email: valletta@libero.it

Keywords: geodiversity, environmental conservation, speleology and hiking.

The "G. Galilei - M. Curie" High School in Monopoli (BA) has implemented over the past four school years the "Speleo-Trekking Course" Project, aimed at promoting the knowledge and protection of the local territory, starting from the identification and documentation of geological, geomorphological, karstic, and vegetational aspects. One of its objectives is to provide basic knowledge in order to introduce students from different educational paths to spelunking and trekking in a totally safe way.

The activities were developed with the involvement of Natural Sciences teachers and the support of experts from the tourist promotion agency Puglia Escursioni and the Italian Society of Environmental Geology SIGEA-APS (an environmental protection association recognized by the Ministry of the Environment).

The educational program, which includes approximately 25 students at the Institute, was carried out through the attendance of:

4 two-hour laboratory meetings, during which basic concepts of geology, spelunking, and natural elements of the local landscape were introduced;

4 field trips, during which students had the opportunity to visit several locations near Monopoli, some nearby caves, and practice trekking on tested routes in the municipal territory and surroundings.

Participants in the Project were able to enrich their knowledge of local territory and to acquire skills related to the curricular activities of Earth Sciences (types of rocks and their properties, karst processes and phenomenology) and Biology (types of local vegetation and ecological balances).

Students from all classes of the High School Complex had the possibility to visit some sites of naturalistic, geological, speleological, and vegetational interest in their vicinity. The specialized guides of Puglia Escursioni and SIGEA-APS (geologists, spelunkers, foresters) were able to convey precise information, raising awareness about safeguarding the local territory.

Participation in the Courses allowed students to realize the importance of safety in hiking, to practice caving and hiking movement techniques, to understand the main aspects of the local landscape. The students involved appreciated the project activities, and some of them expressed their interest in continuing this experience, by participating in future courses and/or enrolling in proper spelunking courses. Over the years, the Project, included in the Institute's Educational Offer Plan and evaluated as a relevant "experience" for the PCTO (Paths for Transversal Competences and Orientation), continues to represent an important opportunity for an in-depth study of topics related to Earth Sciences.

Outdoor science experiments, hands-on learning in nature: the Nirano Mud Volcano (NMV, Fiorano Modenese, Italy) open-field laboratory

Bianchini G.*, Brombin V., Tagliacollo L., Bonadiman C. & Tassinari R.

Dipartimento di Fisica e Scienze della Terra, Università di Ferrara.

Corresponding author email: bncglc@unife.it

Keywords: environmental geology, mud volcanoes, open-field laboratory.

Mud volcanoes (MVs) are part of the "sedimentary volcanism" due to their morphological resemblance to igneous volcanoes and are characterized by the uplift of sediments and fluids (Martinelli & Judd, 2004; Mazzini & Etiope, 2017). They are widely diffused and, although not always as fascinating as "ordinary" volcanoes, no less investigated by various disciplines, e.g. botanics, microbiology, geophysics, geomorphology, geochemistry and structural geology. In particular, they are taken into account for hydrocarbon prospection, mainly gas, since they are mostly located in petroliferous basins and constitute the second natural source of CH4 (Sciarra et al., 2019) and as earthquake precursors (Martinelli & Judd, 2004).

In Italy, MVs occur in both Northern and Central Apennine and in Sicily (Martinelli & Judd, 2004; Sciarra et al., 2019). Nirano mud volcano (NMV) of the Emilia Romagna region is one of the biggest in Italy, situated close to a small anticline in the outcrop of the Plio-Pleistocene "Argille Azzurre" clays (Martinelli & Judd, 2004), and is widely investigated for the gas composition (Mazzini & Etiope, 2017). Thousands of people of all ages and levels of education visit this magnificent area every year. Master geology students from the University of Ferrara, the course "geochemical prospecting", have been putting into practice the theoretical geochemical skills of measuring in-situ temperature, pH, and electrical conductivity, as well as collecting water and mud samples for analyses (X-Ray Fluorescence, XRF; Inductively Coupled Plasma Mass Spectrometry, ICP-MS; Ion Chromatography, IC; Elemental Analyzer for coupling to Isotope Ratio Mass Spectrometers, EA-IRMS) in the laboratory.

The results of their curiosity and abilities focused on the geochemical composition of NMV mud and water, as shown during the second Italian Geochemistry Society congress. The aim of this work is also to raise and increase awareness of peculiar geochemical threats in the national territory at many levels using the NMV area as an open-field laboratory, which is suitable for everyone interested in improving their geological knowledge and understanding and the processes occurring in the Earth crust (fault formation, fluid circulation, and earthquake indicators). In particular, this outdoor experience fits very well with exploring teens, who can make first-hand observations, mud, water and gas sampling (be prepared to get hands dirty!) and experience simple analyses on the field, such as pH, EC, and water salinity measurement throughout specific probes.

The didactical experience of the "Laboratory of climatology and environment" of the Master Course in Environmental Science of the University of Pisa

Bini M.*[1], Zanchetta G.[1], Lazzarotti M.[1], Luppichini M.[1], Gemignani G.[2] & Tarantino I.[2]

[1] Dipartimento di Scienze della Terra, Università di Pisa.
[2] Istituto superiore G. Galilei, Viareggio.

Corresponding author email: monica.bini@unipi.it

Keywords: geoscience comunication, high school, Massaciuccoli Lake.

In the 2020 the master course in Environmental Science of the University of Pisa promoted a convention with the Viareggio Municipality, thanks to a financial support of the "Fondazione Cassa di Risparmio di Lucca" to develop a laboratory on the shore of Massaciuccoli Lake, for monitoring climate and environmental conditions as part of wider project of environmental protection. The selected area has a great environmental value, and it belongs to the Migliarino San Rossore Massaciuccoli Natural Park, and it is a protected area by RASMAR convention, it is an archive to study past climate condition, but it also has several environmental issues (e.g. eutrophication, salinization). Although motivated by scientific interest, the main aim of the initiative was to create a scientific structure on the territory able to involve local administration, school and local community to disseminate geo and environmental science knowledge. Specifically, the Laboratory wanted to promote active interaction of local school to disclose scientific methods applied on the environment and the climatic system, as a part on long term continuous support of the geo and environmental sciences. In the last three years the laboratory promoted important initiatives with primary and secondary school and was recognized as an important centre for innovation in the didactical methods (https://labclimambiente.dst.unipi.it/). Among the others (e.g. #io_sono_ambiente project; Adotta_una_duna Project) the lab hosted the project LAGOrà promoted by High School G. Galilei Viareggio that passed the national competition Science on stage and will be presented this year at Science on stage Europe. The project and the lab would like to transform the Massaciuccoli Lake in an open lab for monitoring and analyses of environmental data. High school students had the opportunity to work tougher with Phd Students, University students. Students of Industrial Technical Institute and Scientific High School of Applied Sciences realized low cost monitoring instruments used in didactic and in research activities. Thanks to the lab activities, Administrative Entities acquired new data improving the territory knowledge and its management. The scientific activity promoted by the laboratory and supported by local institutions also produced important scientific achievements (Bini et al., 2020; Luppichini et al., 2021; Luppichini et al., 2022; Luppichini et al., 2024).

Keywords: piano lauree scientifiche, geology, secondary school.

The Piano Lauree Scientifiche, known simply as PLS, was born twenty years ago as a joint initiative of the Italian Ministry of University and Research, the Confindustria association and con.Scienze, the national conference of directors of structures and articulations of science and technology of universities. Its initial mission was to strengthen the recruitment of students in Chemistry, Math and Physics. After then, the PLS expanded to include all scientific disciplines, including geology. Today the whole PLS comprises 9 scientific disciplines that involves more than 260 operative units throughout the Italian university system. The new 2023 call of the PLS has three main aims: to increase student recruitment and reduce the student dropout, to close the gender gap in STEM (Science, Technology, Engineering and Math) enrollment and to reduce social and economic barriers to access the university education system. The duration of this new PLS call is nominally 4 academic years, from 2022/23 to 2025/26.

The Progetto Nazionale Geologia features all the 28 public universities that offer the 1st cycle degree in Geological Sciences and its main activities are: 1) active orientation for enrollment in the Geological Sciences degree, 2) training of tutors to contrast the dropout rate within the first year of enrolment, 3) design and implementation of indoor and outdoor laboratory activities for the secondary school students and teachers, 4) design of self-assessment and knowledge recovery pathways for university entrance, and 5) professional development of secondary school science teachers.

To date, most of the initiatives of the Progetto Nazionale Geologia are aimed at the active orientation of prospective students (44% of all initiatives, n = 239) and the laboratory activities (40%), the latter often involving experiences outside the classroom. This reflects (a) the urgent need to increase the number of students enrolled in a Geological Science degree, given the nearly 20% loss of enrolled students in 2022 compared to 2018 and (b) the firm belief that field experiences are those that add value to a Geological Science degree. Almost 10% of the initiatives of the Progetto Nazionale Geologia is aimed at the professional development of the secondary school science teachers, who generally have a background in biology and related disciplines and are keen to improve the quality of their teaching of geology.

Our contribution will outline the essentials of the new Progetto Nazionale Geologia of the PLS and will showcase a few examples on how we reach the secondary students to make them discovery geology and its societal impacts.

A journey in the Caput Mundi geodiversity

Brustia E., Lucarini M., Pompili R.* & Primerano P.

Dipartimento per il Servizio Geologico d'Italia, ISPRA, Roma.

Corresponding author email: roberto.pompili@isprambiente.it

Keywords: geoheritaghe, urban geology, education.

Within the framework of the initiatives for the dissemination of Earth Sciences knowledge promoted by the Geological Survey of ISPRA, a project called "Conoscere la Geodiversità" was proposed to secondary school students. In particular, the project was carried out with four fourth-year classes of a scientific high school in Cisterna di Latina.

The project was articulated in three different moments.

A workshop dedicated to the recognition and classification of rocks was held at first. The workshop consisted in an initial theoretical part where the basic concepts of minerals and rocks, the rock cycle and their classification into igneous, sedimentary and metamorphic rocks were explained. The second part of the workshop was practical and was dedicated to the identification and classification of rocks by the students. A "dichotomous key" approach was chosen, in which choosing the correct definition among those proposed in the recognition path allowed the students to arrive at the definition of the chosen rock (Schirolli, 2012). Some of the stages of the recognition path, in addition to the simple observation of the samples with the help of magnifying glasses, included physical (hardness, determination of the specific weight of the rock) and chemical (reactivity of the rock with acid) tests.

The second meeting of the project was dedicated to a theoretical lesson on the concepts of geodiversity, geological heritage and geosites. On this occasion, ISPRA's inventory of Italian geosites was presented and illustrated to the students, and a search was made for the geosites listed in the inventory closest to the school, with a brief description of their characteristics. The meeting ended with an excursion on the geological history and geodiversity of the Roman territory, a preparatory moment for the third meeting. The third day of the project was dedicated to an urban excursion in the centre of Rome to discover the geodiversity of the city and the relationship between geology and urban development (Pantaloni et al., 2023). The itinerary started at the Basilica of San Clemente, followed the Via dei Fori Imperiali from the Colosseum to Campidoglio, and ended at the churches of Baroque Rome (Santa Maria sopra Minerva and Sant'Ignazio di Loyola), where it is possible to admire the decorative stones from the different areas of the Mediterranean basin that belonged to the ancient Roman Empire. This excursion was previously proposed to other high school students on the occasion of the second World Geodiversity Day, 6 October 2023. In this case, which only included a visit to the city, a lecture (after the excursion) proved necessary to clarify many issues that could not be dealt with on the day. From this test came the idea of holding the workshop on rock identification and the lecture on the geology of Rome before the field day. Questionnaires were given to the students to assess their involvement and interest after the three project days.

Georesources: finding the perfect mixture between science and dissemination in PCTO activities

Bussolesi M.*[1], Battiston T.[2], Comboni D.[2], Cavallo A.[1] & Grieco G.[2]

[1] Dipartimento di Scienze dell'ambiente e della Terra, Università di Milano-Bicocca.
[2] Dipartimento di Scienze della Terra, Università di Milano.

Corresponding author email: micol.bussolesi@unimib.it

Keywords: georesources, dissemination, PCTO.

The critical role of georesources and the environmental footprint of human activities in shaping the current and future societies are sometimes overlooked by the public, especially by the youngest generations. Mining is often associated with environmental threats and dangers while the importance of georesources is greatly underestimated or, worse, neglected. This could be a major issue as social acceptance will be pivotal in the implementation of mining in EU countries as required by the 2023 Critical Raw Material Act. The responsible exploitation of georesources is a key requirement to reshape the current economic model into a more environmentally friendly one while still maintaining a sustainable economic growth. In the framework of PTCO (Paths for Transversal Skills and Orientation) activities we have organized a 15-hours project aimed to sensibilize students to the needs and risks of mining activities. Laboratories, movies, frontal lectures, thought experiments and interactive visits to the Earth Sciences facilities at University laboratories have been organized paying attention to keep high levels of engagement and participation through the involvement of the students in the activities and an informal context. The project has so far been presented to 19 high school classes and over 360 students. Following each cycle, students were invited to fill a three-minute anonymous questionnaire to evaluate the project offering valuable insights for further improvement and development of the activities. The general evaluation was positive to highly positive for all the activities. Not surprisingly, the most appreciated one was that at the University lab facilities, which was deemed by the majority "too short", highlighting the need to produce more active-oriented environments to engage the students.

Teaching geosciences with ChatGPT during the first year of an upper secondary school

Cattafi I.[1], Sticchi A.[2] & Braga R.*[1]

[1] Dipartimento di Scienze Biologiche, Geologiche e Ambientali, Università di Bologna.
[2] Liceo Scientifico Allegretti, IIS Paradisi, Vignola.

Corresponding author email: r.braga@unibo.it

Keywords: ChatGPT, teaching, learning.

Chatbots are computer programs based on artificial intelligence (AI) that can answer human questions in a chat-like manner. They are now publicly available and can generate a wide range of features including text, images, videos, software code and so on. One of the most famous chatbots is ChatGPT. Since its launch in late 2022, it has generated an exponential growth of excitement and concern among science teachers and educators, who are discussing risks and opportunities of chatbots in the learning and evaluation processes (Cooper, 2023).

In this contribution we explore (1) the attitudes of science teachers and students of a Istituto di Istruzione Superiore towards generative AI tools and (2) the use of ChatGPT as a collaboration coach, i.e., students enter prompt into Chat GPT to complete learning tasks during a part of the geoscience curriculum. We considered two first-year classes attending the Earth in the Solar System topic: one class used ChatGPT to assist their learning activity while another class used more conventional learning activities without the assistance of AI-based chatbots. We will discuss the results of our experiment, our decisions about the content, structure and timing of the learning activities, and the challenges we faced in terms of the accuracy of the information retrieved by the students.

Cooper G. (2023) - Examining Science Education in ChatGPT: An Exploratory Study of Generative Artificial Intelligence. J. Sci. Educ. Technol., 32, 444-452, https://doi.org/10.1007/s10956-023-10039-y.

Building bridges between academia and high school: the experience of "Open river Laboratory" project (in the framework of Percorsi per le Competenze Trasversali e l'Orientamento)

Comino E.*[1], Balestra V.[1], Bellopede R.[1], Fazli M.[1], Tamietto M.[1-2], Treves A.[1] & Zambrotta M.[3]

[1] Dipartimento di Ingegneria per l'Ambiente il Territorio e le Infrastrutture DIATI, Politecnico di Torino. [2] A.K.A.Noah, Team studentesco. [3] Istituto Istruzione Superiore Santorre di Santarosa,Torino.

Corresponding author email: elena.comino@polito.it

Keywords: environmental school education, urban river ecosystem, citizen awareness.

The study and monitoring of water resources are increasingly important, not only for better understanding natural processes but also for evaluating the human impact on ecosystems. The winning key for the study of environmental ecosystems is therefore a transversal and multidisciplinary approach, which requires technical-scientific skills but above all a strong propensity towards the surrounding environment. Added to this is the need for training aimed at all levels. Based on these considerations the research group coordinated by prof. Elena Comino, with the support of the AKANoah student team of the Department of Environmental, Land and Infrastructure Engineering (DIATI), proposed the "Open River Laboratory" training project for high school students. The project has two objectives: the first offer to the students an opportunity to better understand the value of water resources and environmental monitoring, with particular reference to the topic of micro and macroplastics, the second give to high school students a first opportunity to begin themself towards a university future.

In the framework of the whole school approach, the integration of university research with basic level education activities takes on a leading role in the process of greening the school and makes environmental education a central component of schools curricula. The value of academic research for the development of environmental education high school is often overlooked. However, what better utility could academic research have other than promoting awareness and spreading knowledge to the younger generations? There is a lack of research in the role of academia, in terms of its utility as a tool for social improvement through environmental education. Specifically, the creation of environmental and sustainable education programs will form the citizens for tomorrow world.

In the poster we will start by describing the project idea and the implemented methodology, which is not only for this specific project, but more generally the importance of creating a connection between Academia and High School will be underlined. The results achieved, both by the students and by the teachers involved in the "Open River Laboratory" project, will be referred, as a case study. The strengths of the project itself will be underlined by suggesting approaches to the integration of academic research in institutions of high school in the form of best practices

Findings show the benefits that can be obtained from the involvement of the academy in the creation of environmental and sustainable education programs. First, the academic involvement bridges the gap between high school and research world by providing continuity to the very role of teachers and educators alike. Second, the dissemination of results of pedagogy and sustainability research to a larger public and staff involved in the development of educational programs and their implementation, it would promote awareness and dissemination of knowledge on multiple levels, vertically and horizontally. Finally, the analysis of different experiences underlines the advantageous role of academia in facilitating the development of educational experiences which create critical reflective thinking.

Geosciences through the eyes of primary school students: a visual journey

D'Addezio G.*[1] & Besker N.[2]

[1] INGV, Roma. [2] CINECA, Information systems for Universities and Research.

Corresponding author email: giuliana.daddezio@ingv.it

Keywords: children drawings, perception of science, statistical analysis.

Starting in 2005, the Istituto Nazionale di Geofisica e Vulcanologia (INGV), initiated a project involving the creation of calendars designed for schools, featuring drawings from a contest for primary school children. Each year, schools eagerly participate by submitting pupils' drawings on specific themes, which vary annually and align with Earth science subjects. Engaging primary school children in this project serves a dual purpose: it brings them closer to science and provides an opportunity to explore their perspectives on the Earth, science, the environment, and sustainable behavior. In fact, children's artwork can offer valuable insights into their feelings and thoughts about the world and its workings. Drawing plays a crucial role in children's development, as it fosters imagination and serves as an effective means of expressing emotions.

Over the years, we have collected more than 35,000 drawings. We have decided to analyze this extensive and unique dataset by comparing drawings related to competitions with similar and comparable main topics, such as children's perceptions of science, scientists, and their views on the Planet Earth, its sustainability, and its future. The methodology involves a qualitative and statistical analysis of the drawings, representing the first comprehensive comparison of drawings created by primary school children across the entire Italian territory. This spans a decade or more, providing insights into how children's visions of Earth science subjects have evolved over time.

Furthermore, the results contribute to evaluating how science is portrayed, assessing whether it has fostered a shared understanding and a less stereotyped image. Additionally, we aim to examine how environmental science and sustainable behavior are conveyed to the future leaders of the world.

STEAM project to raise young people's awareness of land protection

D'Amato M.*[1] & Stornelli C.[2]

[1] Istituto Tecnico Economico "Vito Vittorio Lenoci", Bari.
[2] Liceo Scientifico "Gaetano Salvemini", Bari.

Corresponding author email: prof.maria.damato@itelenoci.edu.it

Keywords: STEAM, Matilda effect.

The aim of this work is to describe the activities of the inter-school project, financed by the Puglia Region (Schools in STE@M). Matilda effect: a stereotype to overcome is the name of the project.

Secondary school students involved in the plan of activity, worked in an inclusive climate between three different schools in the Bari area.

The first step was to visit the Lama Picone. The blades, which starting from the highest points of the Murgia and following the inclination of the land, head towards the sea, were formed over time by the dissolution of limestone rocks, constituting natural channels.

The involved students photographed and recognized the plant species of the area, learning to appreciate their characteristics: from colors to scents, to finally recognize some properties in the geometry of nature, such as symmetries and self-similarity (fractals).

From the knowledge of the rich native botanical heritage we moved on to the creation of a prototype, through the art of images (photography) and 3D modeling (autocad) up to the creation with a 3D printer.

REKHOVER-Science: REalizing Kits for HOspitals to Visualize EaRth Sciences

Della Seta M.* & Medeghini L.

Dipartimento di Scienze della Terra, Sapienza Università di Roma.

Corresponding author email: marta.dellaseta@uniroma1.it

Keywords: inclusion, education, hospital school.

One of the primary goals of institutions is to promote activities with an inclusive approach, to cancel physical and social barriers that prevent the individual fulfillment.

The REKHOVER-Science project, led by the Department of Earth Sciences at Sapienza University of Rome, aims at developing hands-on kits to support Earth Science education in Hospital Schools.

Hands-on experiential activities have been demonstrated to be highly effective as learning tools, enabling users to visualize concepts and enhancing learning by involving all senses. This is particularly significant for Earth Sciences, which are often overlooked in school curricula, despite their relevance to pressing environmental issues.

The general project objective is to provide hospitalized or homebound students with access to laboratory experiences to augment their learning. These kits will be co-designed with teachers from Hospital Schools or involved in home education services from the Hospital School at the “Bambino Gesù” Pediatric Hospital, the “Policlinico Umberto I” University Hospital, and the “Agostino Gemelli” University Polyclinic in Rome, covering primary, secondary and high-level education. Working groups are being formed with teachers from various institutions to identify concepts and topics in the field of Earth Sciences that require laboratory kits for hands-on activities, aiming at enhancing understanding through practical engagement. Co-designing is crucial because it enables the creation of kits tailored to specific needs and personalized training plans, ensuring maximum functionality.

The kits will be practically developed by children and young adults from Roma Capitale within workshops held at the Technotown creative science hub at Villa Torlonia, which will provide both space and expertise for designing and practically implementing the laboratory kits during the second phase.

Interdisciplinary approaches in geoscience education: exploring the application of entomology in ichnoentomology

Faedda G.L.* & Pascucci V.

Dipartimento di architettura, design e urbanistica, Università di Sassari.

Corresponding author email: giuliafaedda@gmail.com

Keywords: ichnoentomology, geosciences, interdisciplinary-education.

This study presents an innovative approach in the field of ichnoentomology, a discipline focusing on the analysis of insect fossil traces, situated within the geological context of ichnology. This expanding research area unveils new horizons in paleoclimatology by leveraging the observation of insect fossil traces to identify humid and arid periods associated with Dansgard-Oeschegert (DO) (high frequency climate changes) events, providing insights into paleoenvironmental conditions from late Pleistocene related to insect activity.

One limitation of this discipline is that, from various perspectives (sampling, statistical analysis, morphological studies), ichnoentomology is still predominantly regarded as a branch of geology, and thus studied solely from a geological standpoint. The work elucidates an intriguing biological perspective grounded in entomology. Through a mentoring project within the doctoral school of the University of Sassari, students from the Faculty of Agriculture explored the challenges of scientific research in an attempt to integrate two seemingly distant disciplines: geology and biology.

The educational approach centered around problem-solving methodologies, fostering an interactive exchange of knowledge across diverse domains: on one hand, the dissemination of geological research to an audience with a biological background, and on the other hand, the welcoming and assimilation of new perspectives from students and the professors in the entomology course. In fact, during frontal lectures, research challenges were presented, followed by engaging discussions and Q&A sessions with students.

The mentoring program was structured over a total duration of 30 hours, divided into laboratory activities (25 hours) and instructional sessions (5 hours). Concurrently, the entomology course, valued at 3 CFU, aimed to provide students with a comprehensive understanding of insect morphology, anatomy, and physiology, as well as biological cycles and population dynamics, with a focus on recognizing major groups and species harmful to agricultural crops.

The findings underscore the importance of interdisciplinary education in geosciences, promoting inclusivity and diverse teaching approaches. Collaborative learning enriches students' educational experiences and prepares them for multidisciplinary challenges in academic and professional contexts. Emphasizing geosciences education for students from diverse backgrounds highlights its multidimensional nature, enhancing their problem-solving abilities from various perspectives.

Geoscientific school heritage: from the past to the future

Franza A.* & Pratesi G.

Dipartimento di Scienze della Terra, Università di Firenze.

Corresponding author email: annarita.franza@unifi.it

Keywords: geoscientific school heritage, Collegio Nazareno, Joseph II.

A considerable amount of literature has been published on school-museum partnerships. However, relatively few studies investigate school museums, particularly natural history school collections. This work presents the recovery, study, cataloging, and valorization of the 18th-century geo-mineralogical collections belonging to the Mineralogical Cabinet of the Collegio Nazareno (Crocetti et al., 1997), one of the most important Roman institutions for the study and learning of physical and natural sciences in the modern era. The collection is now housed at the Istituto San Giuseppe Calasanzio (Roma).

The project, which was participated in by science and history teachers along with the students enrolled in the fourth- and fifth-grade high school classes, retrieved 1724 geo-mineralogical samples. All the recovered specimens and their accessory parts (i.e., original display containers and labels) were photographed and inventoried in an online database to be used to program cross-curricular learning activities. Two hundred samples were cataloged using the national standard for the cataloging of mineralogical and petrographic heritage (BNM and BNPE catalographic standards) issued by the Istituto Centrale per il Catalogo e la Documentazione (ICCD), part of the Ministry of Culture, and published in open access on the Catalogo Generale dei Beni Culturali database. The results of this study found that most samples were collected by renewed naturalists such as Scipione Breislak and Giuseppe Gismondi or donated to Collegio Nazareno's Mineralogical Cabinet by popes and prelates (e.g., Pio VI and the Cardinal Stefano Borgia) together with members of the Italian and foreign nobility (e.g., Francesco Maria Ruspoli, Prince of Cerveteri and Karl Theodor, Elector of the Palatinate). The most striking finding was the recovery of the geo-mineralogical collection donated by the Holy Roman Emperor Joseph II of Habsburg-Lorraine in 1785 (Mottana et al., 2012). This collection is the only one that can be attributed with certainty to Joseph II since no other samples, kept in natural history museums preserving 18th-century Habsburg geo-mineralogical collections, show proper labeling (Franza & Pratesi, 2023). Joseph's II collection and 250 specimens from the general collections were displayed in the new permanent exhibition area.

In conclusion, this work proved that geo-mineralogical school museum collections can be positively used as scientific-educational tools in object-based learning experiences to promote science literacy (Franza & Pratesi, 2024). For instance, the cataloging activities, included in PCTO plans, represent valuable tools for developing interdisciplinary proposals even in traditional classroom lessons. The case study illustrated in this work showed that geo-mineralogical school museum collections are a unique heritage deserving to be rediscovered and made accessible to anyone interested in learning more about the history of geoscientific education.

Keywords: Geosciences, natural sciences, interdisciplinarity.

The need to consolidate and facilitate the teaching of Geosciences in Italian upper secondary schools has been evidenced by several studies (Greco & Gualtieri, 2010; Realdon et al., 2016; Furfori I. et al., 2023; Gravina T. et al., 2023). To investigate the possible effectiveness of interdisciplinary pathways in the Natural Sciences, with a focus on the Geosciences, in upper secondary school, some teaching programs were designed and realized with an interdisciplinary approach linking geosciences, biology and chemistry. The objectives of these teaching paths were: (i) to assess the feasibility and effectiveness in introducing or consolidating the teaching of Geosciences; (ii) to examine whether such paths can facilitate the teaching of Geosciences to Natural Science teachers who do not have specific training in geology. Three schools were involved in the study: ITIS, Liceo Classico and Liceo Scientifico. The classes involved were first through fourth year, with the ITIS offering a course in environmental biotechnology. The schools were contacted by e-mail, sent to school principals, explaining the purpose of the project and asking for contacting and starting a cooperation with the Natural Sciences teachers themselves. After contacting interested teachers, in several meetings, both in person and online, the teaching materials to be used were presented and discussed/adapted and the time frame was agreed upon. Seven pathways were proposed, from which three were chosen:

1. A survey of geodiversity and biodiversity for the Agenda 2030 Goal 15 - Life on Earth. Aim: understanding the relationship between biodiversity and geodiversity and the importance of preventing environmental depletion.
2. Oceans: hydrosphere and biosphere for the 2030 Agenda Goal 14 - Life Under Water. Aim: investigating the relationships between the Earth's different spheres.
3. The carbon cycle: Where does a tree's carbon come from? Aim: understanding how the inorganic and organic worlds are connected in this biogeochemical cycle.

To investigate the previous students' knowledge (including informal and nonformal one) of the chemistry, biology and geosciences topics that would be covered, a pre-test, consisting of 10 multiple-choice questions, was provided in each pathway. These questions were the starting point for examining the topics together. The teachers involved were asked to fill out a questionnaire in order to verify how effective this type of approach really was in improving the teaching of Geosciences in the upper secondary school.

Between November and December 2023, the "Geothermix" (http://geothermix2023.dst.unipi.it/index.php/en/) conference took place in Pisa. It was organized by PhD students of the Department of Earth Science of Pisa and addressed various aspects of geothermal energy, from specific studies on geothermal areas and technologies used to obtain the energy resource, to the didactic activity needful to correctly disseminate the geothermal energy concept. With a dedicated session, one of the main objectives was also to share innovative teaching methods and detailed information to provide teachers with the necessary tools to develop such topics effectively.

The main goal of the session concerned teaching and dissemination in the georesources sector and in particular for geothermal energy, sharing different teaching methodologies and insights to provide tools for teachers in developing these issues (Invernizzi et al., 2011). Several aspects have been considered in the different presentations. Among these: the potentialities of introducing an ecocentric perspective in geoscience teaching, founded on the relationships between humans and Earth, and how this can affect the discussion on geothermal energy; the geothermal energy for thermal energy production and storage and its integration in multivalent district heating and cooling grids; examples of innovative Geosciences Education through Episodes of Situated Learning, ESL (Piangiamore & Maramai, 2024), as interactive teaching tools for geothermal resources; didactic approaches for geothermal energy and sustainability; a laboratory approach on geo-resources; a survey on the presence of geothermal energy in the curriculum (topics dealt with at school) in Tuscany upper secondary schools (Indicazioni nazionali per i licei, 2010).

Geological narratives, a new approach to assensing skills

Gallo Maresca M.*

Liceo Scientifico "Fermi", Bari.

Corresponding author email: m.gallomaresca@gmail.com

Keywords: IBSE, elaborate phase.

IBSE, Inquiry-Based Science Education, offers the possibility of developing consolidated skills not only in knowing how to do but above all in knowing how to think, argue and transfer what has been learned into new contexts. The IBSE teaching action is based on the 5E cycle, the 5 phases: Engage, Explore, Explain, Elaborate and Evaluate. Creating didactic learning units with this approach is not easy and there is a risk of achieving it only partially by having to resort to missed lessons, the "program" to be finished, grades, etc. This work presents a learning unit on "minerals and rocks" created in a third class after understanding chemical bonds.

The Engage phase consisted of reading two newspaper articles on the "Fibronit" case in Bari and the damage caused by asbestos. Some stimulus questions were thus asked through brainstorming, "what is asbestos?", "what are minerals?", "which minerals do you know?", "are all minerals dangerous?" to bring out prior knowledge on the topic. A double Explore phase followed, a first phase of searching for information on minerals and their characteristics followed by a laboratory phase in which the students found themselves having to try to classify unlabelled minerals on the basis of their characteristics and properties such as the crystalline appearance, the scratching, the reaction with dilute solutions of hydrochloric acid and the colour.

The Explain phase consisted of arguing and explaining their classifications. At this stage they were also asked to explain the danger of asbestos minerals.

From minerals to rocks it was a short step. The term "rock" had already appeared in the initial brainstorming and now, looking at a granite, the students are able to say that it is an aggregate of minerals but recognize minerals in other types of rocks is not easy. Engage's trigger question becomes "why don't we see minerals in all rocks?".

The following Explore and Explain phases follow the same approach as that of minerals with study of the different characteristics of the rocks and subsequent recognition and classification phase. For the Elaborate phase it was the most surprising one. The students were asked to write a story "Imagine you are a rock or a mineral and talk about your life, your expectations, your fears....". The students, after choosing the mineral or rock to give life to, further researched themselves by inserting references into the text on the use of different materials today as in the past, thus creating imaginative stories but with solid scientific bases, some were able to insert interdisciplinary ideas with the use of materials in the history of art, exceeding the teacher's wildest expectations.

For the Evaluate phase, all student feedback, participation, laboratory activities, multiple choice questionnaires and the final paper were used.

Fostering inquiry and engagement in Earth Science: designing and testing a specialized curriculum for Italian liceo students

Gravina T.* & Iannace A.

Dipartimento di scienze della Terra, dell'Ambiente e delle Risorse, Università di Napoli "Federico II".

Corresponding author email: tgravina@unina.it

Keywords: upper secondary school, Earth science teaching.

In the Italian upper secondary school system, Earth science is included in the Natural Science curriculum, mandatory for a specific 4-year period. However, Italian natural science teachers often overlook Earth Science in favour of Chemistry and Biology (Greco & Gualtieri, 2010). Gravina & Iannace (2023) investigated the challenges of teaching Earth science in Italian upper secondary schools through a survey and explored the type of support needed for Earth science education. The findings underscored the necessity for new teaching materials in Earth Science that align with National Guidelines, particularly regarding the allocation of hours dedicated to Earth Science lessons.

Therefore, we have embarked on developing a specialized 5-year Earth science curriculum tailored specifically for Liceo students (Classico, Linguistico, Scientifico, Scienze Umane) that fully aligns with Italian national guidelines. The curriculum focuses on the following key points:

- Adherence to national guidelines concerning knowledge, methodologies, and skills;
- Integration of inquiry-based learning and historical approaches;
- Utilization of authentic Earth Science data and reliable sources;
- Adoption of a STEM approach.

This curriculum is designed to provide engaging and hands-on Earth science lessons, specifically addressing the challenges faced by teachers who may not have a background in geology. Additionally, comprehensive lesson plans have been developed for each activity within the curriculum. These plans encompass references to national guidelines, digital resources for hands-on activities, civic education components, and assessment rubrics. The curriculum underwent review by a group of Italian upper secondary school teachers during a focus group aimed at gathering feedback and finalizing it before implementation in schools. The participants of the focus group were selected from a pool of teachers who responded to a call shared within the online teacher community. The selection process aimed to form a group that could adequately represent the Italian teacher community in terms of geographical diversity, years of teaching experience, and educational background. Additionally, we decided to invite two expert teachers with extensive experience in teaching earth science. Participants analyzed the proposed Earth science curriculum, identifying strengths and weaknesses in its conceptual design and organization of materials. In this contribution, we present the results of the focus group and how we utilized them to finalize the curriculum. Furthermore, we discuss teachers' remarks regarding Earth Science education in Italian upper secondary schools.

Gravina T. & Iannace A. (2023) - Earth science teaching in Italian Upper secondary school: the floor to Natural Science teachers. In: The Geoscience paradigm: resources, risk and future perspectives. Congresso congiunto SIMP, SGI, SOGEI, AIV, Potenza (Italy), 19-21 Settembre 2023.

Keywords: geoscience education, earthlearningidea, european geosciences union.

Although Earth Sciences are part of both primary and secondary school curricula in Italy, they are not given enough attention in Natural Science education. Moreover, these subjects are often taught by teachers who do not have the necessary academic qualifications (e.g., Realdon et al., 2016; Bonaccorsi et al., 2020). This issue, which is prevalent in several European and non-European countries (King et al., 2021), has been worsened in Italy due to the limited availability of professional development opportunities for educators in the field of geosciences.

In 2018, the Committee on Education (CoE) of the European Geosciences Union (EGU) suggested improving the professional development of teachers through a pilot initiative, which involved the appointment of Geoscience Education Fieldwork Officers (GEFOs). Four school and university teachers from EU countries (France, Italy, Portugal, and Spain, funded by EGU) and two from India and Morocco (funded by International Union of Geological Sciences-IUGS and the International Geoscience Education Organisation-IGEO) were trained to run interactive hands-on workshops tailored for "teachers of science or geography who incorporate some geoscience into their teaching but have limited expertise in this area." The workshops utilized teaching resources from Keele University' Earth Sciences Education Unit, which were developed by the late professor Chris King and have been available in the Earthlearningidea open access repository since 2008 (https://www.earthlearningidea.com).

In 2022, after the period of forced interruption due to the COVID-19 pandemic, the GEFO project was extended to include the training of additional fourteen GEFOs from various countries, such as Albania, Burkina Faso, Chile, Colombia, Estonia, Germany, Greece, India, Malaysia, Romania, Togo, Turkey, and the United Kingdom. Since 2019, GEFOs have organized 156 in-person workshops, with approximately 3000 participants, 23 conferences and webinars, published research papers and teaching articles, fostering the diffusion of geoscience teaching among a growing global education community.

The purpose of this presentation is to showcase on the outcomes of the Italian GEFO program and highlight the relevance of conferences in promoting workshops as an opportunity for teacher professional development and sharing of best practices.

Keywords: climate change, educational game, MACMAP project.

MACMAP is a project funded by INGV and devoted to study climate evolution in the Mediterranean and polar regions. The period of interest covers the recent past to the near future.

Important components of the project are the interdisciplinary approach to study climate, the data sharing and management of data following international standards and best practices, the support of observing systems and the integration between measurements and models, with the aim to provide more accurate indicators of the ongoing climate change. The topics covered span from atmospheric sciences to oceanography, from space to sea level studies, from seismological to geochemical and glacial sciences. A peculiarity of the project is also the historical approach to climate change in the past. An attempt has been made to extrapolate historical oceanographic data by ancient volumes, in detail by the book considered one of the first treatise about oceanography: Histoire physique de la mer of L.F. Marsili (1725). This activity was possible, amongst the others, through the study of the volumes of the collection preserved at INGV's historical oceanography library. In addition, MACMAP puts a particular emphasis on outreach activities, to bring to the public's attention both the issues being addressed, the research process being used to study this topic. For this purpose the design of an "educational-scientific game" was planned, covering the topics involved in the project and drawing the attention to the importance of the multidisciplinary approach, both addressing specific project activities and more broadly scientific research in general. INGV has long experience in creating this type of games (Garvani et al., 2017; Locritani et al., 2020), but in this case the novelty lies in the involvement of high school students who designed the game directly, through a School & Work Project (PCTO - Percorsi per le Competenze Trasversali e l'Orientamento) supervised by their Science, Physics, Art and Foreign Language teachers, and in collaboration with the research centers (INGV and CNR's Institute of Marine Science (Merlino et al., 2019). The rules, the game strategies and the drawings are completely prepared by the students during the school time in 2022/2023 and 2023/2024. Before releasing the final version, a tryout will be organized to identify and correct potential errors. Then the resulting final version will be made available (downloadable online and printable at home on paper or cardboard) and printed in larger size for use during temporary exhibitions, educational workshops, schools' open days, science festivals, etc.

Geology in down town: easy fieldtrips for learning Earth sciences out of school

Lupi C.*[1], Pelfini M.[2] & Pettinari C.[1]

[1] Dipartimento di scienze della Terra e dell'Ambiente, Università di Pavia.
[2] Dipartimento di Scienze della Terra "A. Desio", Università di Milano.

Corresponding author email: claudia.lupi@unipv.it

Keywords: out-of school learning, urban geomorphology, effectiveness of teaching activity.

The historical centers of cities offer many opportunities to talk about Geosciences. Ancient buildings are often made from local stones which can tell the geological, economical and cultural history of the area. Very often the first settlements from which our cities originated were built in places with natural defenses, such as next to river or close to natural reliefs, and the history of their evolution goes hand in hand with the geomorphological changes of the area.

Here, we offer a short guide consisting of three activities to carry out in cities crossed by rivers. The case study is the town of Pavia and the starting point was the urban geomorphology and geocultural heritage work published by Pelfini et al. in 2020.

The guide presents three distinct activities:

– a geomorphological fieldtrip to discover the landforms of the river landscape and their integration with the urbanization of the city;
– a geological - lithological fieldtrip with the recognition of the different lithotypes present in the buildings of the city centre;
– a practical activity directly on the river bed with observation of the modern depositional and erosional features, the anthropic defense systems and the river sediments.

The guide is designed to be used by teachers not only in Pavia schools since the practical activities are easily extendable to other similar contexts. For each activity, the guide reports educational goals, class targets, keywords, additional materials to view before going out into the field and a trace of the observations that can be made during the activity with images or simple portable experiments. The activities also include the collection of photos and short videos that can be used by students create short documentaries or presentations useful both for the acquisition of transversal skills and for the evaluation process. The three fieldtrips include increasing levels of difficulty and student participation and are easily adaptable to the age of the participants. The activities are connected to each other but can be carried out at different times and even in different school years.

The effectiveness of the geomorphological fieldtrip was verified in 3 high school classes (Liceo Scientifico Copernico di Pavia): a first-year class with few rudiments relating to fluvial geomorphology, 2 fifth-year classes with greater preparation.

The students participated in pre- and post-activity surveys and a good level of learning and correction of misconceptions emerged. The activity was appreciated by the students who actively participated, demonstrating the educational effectiveness of out-of-school activities.

Pelfini M. et al. (2020) - Papai civitas gloriosa: urban morphology for a thematic itinerary on geocultural heritage in Pavia (Central Po Plain, Italy). J. Maps, 17(4), 42-50, https://doi.org/10.1080/17445647.2020.1736198.

Two virtual reality tools to enhance earthquake and tsunami awarness

Maramai A.*[1], Lombardo V.[1] & Piangiamore G.L.[2]

[1] INGV, Roma. [2] INGV, Lerici.

Corresponding author email: alessandra.maramai@ingv.it

Keywords: virtual reality, earthquake, tsunami.

Knowledge is the basis for risk reduction and the dissemination of knowledge of Geosciences to the widest possible audience it's an essential goal to increase awareness towards natural events.

Making people aware of the correct behaviour to adopt in case of an earthquake and/or a tsunami is one of the skill of science communicators. Therefore, researchers are constantly searching for new appealing methodologies to communicate science arousing public interest.

The BET-VR (Big Data Earthquake and Tsunami-Virtual Reality) project of INGV uses Virtual Reality for visualization of earthquake and tsunami. Virtual technology has interesting educational potential, allowing an immediate approach that carries the users into a reality where they can learn in a direct way. Considering children's high comfort level with smart devices and gaming, portable devices for education could have a positive impact on children's interest and engagement. Therefore, the virtual reality represents an innovative and unconventional forms of knowledge transfer. Exploring geophysical phenomena, such as earthquakes and tsunamis, through digital tools like virtual reality, can certainly facilitate the understanding of these processes and, consequently, enhance the natural risk perception.

The BET-VR is mainly addressed to children of Primary School but it can be also performed for the dissemination to general public. The general purpose is to increase awareness of the risks related to earthquakes and tsunamis through the knowledge of the main characteristics of these natural events. To this end, dedicated 3D environments have been designed, aimed to achieve a most effective embodiment edutainment.

Concerning earthquakes, the "3D Earthquake journey" virtually lead the children inside the seismogenic structure originating the 2016/2017 seismic sequence in Central Italy. Simulating a person's physical presence in that specific environment, the users stand in a privileged observation point, acquiring relevant geological and seismological information during the journey.

The "3D Tsunami journey*"* is focussed on the tsunami topic: through two virtual characters facing a tsunami, the user virtually experiences this event, learning the main concepts and acquiring the correct behaviour to adopt in case of a tsunami.

Virtual reality is entirely digital and immersive, isolating the user from the external environment. By wearing a specific helmet visor, he is transported into a completely absorbing parallel reality and through the controllers he can interact or move within the digital world.

Thanks to the very realistic immersive scenarios, this didactic software is a very useful tool for scientific dissemination, engaging children with geophysical topics as earthquakes and tsunamis.

It also allows to explore the potentials of entertainment technologies in educational processes and it contribute to innovative Technological Enhanced Learning (TEL) pedagogies for scientific learning.

A web virtual world activity on critical minerals in smartphones for 14-years old students

Occhioni M.*[1-2] & Paris E.[1]

[1] School of Science and Technology, Geology Division, Università di Camerino.
[2] Istituto Comprensivo 12 Farini, Bologna.

Corresponding author email: michelina.occhioni@unicam.it

Keywords: critical mineral, web virtual worlds, education.

Critical minerals are essential components in the manufacturing of smartphones, playing a crucial role in their functionality. These include indium for touch screens, lanthanum and europium for displays, lithium and cobalt for batteries. These minerals enable the high-tech capabilities of modern smartphones (Bookhagen et al., 2020). The extraction and processing of these minerals have significant industrial and environmental impacts and social issues (Berthet et al., 2024). Understanding the importance of critical minerals is crucial for fostering awareness among students about sustainable consumption, the environmental implications of technology, and the geopolitical complexities of mineral supply chains. Education can empower individuals to make informed decisions regarding the use and disposal of technology, and it can inspire innovation in recycling and alternative materials. (Helmi & Zwolinski, 2020). Web virtual worlds, such as Framevr, are suitable platforms for collaborative projects (Jeong, J. et al., 2022) acting as online repositories and exhibits in schools. They are engaging educational scenarios for students, which can share ideas and divide jobs according to the project-based learning approach.

The activity described here, targeted to K8 students (14-year-old) aims to improve the knowledge of the properties and uses of critical minerals, especially those used for smartphone components. The experimentation (total time 1 month) was divided into four steps:

1. a lecture held by a researcher of the National Research Council (CNR) to introduce the concept of critical elements and their importance
2. students' semi-guided web research to get information about critical minerals
3. organization of the retrieved contents in a virtual exhibition using multimedia presentation, images, online games and 3D models.
4. definition of a phase of assessment to evaluate the students' work on the platform and the acquired knowledge, using multiple choice and true/ false questions (online test).
5. a survey to determine the students' opinion about the activity

Based on observations of students' behavior, test, survey and the virtual exhibition, the results are highly satisfying . Students got good mean test score on knowledge acquisition, cooperated during the team works and were highly involved in the activities. They appreciated the possibility to carry out the project in autonomy and judged positively the experience.

The learning process in Geosciences: analysis, evaluations, and proposals

Occhipinti S.*[1-2-3]

[1] ANISN, Aosta. [2] Scuola di Scienze e Tecnologie, Sezione Geologia, Università di Camerino.

Keywords: curricola, education approaches, unexpected connections.

The fragility characterizing the teaching and learning process of Geosciences throughout the educational cycle in Italy, as well as in many other countries, is unfortunately well known, despite data clearly showing how environmental and geological issues are universally prevalent in all these countries. This situation persists even though Geosciences represent the discipline most implicated in the Sustainable Development Goals of the UN's 2030 Agenda. Geosciences are indeed directly relevant and serve as repositories of content related to environmental issues, including risk factors such as global warming or extreme weather events, as well as economic aspects such as georesources for energy transition or the search for critical raw materials.

The study presents the results of research conducted through a long process of experiences, workshops, and projects aimed at schools of different levels, but particularly focusing on final classes, which are particularly interesting for university and professional orientation choices. The main objective is to understand the reasons for this lack of attention to this discipline and to try to find some ideas and solutions to make it more attractive, particularly by analysing the teaching and learning process.

Several factors contributing to the construction of the teaching and learning process of Earth Sciences have been analysed. Some historical and intrinsic peculiarities make this process particularly problematic: the lack of unity and disciplinary cohesion that makes it difficult to build an epistemological identity, the difficulty of constructing meaningful experimental approaches, the progressive structure of ministerial curricula, often limited to lists of information distributed with little coherence in the school path, not integrated into other disciplines, in a metacognitive process based on assumptions and a sequence of events and information that does not favour the construction of reasoned knowledge.

A substantial modification of methodological approaches that avoid frontal communication valorising effective communication styles, the use of experimental practices that, even through the use of new technologies, promote investigative activities even in virtual environments, a radical revision of the curriculum and learning path that promotes the understanding of processes, and cycles, the complexity of phenomena of global dynamics, to replace the current fragmentation of notions, often reduced to a checklist of names, devoid of prerequisite and above all connections with the geographical, geological, and historical context, effective collaboration between the school system and academia, which, each for its competencies and experiences, builds collaborations and bridges aimed at producing a different vision of a Science for the Earth.

Soil ecosystem: STEM approach for developing scientific thinking

Onida M.C.*, Fusi N. & Bonomi T.

Dipartimento di Scienze dell'ambiente e della Terra, Università di Milano-Bicocca.

Corresponding author email: monica.onida@unimib.it

Keywords: soil, exploration, science education.

In order for education to produce meaningful and lasting learning, it is necessary to implement skills-based teaching at school (GUUE, 2006). Earth Sciences are naturally multidisciplinary and allow for a strong connection between theory and practice starting from real and complex situations, as suggested by STEM guidelines promoted by the Italian Ministry of Education since 2023 in all school levels. With this contribution, we aim to provide an example of a possible active didactic approach aimed at building scientific thinking from early childhood (Onida, 2021), with increasing levels of formalization throughout the entire educational path. A fragment of soil is a small, complete and precious ecosystem, whose care and conservation is very important for global climate change. Its observation allows us to put into practice a methodology based on learning by doing and Inquiry science education. The research process is at the heart of the proposal and generates curiosity, questions and discovery possibilities. It starts with a systemic approach, at the core of ecological thinking that encourages the search for interconnections between parts. Then, the different components (organic and inorganic) of the soil sample are separated based on their physical variables by implementing classification and seriation procedures (Arcà & Guidoni, 2008). Observing living beings, both plants and animals, allows for understanding the relationship between structures (how they are made) and functions (nutrition, support, movement, vision, etc.). Observing how animals move and what they eat also confronts us with the key ideas of life sciences related to the growth and development of living organisms in relation to the flows of matter and energy (NRC, 2012). Exploring the inorganic parts of the soil allow us to investigate the relationship between the structures and properties of matter, discretizing an apparently continuous material like soil: from stones to sands to clays, separable through the use of sieves or water decantation. Thus, it is discovered that the soil is made up of particles of different sizes, each of with different absorption, filtration and retention properties. From here, different paths can be taken depending on the school level, from sensory manipulations to consistency transformations with the younger ones, to the exploration of non-visible components (microorganisms collected with the Berlese funnel, presence of air, water retention, pH) or to the study of original rocks and minerals, in progressively higher grades. The important thing is to maintain the focus on working methodologies, implementing real research paths to promote the development of STEM skills. These methodologies are inherently inclusive and allow the involvement of everyone at any age, contributing to strengthening motivation to learn and fighting the gender gap.

#Io sono ambiente, a laboratory path on education for sustainable development in the "I.I.S. Duni-Levi", a secondary school at Matera (Southern Italy)

Panza M.O.[1], Parentini L.[1], Pomarici R.L.*[2] & Serinelli M.L.[2]

[1] Liceo Artistico C. Levi, "I.I.S. Duni-Levi", Matera.
[2] Liceo Classico E. Duni, "I.I.S. Duni-Levi", Matera.

Corresponding author email: rita.pomarici@gmail.com

Keywords: environment, education, sustainable development.

The October 2023 saw at the start of the "# Io sono ambiente" (I am the environment) project, a secondary school project devoted to the education for sustainable development. The "I.I.S. Duni-Levi" Secondary School of Matera (southern Italy) was part of the network of schools that have joined the "#Io sono ambiente " project, aimed at the diffusion of the values of environmental protection and sustainable development, and whose school leader was the Liceo Ginnasio Statale "M. Cutello and C. Salnitro" of Catania (Italy).

The school classes 3^B of the "Liceo Classico E. Duni" and 3^D of the "Liceo Artistico C. Levi" were involved in the project, based on an agreement between the "I.I.S. Duni-Levi" of Matera and the "Dipartimento di Scienze della Terra e Geoambientali" of the Bari University (Italy).

The activities were performed at school and in the field with the aim to study natural events that during the geological eras moved plates and led to relative variations of the sea-level, inducing deep changes in the observed/analyzed region. Students were encouraged to understand how, through a careful reading of the territory and the analysis of marine fossils found in present-day exposed areas, it is possible to trace the presence of the Mediterranean Sea in past geologic history of the region and to reconstruct the climatic variations that have affected the same region over time.

Adopt-a-Dune project: use of 'virtual adoption' and citizen science approach to increase knowledge and raise student awareness on coastal systems management

Paterni M.[1], Alvisi F.[2], Bianucci M.*[3], Bini M.[4], Casanova E.[5], Caselli L.[6], Castiglioni G., Castagnetti T.[6], Ferdeghini F.[6], Gigantesco P.[6], Godani M.[5], Locritani M.[7], Luppichini M.[4], Perfetti A.[6], Rossi A.[6] & Merlino S.[3]

[5] Istituto Fossati-Da Passano, La Spezia. [6] Istituto Capellini-Sauro, La Spezia. [7] INGV, Roma.

Corresponding author email: marco.bianucci@cnr.it

Keywords: coastal environment, citizen science, geoscience at school.

Sand dunes are typical component of lowland coastal landscape. Fascinating formations, they are also fragile habitats that suffer from human impact and natural hazards. They have an important function in coastal dynamics by counteracting beach erosion and saline waters ingression. Many countries have designated dune and sandy areas as protected sites to preserve their unique ecosystems and prevent further damage due to human intervention.

The aim of this project was to bring the pupils closer to the coastal zone with a special focus on dune formations and evolution. They used different types of investigation tools and technologies to carry out multi-perspective research activities, supported by their teachers and mentored by a team of experts in different disciplines. The activities took place during the school year 2023-2024 with a citizen science approach. This made it possible not only to understand with direct experience the peculiarities of the studied fragile system, but also to collect data useful for scientific research purposes.

The project used the "virtual adoption" of the stretch of coastline located in the locality of Marinella di Sarzana, near La Spezia. Here, a previous LIFE project took a stretch of beach away from seaside use to make it an SCI area within the Montemarcello Magra Park. Thanks to this action, the dunes that were once typical of this stretch of coastline are being reformed in this area.

The pupils then began to learn about the Site of Community Interest through introductory classroom lessons and then monitored it in the field, between November 2023 and May 2014, through its sedimentological, geomorphological, and ecosystem components, also assessing any human impact on it. As part of the activities, the students had access to the dune to carry out sampling and measurements based on the knowledge acquired in the classroom training. The sampling activities were supplemented with an aerial survey carried out with a drone. All the data collected were analyzed and integrated in order to draw up a final report of the activities. They will also produce audiovisual and multimedia material dedicated to dissemination and awareness-raising activities on the importance of dune systems. The pupils acquired theoretical and practical knowledge and skills in scientific tools and methods that may be useful to them in their further studies and possible future work. The activities can be continued by their peers of future classes with the intention of maintaining the adopted site in good health.

Acknowledgements: This project received financial support thanks to the #iosonoAmbiente Call for Proposals of Ministry of the Environment and Energy Security. Participation in the Call for Projects includes the establishment of a network of schools: IIS Capellini-Sauro (lead partner), ITCT Fossati-Da Passano, ISA13 and ISA8, all in La Spezia province. The project was accredited by the EUBLUESCHOOL network, present on the European ATLAS of the SEAS.

IN-MUST: for an inclusive Earth Sciences museum

Pioggia M., Della Seta M. & Medeghini L.*

Dipartimento di Scienze della Terra, Sapienza Università di Roma.

Corresponding author email: laura.medeghini@uniroma1.it

Keywords: inclusivity, sustainability, PCTO.

In the last decades inclusiveness has become an integral concept in the valorization of museum exhibitions for informative and educational purposes. Indeed, the aim of cultural institutions has shifted from simply increasing the numbers of visitors to adopting valorization strategies to make exhibition venues more receptive to social changes and universally accessible.

The IN-MUST project (funded by Sapienza Third Mission Grant) aims at creating an open culture hub model, where the exhibits are co-designed through the synergy and cooperation of different social actors.

The project is focused on the University Museum of Earth Sciences (MUST) at Sapienza University of Rome and is aimed at finding inclusive strategies for the dissemination of issues related to the objectives of the 2030 Agenda in a dedicated space inside the museum.

A dedicated Path for transversal skills and career counseling (PCTO) IN-MUST was organized to involve schools and teachers in the project with the aim of highlighting both the importance of a sustainable global development of planet Earth and the need to create an inclusive society open to all.

The PCTO started in January 2024, and involved, for the first year, 8 high schools in Rome and districts (169 students), whose students were challenged to design and develop exhibits for visitors with special needs. The activities included an initial training to provide tools on sustainability, the 2030 Agenda and the Museum as well as an introductory meeting with associations or bodies that support the activities of people with different disabilities.

The exchange and discussion with those associations resulted in 15 different projects on the themes of risk and resources that the students presented in Sapienza at the end of March 2024 and that will be included in the executive project for the MUST renovation.

European Museums' Night 2024: understanding radiometric dating through a scavenger hunt inside the MUST (Museo Universitario di Scienze della Terra, Sapienza)

Pioggia M.*, Sardella R., Della Seta M. & Medeghini L.

Dipartimento di Scienze della Terra, Sapienza Università di Roma.

Corresponding author email: marta.pioggia@uniroma1.it

Keywords: hands-on activities, radioactive decay, MUST.

Hands-on activities are experiential learning opportunities that allow students to engage with a topic through direct interaction. These "learning by doing" activities achieve, through the active involvement of the participants, an improved understanding and a long term retention of the studied topics. Hands-on activities allow to see, touch, manipulate, hear and even smell or taste aspects of the learning material, in a process that caters to the needs of students with different learning styles. When involving collaboration and teamwork, hands-on activities are also powerful tools to improve students' soft skills. Such tools, if introduced in dissemination and outreach activities, can have an effective impact in enhancing the understanding of difficult topics (e.g. the concept of deep time) by the general public. For this reason, during the European night of Museums 2024, at the Sapienza University Museum of Earth Sciences in Rome (MUST), children and young adults were offered the opportunity to join a scavenger hunt and to date their geological find. This activity used recycled materials such as bottle caps and paper clips to build specimens that explain the basic concepts of radioactive decay and half-life. The participants witnessed radioactive decay "in real time" by manipulating the specimens and watching the caps "decaying" into paperclips and then proceeded to the radiometric dating of their own sample based on its caps to paper clips ratio.

Raising environmental awareness in the students through geosciences: the educational importance of geotrails

Punturo R.*[1-2], Visalli R.[1], Sturiale G.[3], Maniscalco R.[1] & Cirrincione R.[1]

[1] Dipartimento di Scienze Biologiche, Geologiche e Ambientali, Università di Catania. [2] Istituto di Geologia Ambientali e Geoingegneria, CNR, Roma. [3] Area Terza Missione, Università di Catania.

Corresponding author email: rosalda.punturo@unict.it

Keywords: geotrails, education, nature paths.

In a student's educational path, adopting an experimental scientific approach holds the utmost significance. Within this framework, the laboratory serves as a pivotal educational setting, offering valuable learning opportunities both in the classroom and the field. Geosciences are particularly indicated for field-based laboratory activities, thus serving as a useful tool for facilitating the learning process. Indeed, through these activities, educators can effectively provide students with essential skills, such as the ability to draw logical connections, discern and establish correlations, generate hypotheses based on available data, and critically and consciously engage with scientific and technological subjects, by the journey's end. In this scenario, nature trails constitute the best educational laboratories to implement a tailored teaching approach across various student classes (Huguet et al., 2019; Palacio Prieto et al., 2019), as these trails serve as ideal learning spaces, catering to both elementary school students engaged in nature exploration and description, and high school one approaching into deeper interpretations from initial observations.

The aim of this contribution is to highlight the importance of two educational geotrails selected on the base of their geological aspects to underline their effectiveness for teaching geosciences. One of these trails is located on the southern flank of Mount Etna, where distinctive features of the volcano have been pointed out and chosen for educational activities conducted directly in the field (Punturo et al., 2019). For each of these features, a corresponding informative panel has been created and installed along the pathway. The second one, is located on the left bank of Loddiero river Valley, (Scordia, Italy) where the stratigraphic relationships between Plio-Pleistocene tholeiitic and alkalic lavas as well as the morphology of an ancient lava delta can be observed. Furthermore, along the pathway it is visible the complex interplay of subaerial and submarine volcanism, eustatic sea level variations, and shallow water carbonate sedimentation (Sturiale et al., 2016).

This nature trails showcases various distinctive volcanic and sedimentation features ideal for on-site educational activities. These educational approaches are crucial to promote people engagement with geosciences, encourage student enrollment in geology courses, and increase broader environmental awareness and appreciation.

Ocean Literacy beyond knowledge: investigating ocean connections among a sample of children in Friuli Venezia Giulia (N-E Italy)

Realdon G.*[1-2], Gallo M.T.[3] & Occhioni M.[1]

[1] Scuola di Scienze e Tecnologie, Sezione Geologia, Università di Camerino. [2] EMSEA – European Marine Science Educators Association. [3] Associazione Scienza under 18, Isontina.

Corresponding author email: giulia.realdon@unicam.it

Keywords: ocean literacy, ocean connection, content analysis.

The Ocean Literacy movement, born twenty years ago in the US, initially focused on the dimension of knowledge by issuing the Ocean Literacy Principles that every adult should know, also highlighting communication and responsible decision-making as skills needed to be an ocean literate citizen (NOAA, 2021). In recent decades, though, Ocean Literacy has been evolving and including multiple dimensions, with the final goal of achieving a desired pro-environmental behaviour change.

According to social psychology research, behaviour change is a complex issue, affected by different internal and external factors, which can foster of hinder the achievement of this goal. Among the internal factors, emotional connections seem to have an important role in affecting human behaviour (Kollmuss & Agyeman, 2002). Starting from these elements, we undertook a survey among 146 children (age 8-14) attending workshops on Ocean Literacy run in 2023 in different settings: a sailing school, a summer camp in a Marine Protected Area and a school located about 30 km from the coast. The used tool was an was an anonymous post-it note written by the children in response to the question "what is the sea to you?" and collected before running the workshops. This procedure was authorized by the adults in charge of the children's groups and in accordance with EU GDPR. The answers were processed by means of inductive content analysis (Bengtsson, 2016) performed by three independent coders (science teachers), who first developed a list of categories, then agreed on a consensus list and used it for an independent analysis of the children's texts. The categories identified in the students' answers largely fall within the dimensions of Ocean Literacy recognised by McKinley and colleagues: knowledge (descriptive remarks on biological and physical aspects of the sea), emotional connections (e.g., joy, peace, freedom), access and experience (leisure, memories), awareness (ocean as source of life, anthropogenic impacts) and attitudes (need for sea protection) (McKinley et al., 2023). Despite the use of a very basic tool, children's answers expressed an interesting range of concepts, with a significant share of answers related to knowledge and emotions about marine environment. Also, the awareness of the importance of the sea for life evidenced an unexpected connection, given respondents' young age; on the other side, the many comments on leisure at sea were obvious for children. Finally, we can infer that the proximity and experiences of coastal environment gave our sample an advantage in developing multiple connections with the sea that could lead to pro-environmental behaviour over time.

Education and training activities in the frame of the ecological transition: insights from the Earth and Geoenvironmental Sciences context

Roberto R.[1], De Tullio M.[2], Liso S.[2], Rizzo A.*[2-3] & Mastronuzzi G.[2-3]

[1] "I Lincei per la Scuola" Foundation, Roma. [2] Dipartimento di Scienze della Terra e Geoambientali, Università di Bari "Aldo Moro". [3] Interdepartmental Research Centre for Coastal Dynamics, Università di Bari "Aldo Moro".

Corresponding author email: angela.rizzo@uniba.it

Keywords: teaching, inquiry, geoscience.

In the context of teaching tasks related to the "Earth and Geoenvironmental Sciences", it is essential to preserve the value of "situated" scientific knowledge, in which theorization is strictly connected to direct experience, and to promote methodological approaches capable of generating applications in daily teaching activities. To these aims, in situ field surveys, together with laboratories and the use of suitable software that allows for numerous preparatory and in-depth individual activities, appear indispensable.

In this work, we present the activities and outcomes concerning the educational course "Geological risk and ongoing climate change: environments and laboratories for education and training in the frame of the ecological transition". It was organized by the Polo Pugliese of the "I Lincei per la Scuola" Foundation in the year 2023/24, and it has been carried out at the Department of Earth and GeoEnvironmental Sciences of the University of Bari Aldo Moro (Bari, Italy), as part of the educational project "Lincei for a new didactic in the school: a national network."

The training course was attended by teachers who, through laboratory activities, the use of freely accessible web platforms and software (e.g., Google Earth, QGIS), and field trips, were able to experience a methodological approach based on research (inquiry), fruitful of applications within their classrooms.

The results achieved in terms of participation and educational spin-offs are encouraging: teachers identified different disciplinary areas in which to place the scientific-based information and developments learnt during the attended course, proving capable of comprehending the necessary multidisciplinary vision for the analysis of current and expected environmental issues.

Disaggregation of geological dissemination activities in focused initiatives: "hands-on" approach for stimulating geological curiosity and knowledge

Ronca S.[3], Berra F.*[1], Crippa G.[1], Fumagalli P.[1], Garavaglia A.[2], Lustrino M.[3], Mosconi A.[1], Saracino G.[4] & Sottili G.[3]

[1] Dipartimento di Scienze della Terra "Ardito Desio", Università di Milano. [2] Dipartimento di Filosofia "Piero Martinetti", Università di Milano. [3] Dipartimento di Scienze della Terra, Sapienza Università di Roma. [4] Sapienza Università di Roma.

Keywords: geology, dissemination, citizen science.

Geology covers a social role that is not perceived by people not familiar with Earth Sciences, especially in countries, such as Italy, where the awareness of the role of geology in everyday life (both in terms of scientific knowledge, risks, and resources) is limited. When considering the different aspects of geology, it becomes evident that dissemination of this science requires to split the geological knowledge in a set of themes that, despite their common Earth Science background, need to be faced separately.

The experience of hands-on activities in different contexts (such as schools, associations, exhibitions) of a working group from the universities of Rome La Sapienza and Milano Statale led to the identification of geological "targets" distinguished for age (from primary school students to retired persons), scholarity level (from basic schools to college and PhD) and society roles (schools, hospital, third sector institutions or general public).

Activities were grouped in a few main themes according to their appeal to the public: 1) origin and evolution of life and its adaptation to natural conditions, studying real fossils; 2) condition of formation and possible modification of minerals and their synthetic equivalents; 3) development of natural systems by the study of rocks; 4) origin of raw materials, their occurrence and the possibility to partially re-use them; 5) drawing of geological maps and transfer of geological concepts and models into paper sheets or digital support; 6) definition, evaluation and mitigation of natural risks.

Each of these themes has been illustrated with one or more activities: a) associating fossils to reconstruction of organisms (vertebrate and invertebrate, with real fossils and resin models); b) observing microfossils with a stereoscopic microscope; c) observing physical (such as hardness and cleavage) and optical properties of minerals (including fluorescence); d) observing rocks and minerals with polarizing microscope; e) raw materials in rocks and their use for everyday life (applications to everyday objects and to electronic devices); f) "true or false" game, to understand the difference between natural fossils/minerals and artificial ones; g) geological maps as tools to describe the 3D geology of Earth (including digital representations of geological maps in Google Earth); h) simple simulation of liquefaction processes in earthquakes. Furthermore, specific activities have been realized for visually impaired people (but also to explain this situation to people with regular visual).

The planning of these activities highlights that the exposition on a desk of specific objects and instruments triggers curiosity in the public, that was easily involved, frequently asking also for specific topics related to the exposed objects. The possibility to touch real objects (minerals, fossils, rocks, meteorites) is a greatly appreciated experience, and is a great opportunity in introducing geological reasoning.

"Nella fucina di Efesto": a new teaching project to promote meaningful geological learning. Peer tutoring from high school to primary school

Tosetti V.*[1] & Giamborino A.[2]

[1] Liceo Scientifico Musicale Sportivo "A. Bertolucci", Parma.

Keywords: vulcanology, education, peer tutoring.

Geology addresses some of the most important issues our society has to tackle nowadays. This includes issues like green energy and sustainability, climate change, the impact of industrial development on the environment, water management, mineral resources and natural hazards. Actually there is no significant geological learning issue in the curriculum of the Italian "Liceo Sc. ordinamentale", as it mainly focuses on biology and chemistry (Roca & Garcia-Valles, 2020). The focus of this project is therefore on Italian volcanoes, in particular in the Eolie Islands. Educators seek research-based learning practices that can facilitate students' access to contents like "Volcanoes" by means of inclusive learning activities, in particular for special-needs students. The project purpose is twofold: firstly, to train older students about causes, composition and structure of Italian volcanoes, secondly how to pass it to Primary School (PS) children. It is a peer tutoring approach that brings together students of different ages: Highschool Students (HS) as tutors and PS stud. as tutees (Topping et al., 2004; Xu et al., 2008). First of all HS stud. learned about the causes, composition, types and history of Italian volcanoes with a geologist. The project work/learning activities started with an overview of the Earth's inner structure, the formation of volcanoes and their shapes. HS were taught about the different types of (volcanic) eruptions, how to identify igneous rocks and how scientists may predict eruptions and volcanic hazards. After indoor activities, students experienced some outdoor sessions in Eolie Islands.The practical experience, supervised by two experienced volcanologists, included: volcanic gas sampling system with sodium hydroxide ampoules, thermocouple for high temperature measurements of fumaroles, thermal imaging camera and multi-gas component analyser, pH meter and conductivity meter for measurement of pH and conductivity in water, environmental water analysis kit and petrographic microscope to observe rocks sections. In a second time, HS students were paired with PS ones to pass volcanological content suitable for the children's level. HS students prepared creative activities to engage the children in hands-on games about plate tectonics, the formation of a volcano, lava density and the formation of Italian volcanic eruptions. HS stud. were engaged in active learning and kept updated about their progress. The "Nella fucina di Efesto" project not only taught HS stud. about the huge variety of volcanoes and their main characteristics, i.e. different types of eruptions, but it also provided them hands-on learning experiences that required teamwork in order to successfully complete the assignments. The mix of traditional teaching methods, outdoor experiences and peer tutoring, gave teachers the opportunity to take advantage of the different skills in an inclusive way, thus making earth science learning accessible and fruitful for everyone.

GEOLAB is an interactive geosciences laboratory located at the Department of Earth Science, Environment and Resources (DiSTAR) of the University of Naples Federico II (Italy). It is aimed at high school students as part of the PLS (Piano Lauree Scientifiche) and PCTO (Percorsi per le Competenze Trasversali e l'Orientamento) projects. The GEOLAB experience starts with the exhibition of macroscopic fossils and rock mineral samples to be described and classified by students and then observed in thin sections under the polarized microscope. Another educational activity consists of the use of an analogical model made of colored sand layers replicating a stratigraphic succession deformed by a mechanical press to model the orogenic accretionary wedge. In this way the students could appreciate the tectonic processes that act during the formation of mountains (orogeny), such as the Apennines and the Alps. A second Augmented Reality Sandbox allows the active participation of students in the hands-on modelling of kinetic sand aimed to reproduce different topographic landscapes and some natural phenomena such as rainfalls, volcanic eruptions and peculiar climate conditions. GEOLAB module ends with a visit to the DiSTAR laboratories, where researchers and technicians show scientific instrumentation and the way to use it. The PLS activity also includes two seminars and a visit to GEOLAB. This experience represents a valid approach to actively involve high school students in the fascinating field of Geosciences, providing simple educational experiences that could be effectively driven by the entire DiSTAR teaching staff, no matter their scientific specialization.

Keywords: Plio-Pleistocene transition, paleoclimate reconstruction, Mediterranean area.

We present a high-resolution multiproxy study to unravel climate changes during the Plio-Pleistocene transition (PPt) in the Mediterranean Sea. Our proxies relies on micropaleontological (calcareous plankton), organic geochemical (alkenones), and oxygen isotope data.

The PPt, situated between the Mid-Piacenzian Warm Period (~3 Ma) and further intensification of the North Hemisphere Glaciation (iNHG) at ~ 2.7 Ma, is a crucial climate transition in the Earth's history, during which the scenario progressively changed, recording a long-term cooling (Mudelsee & Raymo, 2005; Ruggieri et al., 2009). In this scenario, we analyzed the Monte San Nicola Gelasian type-section, located in the central Mediterranean area. In this study, we updated the recent climate investigation performed in the Monte San Nicola type-section (Addante et al., 2024), reconstructing new proxy data and extending the record from Marine Isotope Stage (MIS) G4 up to MIS 100, the latter considered the first pronounced glacial stage at the iNHG. A complete paleotemperature and paleproductivity reconstruction was obtained.

The biotic and abiotic proxies indicate relatively weak variability in surface waters during the glacial-interglacial MIS G4 to G1, followed by a pronounced amplitude increase in obliquity cycles, starting from MIS 104, indicative of intensifying glacial conditions. Interference between obliquity and insolation resulted in weak glacial conditions during MIS 102. Surface waters conditions strongly varied on a precessional scale: increase in the abundance of specific calcareous plankton taxa and alkenone (C37) concentration, highlight nutricline depth variation, enhance productivity in surface waters and/or organic matter preservation at the seafloor during the deposition of the precession-related sapropel layers. In addition, superimposed to orbital cyclicity, a millennial-scale variability is identified as a distinct feature of the glacial cycles in the investigated time interval, before MIS 100. The short-term events in the Mediterranean Sea seem related to the deposition of Ice Rafted Debris in North Atlantic (Hayashi et al., 2020). Our high-resolution multi-proxy record highlight both low and high-latitude climate forcing in the Mediterranean at the PPt and succeed in reconstructing previously undetected variability.

Keywords: Iberian Margin, Marine Isotope Stage 5, Coccolithophores.

The results concerning palaeoceanographic and paleoclimatic changes, occurred during the Marine Isotope Stage (MIS) 5, at the Integrated Ocean Drilling Program (IODP) Site U1385 and inferred through coccolithophores analyses are shown. The site was drilled on the Promontorio dos Principes de Avis, SW Iberian Margin (37°34.285'N; 10°7.562'W – 2585 meters below sea level), during the IODP Expedition 339. The investigated timeframe spans from ~130 ka to 70 ka and it has been the last major interglacial interval occurred on Earth. This interval, particularly the MIS 5e sub-interval, was characterized by global temperatures warmer than the pre-anthropogenic ones (e.g., Kopp et al., 2009) and it is useful to interpret the natural climate evolution beyond the anthropic impact being interested. The North Atlantic and the Iberian Margin are pivotal areas to reconstruct global climate evolution being characterized by high sediment accumulation rate, providing an excellent millennial-scale record of climate variability (e.g., Hodell et al., 2015).

The coccolith assemblages is characterized by good preservation within the sections analyzed with an averaged time resolution of ~700 years. The total nannofossil accumulation rate (NAR; nannofossils * cm-2 * kyr-1) is calculated according to Flores & Sierro (1997) and it is used as a coccolithophores paleoproductivity proxy. Total NAR values range between 6x109 and 9x1010 nannofossils * cm-2 * kyr-1. Reconstructions of water mass variability and paleoecology patterns are detected and associated to Greenland and Heinrich stadials.

Trace organic compounds in speleothems as a pioneering approach to high-resolution paleofire reconstructrion

Argiriadis E.*[1-2], Denniston R.F.[3] & Columbu A.[4]

[1] Istituto di Scienze Polari, CNR, Venezia. [2] Dipartimento di Scienze Ambientali, Informatica e Statistica, Università Ca' Foscari Venezia. [3] Cornell College, Iowa, USA. [4] Dipartimento di Scienze della Terra, Università di Pisa.

Corresponding author email: elena.argiriadis@cnr.it

Keywords: Speleothems, PAHs, paleofire.

Speleothems are widely used paleoclimate archives given that calcite is often pristine, they can grow continuously for thousands of years, be precisely dated, and provide high resolution paleoenvironmental information (Fairchild & Baker, 2012). Stable isotopes of oxygen and carbon, along with select trace elements, are the primary chemical markers used in speleothems for paleoclimate reconstruction. U-Th dating method allows the construction of high resolution age-depth models, at times with propagated 2 uncertainties lower than 1%, thus obtaining accurate climate-environmental proxy time series. The study of organic compounds in speleothems remains less well developed, despite the fact that they hold the potential to preserve paleoenvironmental signals unattainable by inorganic compounds. Recent applications in speleothem paleoscience used innovative analytical approaches to highlight the huge potential of cave deposits for fire reconstruction. Previous research by Argiriadis et al. (2019; 2024) focused on the use of organic molecules, namely polycyclic aromatic hydrocarbons (PAHs) and *n*-alkanes, for the high-resolution reconstruction of paleofire from speleothems from cave KNI-51, in tropical northwestern Australia, where the absence of permanent water bodies excludes the use of lake sediments for this purpose. A field experiment involving the determination of target organic proxies in soil, vegetation, and cave dripwater prior and following a prescribed fire over the cave is planned for June 2024. Data will be compared with the paleorecord obtained from cave KNI-51, remote sensing data and records from the 20th century.

In addition, the pioneering stalagmite biomarker approach will be tested by the PRIN-PNRR project "PROMETHEUS" on Mediterranean caves. PROMETHEUS will contribute to enhancing the knowledge about paleofires and the role of climate and environmental conditions on the occurrence of fires in the Mediterranean area by producing unprecedented high resolution records. Despite being one of the major contributors to the atmospheric carbon budget, the level of uncertainty related to fire occurrence, frequency, and intensity remains elevated. Understanding past dynamics and building robust databases is vital and complementary to model climate change related future shifts in fire regimes, that will increase risks deriving from fire occurrence in populated areas and the irrecoverable loss of ecosystem services, as observed in the recent past and deemed increasingly likely in the near future.

Pliocene-Pleistocene evolution of the upper central Po Plain (Northern Italy)

Baio M.[1], Violanti D.[2], Pezzotta A.*[1], Tantardini D.[1], Zerboni A.[1] & Crippa G.[1]

[1] Dipartimento di Scienze della Terra "A. Desio", Università di Milano.
[2] Dipartimento di Scienze della Terra, Università di Torino.

Corresponding author email: andrea.pezzotta@unimi.it

Keywords: Po Plain, paleoenvironmental reconstruction, biostratigraphy.

The Po Plain (Northern Italy) subsurface preserves the almost continuous Quaternary and Pliocene sedimentary succession, but outcrops are sparse and difficult to correlate among them. For this reason, data from the few deep boreholes, scanty for the upper portion, are the main indicators to reconstruct the Pliocene-Quaternary stratigraphy of the basin. The upper central Po Plain with its high density of water wells, provides a suitable location for studying the Lower Pleistocene and Pliocene marine sediments and their paleoenvironmental evolution.

We present data from two transects north of Milan comprising 18 wells, 8 of them sampled for sedimentological, petrographic and biostratigraphic analyses on perforation cuttings. From top to bottom, the eastern transect in the Adda-Molgora Valley and the western one in the Seveso-Lambro Valley include a continental succession documenting the transition from gravel-dominated fluvioglacial deposits to braidplain conglomerates and sandy gravels. Both sequences include coarse clasts of alpine and local origin. Below, fine sediments with continental gastropods and wood fragments are reported; they indicate deposition in a meandering alluvial plain. The thickness of the continental deposits increases from east (ca. 40 m) to west, where it reaches ca. 150 m. These deposits have been attributed to the end of Calabrian to Late Pleistocene (Baio & Violanti, 2021). Continental sediments lie on the top of a regional unconformity, which is related to several and diachronous erosional events, and separates the upper continental deposits from the marine/transitional-marine succession. The latter were correlated through micropaleontological data to the neritic domains of the Pliocene-Pleistocene regressive sequence of Northern Adriatic Sea and Po Plain. The marine sequence presents different setting in the two transects. The western transect reports sediments with foraminiferal assemblages typical of delta, beach, and infra-circalittoral environments, dated to the Gelasian and Calabrian stages. Petrographic analysis on interspersed gravel layers indicates sources from alpine and local drainage basins. The eastern transect shows the presence of Calabrian and Piacenzian sediments at similar depth in adjacent wells. The Piacenzian succession includes infra-circalittoral and beach environments with the occurrence of lithodome bores on gravel clasts, derived from local drainage basins. Foraminiferal assemblages in the Calabrian sequence resembles those from the western transect.

The investigations in the two transects show diachronous Piacenzian-Calabrian marine deposits and indicate that from the Piacenzian to the Late Pleistocene the area was characterized by different paleoenvironments, evolving from marine domains to outwash systems. Additionally, the occurrence of Piacenzian and Calabrian sediments at the same depth may suggest local tectonic deformation during the Early-Middle Pleistocene.

Keywords: floods, Arno, Serchio.

There are concerns that current climate change is altering the frequency and magnitude of river floods in an unprecedented way (Blöschl et al., 2020). However, the lack of long-term observational time series of flood events makes the verification challenging. Especially in Southern Europe and in the Mediterranean region where the effect of human agency on the landscape has been more profound, flood frequency and magnitude can have been controlled by climatic and non-climatic-human induced factors like catchment deforestation. Historical studies have identified flood-rich periods in the past millennia in various regions of Europe and the Mediterranean using different approaches, notably analyses of historical sources, archaeological and geological data (e.g., Blöschl et al., 2019; Bini et al., 2020). For the most recent period, direct measurement and historical documentary evidence are the most important sources of data, but their availability decreases exponentially as well as their reliability far in time. One way of overcoming this issue is to extend flood series beyond observational and historical data using sedimentary archives or archaeological excavations. We present a reconstruction of flood frequency from the Arno and Serchio rivers in Tuscany from: 1) accurate revision of historical documents; 2) collection of archaeological data, and 3) from flood layers deposited in a swamp area, which collected overbanks and crevasse splay events of the Arno river. This allowed us to reconstruct a flood record since the Roman Period, and to overlap the historical data at ca. 1100 CE, yielding an unprecedented long flood record for these two rivers.

Keywords: Calcareous nannofossils, Bond events, North Atlantic Oscillation (NAO).

The ND14Mbis marine sediment core was analysed to investigate the climate variability over the Holocene in the North Ionian Sea. The core was collected at a water depth of 665 m below sea level during the Next-Data cruise in 2014, aboard the R/V Urania (CNR). In this work, we focused on the study of the calcareous nannofossil assemblages coupled with the analysis of carbon stable isotopes from *Globigerinoides ruber* white, X-Ray Fluorescence data (Ca/Ti, K/Al). The lower portion of the investigated succession records the Sapropel 1 interval, between 10 and 7.7 ky BP (Checa et al., 2020), which onset is marked by the increase of *Florisphaera profunda* pointing out the formation of stable stratified waters and Deep Chlorophyll Maximum (Cascella et al., 2021). Afterwards, increases in the Warm Water Group (WWG) abundance pointed to warmer periods chronologically correlated with the major archaeological subdivisions such as the Copper Age, Early and Late Bronze Ages, and the Roman Period. Conversely, declines in the WWG and rises in the Cold Water Group (CWG) marked cooler short events at 7.4 ky BP and 4.2 ky BP, and cool intervals like the Middle Bronze Age, Iron Age, Dark Age and Little Ice Age. Calcareous nannofossils also indicated mixed and cooler surface waters during the Medieval Climate Anomaly. Particularly, the spectral analysis of the CWG signal revealed a 1.6 ky periodicity, which resulted correlatable with the onset of some Bond events (Bond et al., 2001). Throughout the record, we noted a positive correlation between *Syracosphaera pulchra* and δ13C values and variations in XRF trends, which indicate riverine runoff, confirming the affinity of this taxon with freshwater inputs. The North Atlantic Oscillation (NAO) atmospheric mode impact on Central Mediterranean continental runoff was investigated over the last 7.5 ky BP, using the NAO index by Smith et al. (2016). Negative NAO phases, which characterize the development of wetter winters at site latitude, coincided with episodes of higher riverine discharge highlighted by higher K/Al, lower Ca/Ti ratio values and increases in reworked coccoliths. However, from 2.3 ky BP upwards the evidence of enhanced continental runoff during positive NAO phases (i.e., drier winters) could be attributed to anthropogenic pressure.

Keywords: benthic foraminifera, North Adriatic Sea, anthropogenic impact.

The temporal distribution of benthic foraminifera was studied in a marine sediment core EL-C01 collected 7 km south of the Po di Goro outlet at a 21.5 m water depth. Integrated geochemical and sedimentological data with trace metal concentrations allow us to document the response of benthic microfauna to anthropogenic influence during the last two centuries. Taxa occurring primarily in natural, oligotrophic conditions (*sensu* Jorissen et al., 2018), dominate the interval from 1840 (base of the investigated core) to ca. 1880, then they are progressively replaced by stress tolerant species toward the first half of the 1900. The observed benthic foraminiferal change is associated to sudden modifications in the Po sedimentary regime (Riminucci et al., 2022). Starting from ca. 1945, the assemblage became characterized by the dominance of taxa related to low oxygen and eutrophic condition (e.g., *Bulimina marginata, Bolivina gr., Nonionella stella*) with episodes of severe anoxia between 1960-1990 induced by the increase of primary production at the surface and high sedimentation of particulate organic matter. This pattern results time associated to socio-economic development and industrialization after the World War II as documented by the Pb and Zn profiles. The increasing biodiversity and decreasing dominance among benthic foraminifera from the second half of the 1980 is probably the effect of the Italian Law 319/76 and anti-pollution environmental policies concerning industrial and urban emitters.

Response of particular taxa to climatic and environmental variations during the evolution of the Mediterranean Sea: from the Messinian Salinity Crisis to Zanclean normal marine conditions

Caruso A.*

Dipartimento di Scienze e Tecnologie Biologiche Chimiche e Farmaceutiche, Università di Palermo.

Corresponding author email: antonio.caruso@unipa.it

Keywords: Mediterranean, Messinian, Zanclean, Bioevents,

During the late Miocene and the early Pliocene, the Mediterranean Sea was devastated by a series of natural disasters that at the acme of the Messinian Salinity Crisis culminated into the complete desiccation, causing drastic changes in marine biota. Despite the over 1400 publications there is no unanimous agreement onto the dynamics that led to the biological revolution with extinctions and appearance of new taxa, as well as on the desiccation and the consequent Pliocene reflooding (Roveri et al., 2014; Caruso et al., 2020).

The exploration of the oceans in the late sixties and early seventies of last century brought important, largely unexpected, discoveries that contributed to recovery of evaporites in the deepest Mediterranean basins (Balearic, Tyrrhenian, Ionian and Levantine) originated the unorthodox deep-basin desiccation model. In the last 30 years the Neogene was investigated in great detail using interdisciplinary approach (i.e. litostratigraphy, biostratigraphy, geochemistry, magnetostratigraphy, astrocyclostratigraphy). The astrocyclostratigraphy permitted to correlate land outcrops with deep marine successions obtaining astronomical ages for the major events. Thanks to this approach, astronomical ages of 7.241 and 5.333 Ma were obtained, respectively for the Messinian and Zanclean GSSPs (Hilgen et al., 2012). Thus, the onset of the Messinian Salinity Crisis (MSC) has been astronomically calibrated, although with some slight differences, at ~5.971-6.04 Ma. Further, from Messinian to Zanclean the climate was not stable, several glacial periods alternated to warmest phases (Herbert et al., 2016) contributing strong changes in marine biota and favouring evaporation phenomena. In this work, some examples are discussed focussing on particular taxa

Distribution pattern of macrobenthic assemblages along the Ideale Section of the Montalbano Jonico succession (southern Italy)

Cervellieri M.*[1], Scarponi D.[1], Crippa G.[2] & La Perna R.[3]

[1] Dipartimento di Scienze Biologiche, Geologiche e Ambientali, Università di Bologna. [2] Dipartimento di Scienze della Terra "A. Desio", Università di Milano. [3] Dipartimento di Scienze della Terra e Geoambientali, Università di Bari "Aldo Moro".

Keywords: climate change, macrobenthic assemblages, mid-Pleistocene transition.

The Ideale Section (Montalbano Jonico Basin, Matera, Italy) is a Standard Auxiliary Boundary Stratotype for the Middle Pleistocene (Marino et al., 2024). This section provides a valuable opportunity to investigate the past macrobenthic dynamics in open marine environments in relation to climate change.

We analyzed the effect of long-term climate and sea-level changes on marine macrobenthic assemblages using 29 samples (about 4,000 fossil remains) from the 80 m-thick clayey succession of the Ideale Section that accumulated between Marine Isotope Stage (MIS) 20 and MIS 18 (Marino et al., 2015). Paleobathymetric reconstructions based on ordination analyses of macrobenthic assemblages indicate inner shelf environments during cold periods (glacials and stadials), which alternated with deeper settings (mainly outer shelf) during warmer phases of the MIS 19, reflecting the orbitally-driven climate shifts also registered by stable oxygen isotopes.

Thus, investigated macrobenthic assemblages have shifted in composition over long-term climate oscillations spanning the Calabrian-Chibanian transition (~810 to 750 ky). Cold climate periods are dominated by macrobenthic taxa indicators of environmental disturbance, such as turbidity exemplified by *Ditrupa arietina*. In addition, such periods are characterized by lower species richness and depressed abundance of species exclusive of Mediterranean to Lusitanian regions (Spalding et al., 2007) compared to warmer interstadials of MIS 19 (see Scarponi et al., 2022). Indeed, samples from warm climate periods show assemblages with higher species richness and equitability, suggesting more stable environments. In addition, the median relative total abundance of Lusitanian and Mediterranean specimens is around ten times higher than during cold climate intervals.

Thus, the high similarity between assemblages from cold climates (glacials and stadials) and their distinct composition and abundance from those from warmer phases of MIS 19 suggest that, over geological timescales, shelf benthic assemblages have been primarily structured by environmental forcing. As for cold climate intervals, the recurrence of macrobenthic assemblages with similar taxonomic structures points toward either remarkable resilience or persistence in the face of major, long-term environmental, and climatic perturbations.

Lastly, as MIS 19 is a climate analog for near-future climate warming, the result presented here could allow us to define baselines for macrobenthic structure and dynamics regarding climate changes in a context of null anthropogenic impact. Thus, the recent fossil record can help us identify important changes that occurred in present-day ecosystems before ecological monitoring that might have otherwise gone unnoticed.

Corresponding author email: g.cheli2@studenti.unipi.it

Keywords: 4.2 event, Holocene, paleoclimate.

The Holocene is distinguished by a multitude of climatic oscillations. The Mediterranean region serves as a significant site for exploring such a climate variability because of its geographical location and diverse geological, geomorphological and orographic characteristics. Among the oscillations that characterize the Holocene, the event known as "4.2 event" holds particular significance. Identified as one of the most cooling/drying abrupt events, it is widely recognized as a period of dry and cold conditions and is often termed a "megadrought". This event is implicated as a primary factor in the decline of ancient civilizations (such as the Akkadian Empire, Ancient Egyptian Culture, Mesopotamian Culture, and Ancient Indian Culture). The nature of the event is at times elusive, as it is not recorded in some sites and appears to be out of sequence in others. Therefore, it is necessary to study and understand the timeframe of this change, collocated at 4.2 ka but possibly spread over a much broader time interval. Indeed, other oscillations at times of greater magnitude with respect to the 4.2 event have been somehow underexplored because the "main" 4.2 event often takes all the importance. The aim of this study is to present new isotopic data ($\delta^{18}O$ and $\delta^{13}C$), obtained from a carbonate stalagmite SARM2 located in the S'Armidda Cave (Sardinia, Italy, Western Mediterranean), to enhance the knowledge about climate variability in the area pre, during and post 4.2 ka. Due to the cave's geographical location, the $\delta^{18}O$-climatic signal of SARM2 is primarily interpreted as reflecting the rainfall amount effect, while $\delta^{13}C$ is driven by the vegetation activity. SARM2 U-Th based chronology demonstrated that the speleothem deposition occurred from 5.6±0.14 to 3.3±0.14 ka. The average proxy chronological resolution is about 16 years. Centered at ca. 4.7 ka, $\delta^{18}O$ and $\delta^{13}C$ demonstrate a centennial long deterioration of climate characterized by lower rainfall and vegetation activity. While SARM2 is mostly composed of calcite, during this period there is an evident layer of aragonite. The presence of aragonite in speleothems is usually associated with particularly dry conditions. From ca. 4.6 ka $\delta^{18}O$ and $\delta^{13}C$ support an increase in rainfall that peaks at ca. 4.35 ka. Then, at around 4.2 ka there is another event of climate deterioration, which appears of minor magnitude with respect to the one found at ca. 4.7 ka. After 4.2 ka, $\delta^{18}O$ and $\delta^{13}C$ decouple, pointing to stable rainfall conditions but increasing vegetation activity. Contrary to previous interpretations that represented the 4.2 event as a single continuous dry period, our findings suggest a scenario in which the 4.2 event is formed by two arid phases framing a wetter period, as other records near the area suggest. This calls for a better climate investigation of the around of this event, with proxy timeseries with adequate resolution (i.e decadal or less).

Impact of the genus *Amphistegina* on the benthic foraminiferal association of the Pelagian Islands, an example of invasion in the Central Mediterranean Sea

Cosentino C.*[1], Guastella R.[2], Mancin N.[2] & Caruso A.[1]

[1] Dipartimento di Scienze e Tecnologie Biologiche Chimiche e Farmaceutiche, Università di Palermo.
[2] Dipartimento di Scienze della Terra e dell'Ambiente, Università di Pavia.

Keywords: benthic foraminifera, non-indigenous species, Amphistegina lobifera.

Irecent years the Mediterranean Sea is increasingly subject to colonization by non-indigenous marine organisms, many of which migrate through the Suez Canal. Its opening, which took place in 1869, connected two different biogeographical provinces after millions of years, facilitating the migration of over 600 non-indigenous species, some of which are seriously threatening the native biodiversity.

This study shows the results of benthic foraminiferal analyses carried out on algal and sediment samples collected in 2014 around the Pelagian Islands (Lampedusa and Linosa). These islands, starting from 2005 (the year of the first report), are undergoing the invasion of the non-native Indo-Pacific species *Amphistegina lobifera* Larsen.

The obtained data have been compared with those of previous sampling carried out in 2005 and 2009 (Caruso & Cosentino, 2014). This comparison highlights how, in most cases, *A. lobifera* is increasing its abundance dominating the assemblages with percentages over 50% and causing the drastic decrease of the native species. Its carbonatic tests, accumulated on the Linosa seabed are progressively changing the composition of marine sediments and for the first time are also giving rise to accumulations in the coastal environment, inside pools filled during storm surges, as happens in the Indo-Pacific atolls.

These results show how, in just a few years, some non-indigenous foraminifera are capable of massively colonize new environments, modifying native biodiversity and influencing sedimentary processes.

Keywords: Early Holocene, paleoclimate, speleothems.

Within the Quaternary period, the Holocene emerges as a notably stable climatic phase. Yet, upon closer examination, it becomes evident that Holocene climate records exhibit greater temporal and spatial variability than the broad generalizations imply. Indeed, notable climate shifts occurred frequently and sometimes abruptly over relatively short timescales. Indeed, over the span of several decades to centuries, intervals characterized by relatively stable and warmer climates were occasionally interrupted by multiple cold episodes, particularly within the extra-tropical regions of the Northern Hemisphere. For example, Wanner et al. (2011) identified six cold events within the Holocene period (at approximately 8200, 6300, 4700, 2700, 1550, and 550 years BP). Nevertheless, these events did not exhibit clear cyclical patterns, and there was considerable spatiotemporal variability in temperature and humidity/precipitation. Similarly, focusing on the Western Mediterranean region, Magny et al. (2002) recognize intervals of declining river activity on a century scale, which correspond to glacier retreat in the Northern Alps and a decrease in lake levels in the Jura (approximately occurring at 11,500, 10,500, 9,000, 7,000, 4,000, 3,000, 2,000, and 800 cal. years BP). Even though the phases at 11500, 9000, and 7000 cal. years BP have not been identified as aridification phases by Jalut et al. (2000). In this context, we present an isotopic record from speleothem of Bossea Cave, which is located in the Ligurian Alps (Southern Piedmont, Italy). By examining of Bossea Cave's $\delta^{13}C$ and $\delta^{18}O$ records, where the $\delta^{18}O$ record is related to humidity changes, and based on several climate records from the Western Mediterranean, we provide an estimate of atmospheric conditions during the early Holocene. Furthermore, leveraging the high temporal resolution of this inorganic archive dated with U-Th, we can attempt to identify various climatic anomalies that occurred throughout this period.

Terrestrial and marine palynomorphs from Holocene deposits and mosses samples in the Mar Piccolo semi-enclosed marine basin (Taranto, Southern Italy)

Degl'Innocenti N.*, Niccolini G. & Bertini A.

Dipartimento di Scienze della Terra, Università di Firenze.

Corresponding author email: niccolo.deglinnocenti@unifi.it

Keywords: pollen, dinoflagellate cyst, Gulf of Taranto, Quaternary.

Palynological investigations on pollen and dinocysts are currently underway in a sedimentary core (S05B), surface sediments, and moss samples collected from and around the Mar Piccolo (MP; Central Mediterranean). This shallow, semi-enclosed marine basin, located between the Ionian Sea and the Apulia region, is surrounded by extensive wetlands consisting of both fresh and salt marshes. The palynological research conducted as part of the PhD theses of Degl'Innocenti and Niccolini (2024) at the University of Bari is integrated into a geomorphology project. The aim is to reconstruct paleoenvironmental and paleoclimatic changes as well as human impacts over the last 12,000 years in Southern Italy. Thanks to the exceptional preservation of palynomorphs, it was possible to create iconographic documentation showcasing the most intriguing and distinctive taxa identified during the palynological analyses. A total of 143 pollen taxa from local (freshwater marsh: e.g., *Sparganium*, *Typha latifolia*; saltmarsh: e.g., Amaranthaceae, *Armeria*), regional (e.g., *Quercus pubescens*-type, *Corylus),* and extra-regional sources (e.g., *Abies*, *A. cephalonica*, *Cedrus*, *Picea*) have been identified (Niccolini & Bertini, 2024). Furthermore, a high abundance of anthropic taxa, e.g., *Olea*, *Juglans*, *Vitis,* and Cerealia groups, along with the occurrence of e.g., *Citrus medica,* have been observed. Moreover, pollen analyses in surface sediments and moss samples reveal the presence of numerous alien taxa (e.g., *Aloe,* Arecaceae, ornamental Cactaceae, and *Eucalyptus),* suggesting a nowadays highly anthropized vegetation around MP. A total of 60 dinocyst taxa have been detected, including 2 belonging to Gymnodiniales (e.g., cyst of *Polykrikos kofoidii*), 30 to Gonyaulacales (e.g., *Operculodinium centrocarpum*), and 28 to Peridiniales (e.g., *Lejeunecysta oliva*). Dinocyst assemblages include 34 phototrophs (e.g., *Spiniferites* spp.) and 26 heterotrophs (e.g., *Brigantedinium* spp.). Estuarine/lagoonal (e.g., *Lingulodinium machaerophorum*), neritic (e.g., *Spiniferites mirabilis, S. hyperacanthus*), and full-oceanic (e.g., *Impagidinium patulum*, *I. strialatum*) taxa have been observed, highlighting a quite diversified association. Several taxa also provide information on surface water parameters such as temperature (e.g., *I. aculeatum*, *Bitectatodinium tepikiense*), salinity (e.g., *S. pachydermus*), and nutrients (e.g., *Lejeunecysta oliva*). The finding of *Peridinium ponticum*, whose discovery in the Mediterranean area is typically restricted to the Black Sea and Marmara Sea, is particularly noteworthy. *Alexandrium* spp., a toxigenic cyst known for causing harmful algal blooms, has also been identified. This comprehensive palynological documentation lays the groundwork for future palaeoenvironmental and palaeoclimatic reconstructions of the MP, as well as expanding the regional database of pollen and dinocyst taxa.

Keywords: biochronology, faunal renewal, large mammals.

Large mammals are widely used for biochronological correlations and palaeoecological reconstructions. A most influential contribution on Plio-Pleistocene large mammal biochronology of Europe was offered by Azzaroli (1983), who, alongside summarizing the then available data, provided an important conceptual framework on large mammal "dispersal events". Azzaroli (1983) defined these events as "short periods of rapid intercontinental migrations and faunal replacements"; often named after some representative species but denoting a major faunal renewal. He further related them to substantial climatic and environmental changes, and with relevant geological transitions. Basically, the so-defined dispersal events had multiple dimensions, including geochronological and paleoecological aspects, which made them prominent concepts in Quaternary large mammal biochronology, especially of western Europe.

Here, we present updated considerations on two of the dispersal events recognized by Azzaroli (1983), the "Elephant-*Equus* event" and the "Wolf event". The Elephant-*Equus* event was regarded as denoting the spread of open environments linked to the onset of cold and dry conditions in the Northern Hemisphere and correlated with the Gauss-Matuyama reversal, today corresponding to the Pliocene-Pleistocene transition and the beginning of the Quaternary (~2.6 Ma). Current evidence indicates that early *Mammuthus* (i.e., the "elephant") spread in Europe at least ~3.2 Ma, while the arrival of monodactyl equids (i.e., the "*Equus*") from North America still coincides with the Pliocene-Pleistocene transition and it is part of the broader middle Villafranchian faunal turnover. In brief, we endorse the use of the "*Equus* event" as a valid alternative for the Elephant-*Equus* event, as most of the meanings associated with this concept are still valid, except for the inclusion of *Mammuthus* in its constitutive bioevents (Iannucci & Sardella, 2023). The Wolf event was considered to denote the late Villafranchian faunal turnover and to approximately coincide with the Gelasian-Calabrian transition (~1.8 Ma). Although it became soon clear that the appearance of *Canis etruscus* (i.e., the "Wolf") and other large mammals pre-dated the age assumed for the Wolf event, the term was still used and associated to the late Villafranchian, focusing on the "massive expansion" of the species involved, rather than their first appearance in the European fossil record (Azzaroli et al., 1988). However, current evidence highlights that the large mammal dispersal occurred in the late middle and early late Villafranchian had a rather diachronic nature, revealing a complex scenario and pushing to critically evaluate the biochronological, paleoecological, and paleobiogeographical significance of each bioevent (Iannucci et al., 2023). For instance, *Hippopotamus* spread from Africa into Europe at ~2.2 Ma, while, roughly at the same time, several species arrived from Asia.

Keywords: MIS 5e e MIS 9e highstand, speleothems, Cilento.

Interglacial highstands have left several morphological and sedimentological traces worldwide, which are utilized for the reconstruction of the past relative sea level (RSL, e.g., Shennan et al., 2015; Rovere et al., 2016) and to constrain geophysical models and fingerprinting ice cap melting and cryosphere response to climate (Dutton et al., 2015; Rohling et al., 2019). Mediterranean coasts, according to variable tectonics and glacial– and hydro–isostatic adjustment, preserve many evidence of these features found at different elevations. A revaluation of the RSL indicators in the Baia di Infreschi (Cilento, Southern Italy) supported by new 30 U/Th dating on speleothems indicates that the upper limit of *Lithophaga* burrows at ~9 m a.s.l. can be correlated to the highstand of the MIS 9e, whereas the local RSL for the highstand of the LIG is reassessed at ~ 5.3 m a.s.l. The upper level of the *Lithophaga* marker can be followed for ~12 km along the coast suggesting a substantial absence of significant relative tectonic movements. In the Baia di Infreschi additional marine indicators (e.g., *Lithophaga* burrows, notches), sealed by a flowstone dated >110 ka indicates several phases of RSL stationing below the maximum highstand of the LIG of ~5.3 m a.s.l. The presence of flowstones as low as 2 m a.s.l. dated to the MIS 7 indicated that the highstand of MIS 7 probably was below the present sea level. All these evidence implies the need to reassess the stratigraphy of some archaeological caves in the area indicating that the sedimentary successions preserved there are older than previously believed.

Greenland ice cores exhibit significant and rapid millennial-scale fluctuations during the last glacial epoch, identified as Dansgaard-Oeschger (DO) events. These events are characterized by periods of relatively warmer and moister conditions called Greenland Interstadials (GI), alternating with intervals of colder and drier climate known as Greenland Stadials (GS, Lowe et al., 2008). While the precise mechanisms governing these cycles remain elusive, prevailing theories emphasize fluctuations in the Atlantic Meridional Overturning Circulation (AMOC), which transports surface and upper-level water masses northward and subsequently returns them southward into the deep ocean. To deeply investigate the mechanism of the DO pattern and the global teleconnections, new proxies with accurate and precise chronologies are essential in different parts of the globe. Here, we present two stalagmite records from Stiffe Cave in Central Italy (Apennine mountain chain) that continuously cover the last deglaciation (from 36 to 10 kyr BP). These speleothems offer high precision, enabling the resolution of millennial-scale events, and an accurately dated chronological framework. The stable O isotope compositions of both stalagmites show a strikingly similar pattern indicating calcite deposition under equilibrium conditions. Interstadial warming and stadial cooling led to an increase and decrease, respectively, in the $\delta^{18}O$ value of calcite. This is in contrast with other speleothem records in Central Italy and the Mediterranean area, which are characterized by a decrease in the $\delta^{18}O$ during interstadial warming and vice versa, due to their strong correlations with fluctuations in humidity.

Stiffe speleothems closely resemble the temperature variations observed in high-latitude regions, such as in Alpine speleothem records (Boch et al., 2011), where, oxygen isotope values are more strongly correlated with air temperature than with the composition of regional meteoric precipitation.

The similarity in shape and magnitude of the interstadials seen in the Stiffe speleothems and the Greenland ice core suggests that the speleothems isotope signal is dominated by atmospheric temperature variability. The Central Apennines appear highly sensitive to stadial-interstadial oscillations during the last glacial period, and the response to Dansgaard/Oeschger events was probably synchronous with Greenland ice core data.

This correspondence offers valuable insights into the dynamics of the last deglaciation period in the Northern Hemisphere and investigates the mechanism of the DO cycles.

Indigenous species are nowadays seriously threatened by the current global climate change and environmental instability. The loss of biodiversity in the Mediterranean Sea is due to increasing temperatures and the consequentially introduction of alien fauna. Therefore, the Mediterranean Sea's "tropicalization" involves a change in environmental parameters and a faunal biodiversity shift from temperate to tropical and sub-tropical species. Nevertheless, there are similar scenarios in the Earth's history during which tropical species inhabited the Mediterranean Sea. This is a typical phenomenon of many interglacial warm periods. Indeed, it is common to find in the Mediterranean Sea typical Senegalese fauna characterized by the presence of *Thethystrombus latus* (Gmelin, 1791) dating back to interglacial periods. In particular, the scientific community focuses on the Last Interglacial (LIG) as analogous to the current one. It allows us to understand the natural climate forcing in a period with temperatures similar to today without the presence of the human footprint. Thus, it could be considered a possible scenario for climate change to predict future climatic conditions. The traces of past climate features are recorded in some biological archives such as the bivalve *Pinna nobilis* (Linnaeus, 1758) and the coral *Cladocora caespitosa* (Linnaeus, 1767) (Freitas et al., 2005; Silenzi et al., 2005). The description of fossil benthic communities could contribute to better describe past climate and environmental conditions. The study of ecological features of faunal assemblages associated with biological archives might reveal paleoenvironmental features. The present work is a paleoecological survey about benthic infauna communities associated with *Pinna nobilis* in coastal deposits of the LIG arranged into widespread marine terraces in the area of Taranto (Puglia, Italy). The survey on fossil fauna assemblages associated with the biological archive allows the reconstruction of fossil biocoenosis of the study site highlighting environmental features that are not recorded in climate proxies.

The climatic and oceanographic setting during the Messinian: what can be learned for present and future deoxygenation dynamics?

Mancini A.M.*[1], Gennari R.[2], Lozar F.[2] & Negri A.[1]

Keywords: anoxia, eutropication, thermohaline circulation.

During the Messinian, the Mediterranean Basin became highly sensitive to environmental changes due to the gradual restriction of water exchange with the Atlantic Ocean. This led to the widespread deposition of organic-rich layers known as sapropels, indicating significant disturbances in the carbon and oxygen cycles. These sediments formed under conditions of oxygen depletion, likely due to periodic weakening of the thermohaline circulation. Understanding the causes and extent of this circulation weakening in the past is crucial for predicting present and future deoxygenation trends in the Mediterranean amidst current climate warming.

For this purpose, we investigate a Messinian sapropel-bearing succession cropping out at Monte dei Corvi (Ancona, central Italy) with mineralogical, petrographic, micropaleontological and stable carbon and oxygen isotopic analyses. Our findings reveal that sapropel deposition occurred due to increased sea surface buoyancy, which inhibited the thermohaline circulation, consequently reducing bottom-water oxygen content and impacting bioturbating organisms. Within the lithological cycle, the recovery of an efficient thermohaline circulation is recorded by thin packstone layers underlying the marly limestone/marlstone, which record intense bottom currents activity. The accumulation of marly limestone/marlstone during periods of high primary productivity and organic carbon export to the seafloor led to bottom hypoxia but not organic matter preservation. These lithological changes were likely influenced by variations in the Adriatic Deep Water formation system driven by precession-driven climatic and oceanographic changes. Integration of previously published sea surface temperature (SST) data with our new isotopic data indicates that variations in sea surface salinity (SSS) primarily controlled sapropel deposition, with the SSTs of sapropel deposits aligning closely with projected SST in the Eastern Mediterranean at the end of this century under climate warming. In this future scenario, warming will be coupled with an SSS increase, which likely counteract the density loss provided by temperature, making the bottom deoxygenation in the Eastern Mediterranean abysses unlikely. However, we caution that additional factors such as winter heat waves and eutrophication could exacerbate Mediterranean oxygen depletion and should be considered in model-based projections.

Climatostratigraphy through a standard auxiliary boundary stratotype for the Middle Pleistocene subseries of the Quaternary System (Montalbano Jonico, southern Italy)

Keywords: climatostratigraphy, Middle Pleistocene SABS, Montalbano Jonico.

The ideale section (IS) at Montalbano Jonico (southern Italy), is a standard auxiliary boundary stratotype (SABS) for the global boundary stratotype section and point (GSSP) of the Middle Pleistocene Subseries/ Subepoch, following the voting members of the International Commission on Stratigraphy's Subcommission on Quaternary Stratigraphy (SQS) on July 8th, 2023 (Marino et al., 2024). The 74 m thick IS, belonging to the Argille subapennine unit of the Quaternary southern Apennine Foredeep and outcropping in the Regional Special Nature Reserve of Montalbano Jonico badlands (Gallicchio et al., 2023), continuously spans the marine isotope stage (MIS) 20-18 interval. The IS provides a detailed stratigraphical record based on multiple chronologically well constrained marine and terrestrial proxies for outlining the paleoclimatic evolution through the Lower-Middle Pleistocene transition (Ciaranfi et al., 2010). The high-resolution carbon and oxygen isotope stratigraphy evidences glacial-interglacial and stadial-interstadial phases as well as the sub-millennial-scale features of Termination IX and the onset of MIS 19c. The sapropel layer equivalent to insolation cycle 74 (784 ka) occurs in early MIS 19c describing distinct centennial-scale paleoceanographic conditions during a $\delta^{13}C$ minimum. A prominent peak in the $^{10}Be/^{9}Be$ record at the MIS 19c-19b transition identifies the low geomagnetic dipole moment associated with the Matuyama-Brunhes boundary interval (Nomade et al., 2019). Two tephra layers (V3 and V4) relevant to boundary interval are $^{40}Ar/^{39}Ar$ dated. The V4 layer, occurring at the MIS 19c-b transition and in the middle of the $^{10}Be/^{9}Be$ peak, has an age of 774.1±0.9 ka, corresponding to the age of the Middle Pleistocene GSSP at the Chiba section (Japan). A high-resolution alkenone sea-surface temperature combined with total C37-alkenones and several paleobiological records enrich the chronological and paleoenvironmental dataset from MIS 20 to the inception of MIS 18. The GSSP boundary interval in the IS is represented from 35.50 to 39.50 m, which corresponds to the interval of the highest values of the $^{10}Be/^{9}Be$ ratio (~776.35-771.87 ka) and includes the V4 tephra layer and the MIS 19c-MIS 19b transition. This SABS is particularly relevant because it extends the correlation potential of the Middle Pleistocene Subseries/Subepoch GSSP interval to the Mediterranean region where most of the Neogene and Quaternary GSSP are historically and formally represented.

Keywords: vertebrate record, Mammals, Mediterranean Europe, terrestrial ecosystems.

Grotta Romanelli is a costal cave located in southern Italy, in the heart of the Mediterranean. Since its discovery, the cave has been recognized as a pivotal site for the Late Pleistocene European stratigraphy, with its basal level attributed to the Last Interglacial (MISs 5e). The extremely abundant archaeological and palaeontological findings collected during the early decades of 20th century immediately established the cave a reference locality for the environmental reconstruction during the last ca. 130 ka.

The recent reassessment of chronostratigraphical setting Grotta Romanelli reveals a late Middle Pleistocene age for the lower levels of the cave, while the record of the ISU3 (level G) can be referred to early Late Pleistocene (MIS 5). By redefining the age of Grotta Romanelli implies that the oldest human frequentation of the cave occurred long before MISs 5e.

Here, selected museum collections from the lower levels of Grotta Romanelli (ISU1-ISU3) and fossils recovered from excavations between 2015 and 2022 are reviewed. Our results will offer new insights into the terrestrial ecosystems of Mediterranean Europe between the late Middle Pleistocene and early Late Pleistocene, as the three main mammal assemblages identified here are associated with three different interglacials occurring over the last ca. 350 ka. The mammal assemblages present here also indicate landscapes that are no longer present in the southern part of the Apulia.

Portable X-ray fluorescence and Milankovitch cycles in coeval marine and continental Upper Pliocene deposits from the Valdelsa Neogene Basin (Southern Tuscany, Italy)

Milaneschi L.*[1-2], Cornamusini G.[2-3], Maffei J.[2], Martini I.[2], Cifelli F.[4], Corti V.[2], Mattei M.[4], Zurli L.[2] & Foresi L.M.[2-5]

Keywords: cyclostratigraphy, Upper Pliocene, Southern Tuscany

Portable X-ray fluorescence (p-XRF) is a powerful tool for cyclostratigraphy investigations and for detecting paleoclimate indicators in the sedimentary record. This contribution presents a case study of p-XRF cyclostratigraphy applied to marine and coeval continental Pliocene deposits located in the central-eastern sector of Valdelsa Basin (Southern Tuscany), one of the wider and most important Neogene basins of the hinterland of the Northern Apennines. The p-XRF data acquisition has been performed on selected sections, mainly composed of mudstone, deposited during the Piacenzian, including the mid-Pliocene Warm Period (from 3.3 to 2.9 Ma, according with Lisiecki & Raymo, 2005). Geochemical data, acquired with equal spacing samplings on cleaned sediment surface, have been integrated with paleomagnetic and calcareous plankton biostratigraphic data. To identify orbital frequencies recorded by geochemical data series, power spectral analysis has been performed first in the space domain. The astrochronological tuning has been realised considering a preliminary age model of the studied section based on correlation between geochemical data and insolation curve (La2004 solution according to Laskar et al., 2004). The studied successions respond to the precession periodicity as for other Southern Tuscany Pliocene sections (Riforgiato et al., 2011). Geochemical, facies and micropaleontological data, all combined together, allow us to define changes in the depositional environment and their relationship to climate forcing driven by the orbital configuration. The high-resolution calibration of the studied successions, allowed to outline of an evolutive paleoclimatic, paleoenvironmental and paleogeographical model of the studied area. The results show the high potential of the pXRF analysis for the cyclostratigraphical application integrated with other paleoclimatical and paleoechological proxy data and the efficacy in detecting changes in depositional conditions.

Keywords: Ostracoda, palaeobiogeography, Atlantic-Mediterranean area.

Global climate and environmental changes during the Late Neogene and Quaternary influenced the distribution of biota in the shallow marine environments. In particular, the ostracod assemblages of the Proto-Mediterranean and northwestern Atlantic Africa were under the influx of a discontinuous cooling, leading to extinctions, range shifts or speciation events. Well-preserved, abundant and diversified ostracod infralittoral assemblages have been studied from the late Neogene Ashtart-1 well (Bonaduce et al., 1992), located in the Gulf of Gabès, in the south-eastern part of the Mediterranean basin, and from Messinian assemblages from the Atlantic section of Oued El Kell (OK), in northwestern Marocco (Aiello et al., 2024). The ostracod assemblages revealed an important relationship between Atlantic and Proto-Mediterranean biota, in tropical, subtropical and warm temperate waters and a complex scenario consisting of different paleoecoregions in the Atlantic-Mediterranean area, with tropical conditions persisting in the southeastern part of the Proto-Mediterranean basin. Tropical and subtropical ostracods such us *Carinovalva* and *Ruggieria*, that were able to enter in the Mediterranean with the Zanclean Flood, at the end of the Salinity Crisis, disappeared during the Late Pliocene and Early Pleistocene (Ruggieri, 1980). After the Salinity Crisis, the Pliocene shallow water subtropical-temperate temperatures in the area of the Strait of Gibraltar prevented the genus *Chrysocythere* to recolonize the Mediterranean waters. Several Miocene Proto-Mediterranean tropical genera (*Syrtica, Okadaleberis, Dallonella*) went completely extinct during the Messinian Salinity Crisis. The ostracod assemblages act as proxies for palaeoclimatic and palaeobiogeographic reconstructions, highlighting the intricate interplay between climate and biogeography.

Ecosystem dynamics, climate change and glacial-interglacial cycles from Quaternary ostracod assemblages in the Corinth Gulf, Greece

Parisi R.*[1], Mazzini I.[1] & Cronin T.M.[2]

[1] Istituto di Geologia Ambientale e Geoingegneria, CNR, Roma.
[2] U.S. Geological Survey, Florence Bascom Geoscience Center, Reston, VA, USA.

Corresponding author email: roberta.parisi@igag.cnr.it

Keywords: palaeoenvironment, Ostracoda, Glacial-interglacial transitions.

In the Gulf of Corinth, glacial–interglacial cycles are associated with changes in sedimentary processes and environment that are well recorded by microfossils (McNeill et al., 2019). During the International Ocean Discovery Program (IODP) Expedition 381 in the Gulf of Corinth, three sediment cores were drilled in two different sectors: M0078 and M0079 in the center of the Corinth Gulf and M0080 in the eastern part of the Gulf of Alkyonides. The analysis of ostracod assemblages has allowed the reconstruction of a detailed history of climatic changes during the Quaternary, specifically focusing on the glacial and interglacial transitions and their associated sea-level changes. Mazzini et al. (2023) found that the ostracod assemblages from the last 20 ka from core M0080 showed complex temporal changes not simply explained by the alternation between marine and freshwater environments during the late Quaternary. Here, we present new data from core M0078 for the last 300 ka (Gawthorpe et al., 2022), encompassing several glacial-interglacial cycles. This allows us to better understand environmental changes that include palaeoenvironmental reconstructions in a setting where global sea-level oscillations connect and disconnect the Corinth Gulf to the Mediterranean and to the global oceans. The ostracod assemblages identify two different types of environments repeatedly following one another along the whole core M0078: Mediterranean marine (*Bosquetina tarentina*, *Cytheropteron* spp., *Henryhowella sarsi*, *Microcythere* spp.) and brackish with Black Sea influences (*Amnicythere* spp., *Euxinocythere virgata*, *Tuberoloxoconcha atlantica*, Candonidae). These ecosystem shifts documented by changes in the ostracod assemblages reflect the rapid nature of glacial to interglacial transitions, from deep-shallow marine environments to marine semi-isolated and brackish lake environments with different degrees of confinement and salinity.

Keywords: paleoenvironmental reconstruction, sea-level change, prograding wedges.

New high-resolution, multichannel seismic data, acquired in the Sant'Eufemia Gulf, provide constrains on the architecture of submarine depositional features (e.g. prograding wedges) formed since the last glacial maximum (LGM). Sedimentological and quantitative micropaleontological analyses of gravity cores integrated with calibrated radiocarbon age of samples allow us to calibrate the seismic profiles, constrain the sedimentation rate and reconstruct the paleoenvironmental evolution of the study area since the earliest Bølling-Allerød. Five sediment grain size intervals and benthic foraminifera assemblages outline the evolution of the sea-bottom environment. Basal coarse sand grains along with shallow water and epiphytic benthic foraminifera (e.g. genus *Asterigerinata, Elphidium*) point to an infralittoral environment. After that, we record a progressive grain size reduction culminating at the top core, where dominant silt, clay and benthic foraminifera assemblages point to a muddy bottom circalittoral environment. A reduced organic matter flux is observed in benthic foraminifera after 5.5 ka, supporting the evidence from calcareous plankton. Sedimentation rates vary from 4.9 to 12.9 cm/kyr.

The prograding wedges formed at distinct water depths at which the sea level was stationed or lowered during the relative sea-level rise from the LGM to the basal Holocene. The erosional surfaces and marine terraces result from wave action above the depth of closure. Therefore, the above features are suitable for reconstructing a relative sea-level curve. The error bar includes uncertainties due to the a) seismic velocities used for the time-to-depth conversion of profiles, b) water depth related to the formation of depositional and erosional features, and c) tectonics. The reconstructed sea-level rise curve shows a step-like trend, starting from the Heinrich stadial 1, followed by sea level rise during the warm and ice-melting period of Bølling-Allerød, with a peak of the rising rate during the Melt Water Pulse 1-A. Subsequently, it shows evidence of sea level still standing during the cold stadial Younger Dryas, followed by a rapid increase in sea level during the Melt Water Pulse 1-B. The obtained curve of relative sea-level rise was compared with the a) eustatic sea-level curve proposed by Lambeck et al. (2014) corrected for the Glacial Isostatic Adjustment (GIA), b) relative sea-level curve by Lambeck et al. (2011) for Briatico, seven eustatic sea level curves plus one calculated in the Mediterranean, all corrected for the GIA. The best overlap was obtained with the high-mantle-viscosity from the GIA correction model of the Australian National University (ANU14-HV). It is noteworthy that the eustatic sea-level curve proposed by Lambeck et al. (2014) overlaps our relative sea-level curve throughout the analyzed time interval.

Keywords: Mid-Pleistocene transition, Eastern Mediterranean, calcareous nannofossils.

The Earth experienced notable influences on both biota and physical environment during the Mid-Pleistocene Transition (MPT). The MPT (~1.25 to 0.77 Ma) corresponds to a time of a progressive increase in the amplitude of climate oscillations from a 41-kyr to quasi-100-kyr rhythm, which resulted in increasing long-term average global ice volume (Head & Gibbard, 2005). In the Mediterranean region, the MPT is recorded in several offshore successions mainly located in the central and western parts of the basin. However, the eastern part of the Mediterranean has received less attention regarding the MPT. We aim to extend knowledge about the eastern part of the Mediterranean and compare the records of MPT in both on-land and offshore successions.

The CAP southern margin hosts Neogene marine sedimentary basins at high elevations (up to 2 km). In the Mut Basin, Middle Pleistocene deposits, reaching up to 1.5 km in elevation, unconformably overlie the Meso-Cenozoic succession of the Central Tauride (Öğretmen et al., 2018). We present the preliminary results on a marine succession cropping out in the Mut Basin (~1.1 km a.s.l.) (TOL 1). The studied section is roughly 71 m thick and is predominantly made up of marls, clayey marls, and calcarenite layers, showing a shallowing-up trend. We collected samples, with one-meter sampling resolution, for micropaleontological, isotopic and geochemical analyses. Although a strong presence of reworked specimens dilutes the concentration of the in-situ species, our preliminary results, based on the calcareous nannofossils biostratigraphy, show two important biostratigraphic events: *Gephyrocapsa omega* First Occurrence (FO), calibrated at 0.95 Ma (Maiorano et al., 2004), which occurs at the basal part of the sampled section, and *Emiliana huxleyi* FO, calibrated at 0.26 Ma (Rio et al., 1990), close to the top of TOL 1. Unfortunately, it was not possible to detect the Top common (Tc) of *Reticulofenestra asanoi*, probably due to interference from reworking.

These biostratigraphic events provide a clear hint that the TOL 1 section records the Mid-Pleistocene Transition. Quantitative biostratigraphic investigations on calcareous nannofossils, planktonic and benthic foraminifera assemblages are currently in progress. To define how the climatic changes that occurred during the MPT are recorded in the TOL 1 section, analyses on stable and clumped isotopes, and Mg/Ca ratio on foraminifera shells are still in progress, as well as magnetostratigraphic and calcimetry analyses.

Keywords: Po Delta, Ecosystem functioning, Anthropic impacts.

Antagonistic interspecific interactions are crucial in shaping the diversity of marine ecosystems (Ricklefs, 2015). However, we often lack long-term data to see how these interactions may have changed during the last few thousand years due to increasing human impacts on ecosystems. Here, we explored the most recent fossil record of biotic interactions archived in mollusk shells. We analyzed the late Holocene mollusk record in two important and laterally coeval depositional settings of the western Adriatic Sea (shoreface and prodelta deposits) to focus on parasite-host (trematode-bivalve) and predator-prey (gastropod-bivalve) interactions, respectively. We specifically targeted the shoreface bivalve *Chamelea gallina* and trematode traces present in the internal part of its valves (Huntley & Scarponi, 2021), to evaluate changes in parasitic dynamics in relation to increasing anthropogenic pressures recorded in the area during the last millennia (Lotze et al., 2011). For predator-prey interactions, we examined the predation traces of naticid or muricid gastropods (Sawyer & Zuschin, 2010) on their mollusk prey across different mollusk species from prodelta deposits. The results of our analysis indicate that parasitic prevalence in the western Adriatic Sea has decreased by an order of magnitude over the late Holocene. Parasite intensity and aggregation have also been reduced significantly signaling a substantial decrease in the effective population size of digenean trematodes. Similarly, predator-prey interactions have also decreased by a factor of four with respect to the late Holocene baseline, mainly due to the loss of predatory gastropods, decreased abundance of preferred prey, and increased abundance of less-preferred prey organisms.

Combined, these results indicate the collapse of antagonistic interspecific interactions among marine invertebrates in concert with increasing human influence on the Adriatic and its transition to an Urban Sea.

Keywords: paleoenvironmental, Early-Middle Pleistocene transition, Mediterranean Europe.

The transition between the Early and Middle Pleistocene marks an important change in the Earth's climate system, when the periodicity change of glacial-interglacial cycles from 41,000 to 100,000 years, influenced the distribution and typology of terrestrial vegetation and fauna. This period, characterized by major ecological transitions and profound reorganization of terrestrial ecosystems, is known as the Early-Middle Pleistocene Transition (EMPT) and occurred during the ~1.4–0.4 Ma interval. In general, the mammal communities proved to be very sensitive to climate and environmental changes of this crucial time.

Discovered during the spring of 1978, the karst infilling deposit of Contrada Monticelli (CM) revealed to be very rich in terrestrial mammals, with over 150 fossil remains discovered. The faunal assemblage has been attributed to the Isernia Faunal Unit (early Middle Pleistocene, ca 0.6-0.55 Ma), and this biochronological placement is of particular interest, representing one of the few sites referred to as early Middle Pleistocene in Mediterranean Europe. The mammal assemblage found at CM mostly includes herbivores turned out to be composed of mixed and highly flexible feeders such as *Palaeloxodon antiquus*, *Stephanorhinus hundsheimensis*, *Bison* cf. *schoetensacki*, *Dama* cf. *roberti*, in addition to *Equus* sp. considered a typically grazing species. Carnivorans are exclusively represented by the isolated and poorly preserved cranium of *Canis mosbachensis*.

In addition to the known paleoecological characteristics, analyzes carried out on the size and relative length of long bones of some species found at CM seem to suggest adaptations to relatively warm and heterogeneous environments, characterized by a mosaic of wooded covers alternating with more open grazing spaces. The recent discovery of micromammals, which have never described before, within the sediment incorporating some mammal remains could further enhance our understanding of the paleoenvironmental conditions at the CM site.

Hydrological variability during the Roman and Medieval periods in the Balkan Peninsula using speleothems

Keywords: Middle Age Climate Anomaly, speleothems, stable isotopes

The most recent European summer droughts have fueled a debate as to whether they are within the range of natural variability or related to anthropogenic warming. This debate is within the more general question if previous climatic change periods (before pre-industrial Era) during the last thousandth of years are globally coherent in terms of chronology or not (Neukon et al., 2019). This uncertainty largely arises because the instrumental records are intrinsically short and sparse and are unlikely to include the full range of natural variability. Historical, archaeological and proxy records supply additional information to be used to reconstruct past summer droughts and more in general on hydrological variability. Southern Europe and the Mediterranean region are particularly vulnerable to drought events and there is evidence that hydrological changes are increasing even if a long-term (millennial-scale) perspective is still at least incomplete. Therefore, to identify regional drought in the last thousands of years of warmer periods has important implications within the current debate on climatic changes and their potential impact (e.g. Zanchetta et al., 2022). The climate during the Roman Age and the Middle Ages has attracted the attention for its potential to be an important analogue for the present warming. However, regionally well-dated records are still sparse. We present two new, well-dated stable isotope (δ18O, δ13C) records of speleothems from Galubarnica and Momicek caves in the North Macedonia Republic. Specifically, δ18O is here considered a good tracer of the hydrological variability (e.g. amount of rainfall during the recharge seasons. They show a prominent aridity during the first century BCE, the beginning of the CE, and during the Middle Ages. These drier periods found some important similarities with regional lake level reconstruction and δ18O from lacustrine carbonates, indicating their severity and regional impact.

Keywords: glaciotectonics, Pleistocene, lacustrine basin.

The spectacular mega-structures of the Early to Middle Pleistocene Pianico-Sèllere lacustrine sediments (Moscariello et al., 2000; Pinti et al., 2001; Ravazzi 2013) are well known since the XIX century and caught the attention of many scientists who visited the site. Despite the quality of the exposures, the interpretation of the deformation structures is controversial, as different mechanisms may be proposed for their origin (deformation induced by slope movements, glaciotectonics, seismic-induced events, neotectonics). Casati (1968), who favoured a glaciotectonic genesis for these phenomena, gives a significant contribution to the analysis of these structures. The occurrence of deformational structures has been mentioned in recent papers but no detailed descriptions have been reported so far.

The deformation structures observed in the basin consist of reverse faults, thrusts, folds and overturned folds, often formed in hydro-plastic conditions suggested by liquefaction and dewatering occurring in close association with some of the largest structures. Normal faults are only present as secondary accommodation structures. Some of the described phenomena can represent slumpings, deforming beds along the slopes of the paleo-basin before diagenesis or during sedimentation, whereas the largest ones seem to be related to other phenomena due to different features.

Oedometric tests performed on the fine-grained lacustrine clays attest a strong overconsolidation of these sediments, possibly due to a significant glacial overload. Based on these results, we suggest a glaciotectonic origin for most of the contractional structures, which may be related to the push of a lateral tongue of the main Oglio Glacier, overriding the lacustrine deposits of the Pianico-Sèllere basin during multiple glaciation episodes (Ravazzi, 2013).

Reactive melt percolation in spinel mantle harzburgites from the Wadi Tayin Massif (Oman ophiolite)

Battifora C.*, Ferrando C., Crispini L. & Rampone E.

Dipartimento di Scienze della Terra, dell'Ambiente e della Vita, Università di Genova.

Corresponding author email: caterina.battifora@edu.unige.it

Keywords: mantle rocks, melt reactive porous-flow, olivine CPO.

The Oman ophiolite shows a complete sequence of oceanic lithosphere providing direct sampling access to understand processes ruling lithosphere accretion in a fast spreading-ridge oceanic setting. Our research aims at studying the composite recrystallization and melt migration history recorded in the Oman lithospheric mantle from spinel- to plagioclase-facies conditions, poorly constrained to date, in spite of a large number of studies devoted to the Mantle Transition Zone.

Here, we provide evidence of reactive melt percolation at spinel-facies conditions, combining microstructural and petrological investigations on harzburgite samples from the upper mantle of the Wadi Tayin massif.

The studied harzburgites display a porphyroclastic association of (Ol+Opx±Cpx±Spl), and granoblastic aggregates of (Opx+Cpx±Spl) that partially replace Opx porphyroclasts. The granoblastic association is formed by the progressive cooling of the harzburgite at subsolidus conditions (T= 900-1000°C). Both pyroxene porphyroclasts and neoblasts show lobated contacts with interstitial olivine crystals, suggesting a melt reactive porous-flow process that involved pyroxenes dissolution and crystallization of new reactive olivine from the migrating and reacting melt. Both pyroxene generations (porphyroclasts and granoblasts) exhibit similar major element compositions and their Crystallographic Preferred Orientations (CPO) is clear and characteristic of upper mantle deformation under high-T and dry conditions. On the other hand, the olivine CPO varies from axial-[100] pattern, coherent with olivine from upper mantle peridotite deformed under high T and dry conditions (Tommasi et al., 2000), to axial-[010] pattern, indicating deformation in the presence of melt (Zimmerman et al., 1999). Such CPO transition is correlated with olivine modal contents ranging overall from 70% to 85%. Harzburgites with lower modal olivine contents show weak axial-[100] olivine CPO patterns, whereas samples with higher modal olivine abundances have well defined axial-[010] olivine CPO. Both harzburgite modal composition and CPO evolution are related to the melt-rock ratio integrated through time and to the deformation accumulated in presence of melt (Higgie & Tommasi, 2012). Accordingly, samples preserving lower olivine modal amount and axial-[100] CPO are representative of harzburgite recording lower melt-rock ratio over time, compared to those characterized by only axial-[010] CPO symmetry and high olivine modal contents. Preliminary results of this study evidence that reactive melt percolation at spinel-facies depth involved the Oman lithospheric mantle after its conductive cooling at subsolidus conditions. Such event, although not causing evident major element changes in minerals, is clearly documented by modal and microstructural evolution of spinel harzburgites, likely reflecting micro-scale variations in melt-rock ratio through the mantle section.

Geochemical and petrological study of eastern limb of Rustenburg Layered Suit (Bushveld mafic complex)

Bonadiman C.*[1], Bianchini G.[1], Braga R.[2], Tagliacollo L.[1] & Tassinari R.[1]

[1] Dipartimento di Fisica e Scienze della Terra, Università di Ferrara.
[2] Dipartimento di Scienze Biologiche, Geologiche ed Ambientali, Università di Bologna.

Corresponding author email: bdc@unife.it

Keywords: Bushveld mafic complex, mafic-ultramafic rocks, cumulates.

South Africa's Bushveld Complex is the most significant and important example of layered mafic complex in the world. It is an iconic geological site, where many generation of geologists were ventured to understand the phenomenology of intrusive magma crystallization process. The interst in Bushveld Compelex expanded since the discovery (Merensky, 1925) of the world's large reserve of platinum (and platinum elements group).

The Complex comprises four exposed sectors - the eastern limb, the western limb, the far western limb and the northern limb, with a fifth limb, the southeastern Bethal limb, obscured by younger sediments. These sectors are formed by mafic-ultramafic layered suite at the base, a granite suite and a sequence of heterogeneous predominantly felsic volcanic rocks of the Rooiberg Group. Both extrusive and intrusive Bushveld magmatism occurred with a time span of a few million years around 2057±3 (Mungall et al., 2016). The majority of the ore deposits are, however, restricted to the intervening group of ultramafic-mafic rocks, or Rustenburg Layered Suite. The Rustenburg layered Suite comprises a package of rocks which range in composition from dunite to diorite. This layered suite is subdivided into marginal, lower (LZ), critical (CZ), main (MZ) and upper (UZ) zones, although their exact boundaries have been the subject of much debate (e.g. Kruger, 2005). Despite the countless published papers since the Twenties of the previous century, there is no consensus yet on the details of its mode of formation. However, it is generally assumed that the layered rocks represent an upward-aggrading pile of crystals deposited on the floor of a vast, long-lived and repeatedly replenished magma chamber (e.g. Mungall et al., 2016).

In 1998 the field excursion poposed by the programme of four-yearly International Vocanic Congress (IAVCEI), held in Cape Town (SA), was focused on the eastern limb of the Rustenburg Layered Suite. Petrologists of the Unviersity of Ferrara (Luigi Beccaluva and Franca Siena) attended the field excursion and collected 31 samples representing all the main rock types of each zone (dunites, orthpyroxenites, pyroxenites, anorthosites). This rock collection remained unworked for many years and just recentely were resumed by the authors of this contribution. Here, the initial stage of a geochemical and petrological study of eastern limb of Rustenburg Layered Suite is presented. On the basis of preliminary bulk geochemistry (major and trace elements) and mineral modal distribution, the majority of the samples are cumulates: dunites, orthopyroxenites, peridotites norite, anorthosites, gabbros; a few metasedimentary rocks of the Transvaal basement are also included. The general order of appearance (and disappearce) of cumulus minerals suggests a multiple a crystallization processes in an open melt-filled chamber.

Pyroxenite generation via high-pressure crystallization of a MORB-type basalt: an experimental study at 1-2.5 GPa

Borghini G.*, Crotti C.F. & Fumagalli P.

Dipartimento di Scienze della Terra "A. Desio", Università di Milano.

Corresponding author email: giulio.borghini@unimi.it

Keywords: pyroxenite, crystallization experiments, upper mantle.

Pyroxenites are widespread lithological heterogeneities found in the upper mantle in various geodynamical settings. They are often observed as veins or layers embedded within mantle peridotites in ophiolitic or orogenic ultramafic massifs and found out as lithospheric mantle xenoliths. The origin of pyroxenites can be attributed to different magmatic or metamorphic processes or a combination of them (Bodinier & Godard, 2003). Many mantle pyroxenites are believed to result from segregation of mantle-derived melts with varying degrees of evolution at high-pressure conditions (P ≥ 1 GPa). In this study, we performed piston cylinder experiments at 1-2.5 GPa and 1100-1350°C to investigate the mineralogy and the composition of mineral phases in pyroxenites formed through high-pressure crystallization of a MORB-like basalt. Our starting material was a natural tholeiitic glass with the composition of moderately evolved basalts (XMg = 0.60, SiO_2 = 48.6 wt.%, Na_2O = 3.48 wt.%, K_2O = 0.81 wt.%). High temperature (T > 1200°C) isothermal experiments revealed that clinopyroxene is the liquidus phase at 1-2.5 GPa. We also conducted experiments that experienced cooling down to 1100 and 1150°C to simulated close-system crystallization following high-pressure melt segregation. During cooling, garnet precipitated from the basaltic melt at P ≥ 1.5 GPa, in association with rutile at P ≥ 2 GPa after significant extents of crystallization (residual glass < 20 wt.%). At 1 GPa, low-fosterite olivine (Fo_{76-79} at 1200°C and Fo_{65-68} at 1100°C) was observed in all runs in assemblage with a plagioclase An_{45-48} at 1100°C. Upon cooling, XMg in clinopyroxene decreases (down to 0.66) accompanied by a slight decrease in Ca and an increase in Ti. At higher pressure, clinopyroxenes exhibit progressively higher Na and Al contents (with Jadeite content up to 0.25 at 2.5 GPa) with decreasing Ca and Cr concentrations. Garnets record upon cooling increase of Grossular and Pyrope contents combined with a decrease of Almandine. By assuming that late residual melt is expelled through compaction, the modal abundances determined in cooling experiments can be used to estimate the final mineralogy of the rock. Pyroxenites generated through infiltration and crystallization of MORB-type basalt at P ≥ 1.5 GPa are garnet clinopyroxenites having garnet modal abundance increasing with pressure from 22 to 38 wt.%. Olivine-bearing clinopyroxenite, with a low abundance (< 5 wt.%) of Ab-rich plagioclase, forms at 1 GPa. Mineral compositions and modal abundances are employed to estimate the bulk compositions of pyroxenites formed through high-pressure crystallization. Preliminary calculations suggest that the reconstructed bulk compositions are similar to those of some mantle pyroxenites observed in natural settings.

Alkaline MORBs mark low-T domains along Mid Ocean Ridges

Brunelli D.*[1], Cipriani A.[1], Verhoest L.[1], Michailow M.[1], Hemond C.[2], Maia M.[2] & Soltanmohammadi A.[3]

Keywords: alkaline MORB, Mid Ocean Ridge, mantle heterogeneity.

Mid Ocean Ridge basalts are generated during decompressive partial melting of the suboceanic asthenosphere under variable PT conditions controlled mainly by the local spreading rate. Once obducted onto ophiolitic sequences MORBs are typically identified by their distinctive chemical systematics, which reveal a significant depletion in incompatible elements in comparison to alkaline lavas generated at hot spots, where fertile mantle material melts at high T-P conditions. Recently, we sampled a suite of alkaline MORBs at the Romanche eastern intersection (Maia et al., 2020), characterized by high K/Ti, steep REE patterns and nepheline normativity. These MORBs are generated at slow spreading conditions in regions of starved magmatic production due to local depression of the mantle potential temperature. They compositionally pair extremely enriched MORBs recovered along ultra-slow spreading ridges, which have been attributed to aggregation of melts from low-degree partial melting of fertile lithological heterogeneities (Standish et al., 2008). Contextually, alkaline MORBs have been identified at the EPR 8 °N along a seafloor spreading flow line at the ridge axis tip, possibly generated in the thinned wings of the subaxial melting region (Anderson et al., 2020). The same source can be postulated for alkaline basalts sampled in intra-transform domains extracted during pressure release of transpressive systems at the St. Paul FZ, MAR (Klein et al., 2024).

All these occurrences are suggestive of partial melting of heterogeneous mantle sources controlled by heat diffusion into low-solidus components. They pose a challenge once retrieved in ophiolitic sequences due to their apparent similarity with hotspot-generated alkaline melts in all compositional systematics, including isotopes.

Variability in Platinum Group Elements enrichments in supra- and sub-Moho ophiolite chromitites: case studies from the Dinarides-Hellenides belt

Bussolesi M.*[1], Grieco G.[2], Cavallo A.[1] & Sinojmeri A.[3]

Keywords: ophiolites, chromitites, platinum group elements.

Platinum Group Elements (Os, Ir, Ru, Rh, Pt and Pd) are listed as Critical Raw Materials by the EU. The main producing countries are South Africa and Russia, where the main mineralization are associated to mafic-ultramafic layered intrusions and magmatic Ni-Cu-PGE deposit respectively.

PGE are also enriched up to subeconomic grades within ophiolites, in particular in mantle chromitites, where they are hosted within Platinum Group Minerals. Due to the PGE geochemical behaviour, mantle chromitites are enriched in Os, Ir and Ru (IPGE) with respect to Rh, Pt and Pd (PPGE), with concentrations rarely exceeding hundreds of ppb.

Some studies, however, report PGE enrichments, in the order of some ppm, in chromitites within the ultramafic cumulates above the Moho, even though enriching mechanisms are still largely unknown. The Dinarides-Hellenides belt hosts numerous ophiolitic outcrops, along with past and active chromite mines. Most of the ophiolites are Jurassic and occur in the Vardar Zone in Greece and in the Inner and Outer Ophiolite Belt in Albania. Older, more scattered occurrences have been dated to Early Triassic and are associated to the Serbo-Macedonian Massif in Greece.

Supra-Moho and mantle chromitites were collected in the Tropoje Massif, Northern Albania, and in the Chalkidiki Peninsula, Northern Greece.

Mantle chromitites in Tropoje show dominantly massive textures. Chromite rims are altered into ferrian-chromite, and the silicate matrix is mainly serpentinitic. Platinum Group Minerals (PGM) were not detected. Base Metal Minerals (BMM) are mainly native Bi and awaruite (Fe-Ni alloy).

Supra-Moho chromitites are small occurrences of massive and disseminated chromitites located in exploration trenches. Chromites show alteration into ferrian-chromite at the rims, and primary silicates are all replaced by serpentine. PGM are relatively abundant and show a high mineralogical diversity. The most abundant PGE is Pt, hosted in Pd-free isoferroplatinum (Pt_3Fe) and ferronickelplatinum (Pt_2FeNi). Pd was detected only as a minor element in isoferroplatinum. Undetermined PGM are: Rh-Ir-Ru-Os sulfosalts and Rh-Ni-Fe-Ir arsenides. The only sulfides are rare laurites $(Ru,Os)S_2$.

Mantle and supra-Moho chromitites in the Chalkidiki Peninsula show disseminated to massive textures. Chromite rims are altered into ferrian-chromite and the silicate matrix is replaced by chlorite. Mantle chromitites (average PGE content: 380 ppb) host rare laurite, while supra-Moho chromitites (PGE content: 3516 ppm) show higher PGM variability, with laurite, erlichmanite $(Os,Ru)S_2$, and undetermined Rh sulfides. Unlike typical ophiolite PGE patterns, supra-Moho chromitites show a positive Rh anomaly (Bussolesi et al., 2022). The variability of the PGM suite in two different supra-Moho chromitites leaves us with important issues regarding the formation mechanisms, the PGE geochemical behaviour and the preferential partitioning into sulfides, alloys, arsenides and sulfosalts.

Bussolesi M. et al. (2022) - Chromite compositional variability and associated PGE enrichments in chromitites from the Gomati and Nea Roda ophiolite, Chalkidiki, Northern Greece. Miner. Deposita., 57, 1323-1342, https://doi.org/10.1007/s00126-022-01109-z.

Using olivine trace elements content as a tool to reconstruct the chemical log of the sub-cratonic lithospheric mantle and the evolution of kimberlite melts

Keywords: peridotite xenoliths, sub-cratonic lithospheric mantle, kimberlites.

Mantle-derived xenoliths and diamonds brought to the surface by kimberlites in cratonic areas provide the best insights onto the deepest realms of the lithosphere. However, a comprehensive understanding of the nature and evolution of the sub-cratonic lithospheric mantle is still hindered by the geochemical similarities between the metasomatic melts-fluids and the xenoliths' host kimberlites. Indeed, mantle xenoliths witness repeated overprint by kimberlitic-like fluids and melts, which induce cryptic to modal metasomatism, but at the same time kimberlite melts also evolve through progressive reaction with/assimilation of the lithospheric mantle.

In this study, chemical-textural characterization of on spinel- to garnet-bearing peridotite xenoliths from the Udachnaya-East kimberlite (Siberian craton) and thermobarometric modelling were coupled to high-precision EPMA analyses of olivine crystals in both peridotite xenoliths and host kimberlites. Results showed that the distribution of elements such as Cr, Al, Ca, Mn, Ti and P in olivine from peridotite xenoliths is variable, and generally increases from the 10s ppm to the 100s ppm level from spinel- to garnet-bearing rocks. We will discuss how the incorporation of the different trace elements in olivine can be dependent on either temperature, nature of co-existing mineral assemblage (presence/absence of clinopyroxene, spinel *vs.* garnet), and/or melt extraction/metasomatic processes. Concomitantly, olivine grains inside kimberlites display marked zoning in trace elements, which dramatically increase from the xenocrystic, mantle-derived cores to the magmatic-derived overgrowth formed in equilibrium with kimberlitic melts.

Altogether, our results demonstrate how trace elements in olivine determined through high-precision EPMA are an extremely powerful tool to: i) unravel the nature and evolution of the lithospheric mantle; ii) understand the provenance depth of mantle-derived cargo in kimberlites; and iii) reconstruct the liquid line of descent of the ascending kimberlitic melts.

MORB melt - harzburgite interaction at 1-2 GPA: experimental constraints on oceanic mantle refertilization

Keywords: melt-peridotite reaction, experimental petrology, trace elements.

Earth's upper mantle is characterized by wide compositional variability, mainly caused by partial melting processes and interactions between migrating melts and peridotites. After oceanic partial melting, refractory peridotites may be modified via reaction with migrating MORB melts at the flanks of melting regions, thus affecting the chemical and isotopic evolution of large lithospheric mantle sectors. This work aims to investigate by high-pressure experiments the effect of Enriched-MORB - peridotite reaction on major and trace elements composition of mantle phases at oceanic asthenosphere-lithosphere boundary (1-2 GPa; 1150-1400°C). We present the results of reaction experiments on a modeled harzburgite, made by depleted orthopyroxene (LaN/YbN = 0.004) and San Carlos olivine (Fo_{90}), homogeneously mixed to tholeiitic basaltic glass (XMg = 0.60, Na_2O = 3.48 wt.%, K_2O = 0.81 wt.%) with E-MORB signature (LaN/YbN = 5.40). Melt-peridotite reaction is simulated by isothermal experiments performed at high temperature (1200-1350°C). In a separate set of experiments, after high temperature step, runs have been cooled at 1150-1200°C to enhance reacted melt crystallization. Isothermal experiments mostly result in orthopyroxene dissolution coupled to olivine dissolution and reprecipitation. In cooling experiments, we observed new orthopyroxene and clinopyroxene crystallized from reacted melt, associated with few modal garnet (2 GPa) or plagioclase (1 GPa). Rims of partially dissolved orthopyroxene and newly crystallized orthopyroxene tend to acquire high TiO_2 and Al_2O_3, and low Cr_2O_3 contents with respect to initial orthopyroxene composition. Clinopyroxenes (XMg = 0.83-0.88) have moderate Al (up to 0.49 a.p.f.u.) and Ti (up to 0.07 a.p.f.u.). Olivines compositions are correlated with temperature and show high XMg (up to 0.95), high Ca and low Ni concentrations in high-T isothermal experiments, whereas cooling experiments have lower XMg (up to 0.84), coupled to moderate Ca and variably Ni contents. Newly formed orthopyroxenes show variable enrichments in LREE (LaN/SmN = 0.83-1.38) coupled to slightly lower HREE contents (SmN/YbN = 0.24-0.33), compared to initial orthopyroxene (LaN/SmN = 0.04, SmN/YbN = 0.10). Such unusual enrichment in orthopyroxenes has been documented in abyssal peridotites metasomatized by variably melts. Several rims of orthopyroxenes relicts are modified and show relatively high incompatible element concentration likely due to REE diffusion during the reaction. Clinopyroxenes show high convex upward LREE patterns at marked MREE/HREE fractionation. Reacted glasses show slight LREE/HREE fractionations at variable absolute REE concentrations as a function of temperature and extent of interstitial phases crystallization. This study provides a set of "reaction" partitioning coefficients (KdREE = CREEsolid/CREEliquid) that allows us to estimate the trace element redistribution in mantle minerals due to reactive percolation of basaltic melts.

Petrographic and structural study of a lower crustal mafic-ultramafic sequence from the Sesia Valley (Ivrea-Verbano zone, Italy)

Keywords: garnet-bearing metagabbros, lower continental crust, virtual outcrop models

The factors and dynamics governing the processes in lower continental crust have long been a source of vigorous debate, due to the lack of direct access to such lithologies on the Earth's surface. The Ivrea-Verbano zone (IVZ) represents a geological unit in the western Southern Alps that offers the possibility to investigate an exhumed quasi-complete section of the continental crust, including the roots of a completely exposed fossil magmatic system (Quick et al., 2009). In addition, there is an active debate about whether the contact between the Balmuccia peridotite and the Mafic Complex in the IVZ might represent a continental crust-mantle transition zone (Ryberg et al., 2023).

The focus of this work is a petrographic-structural study of a mafic-ultramafic sequence within the Upper Zone of the Mafic Complex, cropping out near the Sassiglioni village (Sesia Valley, IVZ; Rivalenti et al., 1984). The study involved collecting field and remotely sensed data, including primary magmatic intrusions, foliations, faults, and fractures. To enhance our understanding of these structures and the chemical-physical processes at a micro-scale, a petrographic and micro-structural analysis on selected samples is also being conducted. The remote sensing part of the study was based on capturing drone images that were used to construct a virtual outcrop model (VOM) of the site. This VOM facilitated the analysis of structures at a macro-scale and enabled the mapping of the outcrop, free from perspective distortion, using orthorectified photomosaics.

The lithological sequence is mainly composed of metagabbros with variable amounts of garnet, olivine and/or hornblende. Foliation varies from sub-vertical to less than 45° dipping toward E-SE or W-NW. Occasionally, the sequence includes anorthosites and pyroxenites layers, pseudotachylytes (PST) and mafic pegmatites. The cm-to-m sized PST, which range in color from black to brown and occasionally include plagioclase-pyroxene grains, are found as I) shear planes, II) injection veins, and III) network of melt surrounding metagabbro blocks. The mafic pegmatite is composed of cm-sized pyroxene-plagioclase crystals and can be observed in direct contact with the metagabbro. Clasts of this pegmatite are also included within the PST. The layers of anorthosite and pyroxenite are found in contact with each other with sharp boundaries. Finally, several dm-sized enclaves of fresh garnet-rich metagabbro were identified near the fracture zones within the main body of garnet-free metagabbro. Contact between the enclaves and the main body is marked by apparent reaction rims. All lithologies and their associated foliations were found to be overprinted by a later tectonic event, consistent with literature data (Quick et al., 1994). This event is characterized by top-to-SE brittle shear deformation, evidenced by a Riedel shear assemblage. It represents the most recent deformational event in the area.

The Se-Te-bearing VMS deposits of Tuscan ophiolites

Dini A.*, Rielli A., Di Giuseppe P., Ruggieri G. & Boschi C.

Istituto di Geoscienze e Georisorse, CNR, Pisa.

Corresponding author email: a.dini@igg.cnr.it

Keywords: VMS deposits, ophiolites, Northern Apennine.

Several Jurassic, ophiolite-hosted Cu-Zn Volcanogenic Massive Sulphide deposits (VMS) occur in Tuscany (Klemm & Wagner, 1982). They are hosted by tectonic units of oceanic affinity (Ligurian Units), such as the well-known deposits of nearby Liguria. Industrial production was small and definitively ceased from the 1960s. Locally, massive ore (chalcopyrite-bornite-chalcocite) having exceptionally high grade was found. The Montecatini Val di Cecina mine exploited the largest "bonanza" and, for few decades in XIX century, became one of the most profitable copper mines in Europe.

This study is part of the PRIN-MUR 2017AK8C32 project, funded by the Italian Ministry of University and Research. It was aimed to make a reappraisal of the Tuscan VMS Cu-Zn deposits and define: i) their structural setting, ii) their potential for precious-critical metals and iii) the reactions involving their sulphides and gangue silicates. It provides an updated review of these deposits (Dini et al., 2024).

Tuscan Cu-Zn VMSs mostly occur in proximity of the contact between the serpentinite-gabbro basement and the overlying basalts. Chalcopyrite-pyrite stockworks occur in serpentinite-gabbro cut by dolerite dykes, while the largest massive sulphide bodies are hosted by polymictic-monomictic breccias at the base of pillow basalts. The early chalcopyrite ores were mechanically-chemically reworked and upgraded to bornite-rich nodular ore embedded in a chlorite, calcic amphibole, Fe-rich serpentine, quartz, andradite, ilvaite and xonotlite assemblage. The bornite-rich ore contains substantial amount of sphalerite and pyrite and ubiquitous grains of clausthalite, hessite, tellurium and gold/electrum. The concentration of selenium, tellurium in bornite-rich ore is extremely high, up to 100,000 times the average for the Earth's crust.

They represent a prime example of the sub-seafloor portion of a hybrid mafic-ultramafic oceanic hydrothermal system formed in an OCC along the slow spreading ridge of the Jurassic Piedmont-Ligurian Ocean (Dini et al., 2024). The peculiar mineralogical-textural character of the bornite-rich ore was driven by an interface coupled dissolution-precipitation process mediated by fluids. Despite their small size, Tuscan ultramafic- and hybrid mafic/ultramafic-hosted VMS deposits provide valuable information for the ongoing definition of a genetic model for this sub-group of VMSs (Patten et al., 2022). This is a potentially relevant mineral resource worldwide not only for base metals, but for possibly recovering energy-critical metals like Co, Ni, Te and Se from mafic/ultramafic-hosted deposits in orogenic and oceanic settings.

Keywords: natural hydrogen, northern Apennines, ophiolites.

In the energy diversification scenario, natural or geological hydrogen (H_2) may represent a clean and cost-effective option. Although it is still poorly studied, its exploration is already a reality. In Mali, a field of H_2 has been in production since 2012. In other countries, such as Australia, U.S.A, France, Oman and Poland, H_2 exploration activities are already allowed.

One of the main H_2-generating process is the alteration of iron-rich rocks. During serpentinization, oxidation of minerals containing Fe^{2+} (e.g. olivine) into Fe^{3+} (e.g. serpentine + magnetite) generates H_2. Therefore, mantle rocks occurring in ophiolite sequences can represent suitable H_2-generating rocks.

In the Northern Apennines, the presence of ophiolites including ultramafic rock bodies is noticeable, and, associated to the multiphase structural framework and gas manifestations, makes the region a favorable place to H_2 occurrences.

Our study aims to evaluate the potential for H_2 occurrence and investigate the H_2-forming processes in the NW sector of the Northern Apennines. The study is conducted through i) measurements of H_2 content in the soil and dissolved in the water, ii) rocks chemistry, and iii) assessment of subsurface geological-geophysical data.

Three study areas were selected for investigation: two in Emilia-Romagna, namely Monte Prinzera (Parma Province) and Bobbio (Piacenza Province), and one in Liguria (Bracco-Levanto).

Located in the External Ligurian domain, Monte Prinzera corresponds to an ophiolitic body primarily composed of serpentinized peridotites and breccias. The presence of a hyperalkaline spring water, containing H_2 and CH_4 reported by Boschetti et al. (2013) encouraged our further H_2 measurements in the soil and dissolved in the water. Additionally, petrographic, and bulk analyses of major elements in peridotites are being carried out to evaluate the potential for H_2 production.

The Bobbio region corresponds to a structural window where deformed sediments of the Tuscan domain are tectonically overlain by ophiolitic bodies from the External Ligurian units. Bubbling gas manifestations previously observed (Scicli, 1972) have led us to investigate the region. We found that two bubbling springs, despite they are not hyperalkaline, contained H_2. Seismic reflection, magnetometric and gravimetric surveys integrated with published geological surveys are currently used to investigate the origin of H_2. The Bracco-Levanto is an ophiolitic massif of the Internal Ligurian domain where a hyperalkaline spring water was reported (Fantoni et al. 2002). However, no dedicated H_2 study was carried out so far. H_2 measurements in dissolved gas in water are being conducted in the area, and if H_2 is found, we plan to conduct rock analysis to investigate its potential to form H_2. According to the results obtained to date, the NW part of Northern Apennines hosts H_2-generation processes, and it deserves further studies to better assess H_2 origin and potential accumulations.

Tests for implementing ophiolitic chromite concentrates from Albania mines to chromite foundry sands quality parameters

Grieco G.*[1], Bussolesi M.[2], Comboni D.[1] & Gjoca G.[3]

[1] Dipartimento di Scienze della Terra "A. Desio", Università di Milano. [2] Dipartimento di Scienze della Terra, Università di Milano-Bicocca. [3] TGT Consulting, Albania.

Keywords: ophiolite chromite, chromite foundry sand, silicate mineralogy.

Chromite is the best performing of the refractory materials used by foundries for casting. Chromite foundry sands form the mould in which molten metal is contained until it solidifies in the desired shape. Chromite is used because of its resistance when exposed to heat and its good heat conductivity. It is chosen when a higher casting temperature is required or for a complex shape of the mould; in these cases it has no substitutes and hence its high economic importance.

To be used for casting, chromite sands must be as pure as possible as small amounts of low-T melting gangue minerals can damage the binding resins. Moreover, a very narrow sand grain size range is required to provide the correct permeability to the sand.

In refractory industry acid demand test (ADT), a titration method that keeps into account the amount of acid consumed at three different pH levels, is used as a proxy of the sand-resin reaction potential, while for grain-size the fineness index (FI) test is used. A third parameter usually determined is the SiO_2 content that should be as low as possible.

The present work reports the first results obtained on testing several chromite sands produced by different gravity enrichment plants at Albanian chromite mines.

Firstly, the sands were checked, together with two samples from commercial South African chromite foundry sand, for all the three quality parameters and compared with foundry industry thresholds. As expected, all Albanian sands did not meet the parameters. Some of the sands meet the FI range but all of them are too high in SiO_2. The worst results were anyway obtained for the ADT value, always quite far from the thresholds. A selection of the Albanian sand closer to the quality thresholds were chosen for further depuration tests aimed to meet all three parameters.

The mineralogy of Albanian and South African chromite gangue minerals strongly differs. Albanian sand derives from metamorphosed ophiolite-hosted deposits, typically enriched in serpentine, while South African ones come from the major layered intrusion of Bushveld and their typical gangue minerals are olivine and orthopyroxene. The presence of serpentine negatively affects the ADT value as it is much more reactive than olivine or pyroxene (Bussolesi et al., 2020).

The first depuration tests were designed with the aim to reduce serpentine content of sands by cooking them in an oven at 800°C for one hour. The results were partially positive as the ADT value was reduced of about 30%, due to transformation of serpentine into a new phase as confirmed by XRD data. This result is not enough to decrease the ADT below the commercial threshold.

To further implement sands quality a separation through a Franz magnetic separator has been conducted. Preliminary results are positive, and it is possible that a combination of cooking and magnetic separation could lead to the production of chromite foundry sands starting from Albanian chromite concentrates.

Serendipity-driven discovery of a new UHP slice in the southern Dora-Maira Massif

Groppo C.*[1-2], Ferrando S.[1], Tursi F.[1] & Rolfo F.[1-2]

Keywords: petrological discovery, new UHP unit, southern Dora-Maira Massif.

The first worldwide report of coesite (Chopin, 1984) in the continental crust of the southern Dora-Maira Massif (DMM), western Alps, is one of the best examples of how petrological discoveries can revolutionize geological and geodynamic paradigms, suggesting that even the relatively light continental crust can reach previously unsuspected mantle depths. Since that discovery, the small Brossasco-Isasca Unit (BIU) has been the subject of an incredibly high number of studies, becoming the archetype of ultra-high pressure (UHP) metamorphic terranes; currently, most geodynamic models seeking to explain the subduction and exhumation processes of crustal rocks from mantle depths are calibrated on this tectonic unit. However, despite all these studies, the interpretation of the BIU in the framework of the southern DMM and, more generally, of the Western Alps, remains controversial.

Progress on understanding UHP metamorphism in the BIU inevitably depends also on our knowledge of adjacent units, which - together with the BIU - define the nappe stack of the southern DMM. After preliminary studies dating back to more than 30 years ago, a new impetus in this direction has recently been given (e.g., Groppo et al., 2019; Bonnet et al., 2022), allowing to reconstruct the lithostratigraphic and tectonic setting, the metamorphic evolution and the ages of Alpine metamorphism for all the units stacked in the DMM tectonic "sandwich".

Although one might think that the southern DMM has no more secrets and that everything has already been said in this small area extending over less than 200 km^2 between the Po and Varaita valleys in the Piedmont region of Italy, serendipity can sometimes lead to new discoveries even in the best-known areas. And serendipity is the basis of this study: while observing under the microscope an apparently common metagranite sample we noticed unexpected microstructures which led us to critically re-examine samples collected more than 30 years ago. Here we report petrological evidence that the tectonic unit overlying the BIU (formerly known as Rocca Solei Unit), so far considered as a high pressure (HP) unit, is actually divided in two sub-units, one of which (the lowermost Rocca Solei Unit s.s.; RSU*) experienced "cold" UHP conditions, while the other (the uppermost unit, here renamed as Grimbassa Unit, GU) reached HP conditions. Therefore, a "new" slice needs to be added to the southern DMM sandwich; this new unit experienced UHP metamorphism, but at significantly different P-T conditions compared to the underlying BIU. Interestingly, the structural position, thickness and metamorphic evolution of the UHP RSU* inferred in this study are very similar to those defined for the Chasteiran Unit, recently discovered in the northern DMM (Manzotti et al., 2022). This new discovery encourages everyone not to cease the quest for petrological novelties and to be prepared to take advantage of serendipitous events.

Keywords: thermal structure, chemical zoning, subcontinental lithospheric mantle.

The petrographic and chemical (major and trace elements) characteristics of garnet and clinopyroxene xenocrysts and of peridotite xenoliths entrained in the Três Ranchos kimberlite have provided valuable insights into the subcontinental lithospheric mantle (SCLM) beneath the Alto Paranaíba Igneous Province (APIP, Brazil) with respect to: (i) the thermal structure and heat flow; (ii) the pristine composition and metasomatic events undergone by the lower SCLM sector; (iii) the nature of the shallow fertile, lherzolite layer. These observations, combined with a re-evaluation of the petrochemical data of the Brazilian SCLM, allow to shed light on the stabilization and evolution processes of the São Francisco Craton (Guarino et al., 2024).

The present-day thickness of the Brazilian SCLM is similar in the Três Ranchos, Canastra, and Osvaldo França areas (~170-180 km depth), and the estimated temperatures and pressures indicate a typical cratonic geotherm, with a surface heat flow of ~40 mW/m^2 slightly hotter than that at the São Francisco Craton margin (35-36 mW/m^2), suggesting lateral heterogeneities in the geothermal gradients, in agreement with geophysical studies.

A deep mantle portion (160 km) is recorded by a lherzolite xenolith (5 GPa and 1200°C). This portion has undergone pervasive interstitial melt percolation of an ultra-alkaline silicate melt and late injection of small silicate melt fractions similar to the host carbonated kimberlite. This pervasive migration extended into shallower SCLM sectors at 124-100 km (3.9-3.1 GPa and ~940-810°C) as evidenced by metasomatized (± phlogopite) peridotite identified by sinusoidal REE garnet compositions. At 120-110 km depth (3.7-3.3 GPa and ~850°C) strongly depleted peridotites also occur, which show garnet and clinopyroxene compositions extremely impoverished in moderately incompatible elements, as a result of extreme, ancient melt extraction. Above the metasomatized and depleted peridotites, at 100 km depth, a layer of fertile lherzolite is identified by garnet xenocrysts, with 'normal', HREE-enriched, steadily fractionated LREE-depleted patterns.

This study highlights the occurrence in the São Francisco Craton of i) a deeper sector (>100 km deep beneath Três Ranchos) originally formed by extremely depleted peridotites, that were largely metasomatized by pervasive melt migration of ultra-alkaline silicate melts and/or LILE-enriched fluids; ii) and a shallower sector of the São Francisco Craton composed of fertile lherzolites unrelated to ultra-alkaline magmatism. Similar fertile lherzolites are found in the uppermost sectors of the Siberian and Kaapvaal SCLM, suggesting that they may be a ubiquitous, primary feature, possibly related to the stabilization of the Archean cratons.

Guarino V. et al. (2024) - Stabilization and evolution of the Brazilian subcontinental lithospheric mantle: insights from garnet xenocrysts and peridotite xenoliths of Três Ranchos kimberlite (APIP, Brazil). Gondwana Res., 130, 18-35, https://doi.org/10.1016/j.gr.2024.01.005.

HT-LP extensional shear zones in the GHS (E Nepal): preliminary data on P-T-D conditions and timing

Keywords: Himalata, Greater Himalayan Sequence, petrochronology.

The medium-to high-grade metamorphic core of the Himalaya belt is represented by the Greater Himalayan Sequence (GHS). Facilitated by its 3D good exposure, the GHS is regarded as a proxy for investigating the structure of the middle-lower crust in orogenic settings. For a long period of time, the GHS has been regarded as single, tectonically coherent, unit. Recent findings (Carosi et al., 2010; Montomoli et al., 2013; 2015), starting from field mapping, down to the microscale analysis, challenges this view. Indeed, nowadays most of the focus on the tectono-metamorphic evolution of the GHS is aimed to characterize how strain is accommodated within this "composite" unit, over the time in response to the P-T evolution.

Here, we present preliminary data, combining field observations, microtectonics analysis, pseudosection modelling, iterative thermodynamic modelling and monazite petrochonology, on the activity of high-temperature / low-pressure ductile shear zones, affecting garnet-sillimanite-bearing and cordierite-bearing anatectic paragneiss, in Eastern Nepal. Field and microstructural data highlighted how these shear zones are associated to a normal (both top-to-the-S and top-to-the-N) sense of shear. Mylonitic shearing developed under upper amphibolite facies (c. 700°C) metamorphic conditions, as testified by syn-kinematic mineral assemblage and by quartz and feldspar dynamic recrystallization microstructures. Phase equilibria modelling (i.e., with the aid of P-T-X pseudosections) and iterative thermodynamic modelling, highlighted how sheared rocks experienced a "peak" pre-mylonitic stage in the medium-pressure, upper amphibolite-to granulite facies melt present conditions. This stage is followed by the mylonitic stage, associated to decompression and minor cooling.

Our multidisciplinary investigation highlights how strain was progressively localized within migmatitic terrain, following melt extraction, from the Oligocene down to Miocene. Possible consequences on the role of the detected HT-LP extensional shear zones on the exhumation and thinning of the GHS are presented.

Corresponding author email: michele.lustrino@uniroma1.it

Keywords: carbonatite, phonolite, ultralkaline.

Nearly 80% of carbonatite outcrops are associated with cogenetic silicate magmas, characterised by compositions ranging from ultrabasic (nephelinites and ijolites) to intermediate (phonolites, trachytes and syenites; e.g., Woolley & Kjarsgaard, 2008). The eastern sector of the Quaternary Eifel Volcanic Province (EVP) hosts abundant evolved compositions (mostly phonolite-syenite) occasionally associated to carbonatites and rare mafic lithologies. On the other hand, the western sector of the EVP comprises abundant basic-ultrabasic mafic lithologies, rarer evolved compositions, and even rarer carbonatites.

The largest volcano of the eastern sector of EVP is Laacher See volcano, characterized essentially by strongly explosive phonolite eruptions associated to the formation of a large caldera, plus very rare ultrabasic low-volume potassic lava flows. Plutonic ejecta, with a size up to 20 cm and compositions spanning from mafic to felsic, are common within the thick phonolite pyroclastic deposits. Less than ~5% of these plutonic ejecta contain a carbonate component that can reach more than 50% of the nodule.

A detailed petrographic, mineral chemical, geochemical and isotopic study on such carbonate-bearing plutonic ejecta from Laacher See volcano (sövite and syenite-carbonatite mixed rocks), as well as on the rare leucitite lavas has been carried out to infer the origin of this igneous association. The geochemical compositions are extremely variable, from nearly SiO_2-free and CaO-rich terms to strongly ultrabasic and mildly CaO-rich rocks and to SiO_2-rich CaO-poor compositions.

The relatively high $^{87}Sr/^{86}Sr$ ratios for composite and silico-carbonatite samples overlap quite well, highlighting a genetic link, possibly associated with assimilation of Devonian country rocks by the phonolite magma. Samples from the eastern district of EVP plot in the enriched isotopes field, also for the $^{143}Nd/^{144}Nd$ ratios, while the $^{143}Nd/^{144}Nd$ for carbonatite belonging to the western district is slightly above ChUR. EVP rocks exhibit uniform $^{207}Pb/^{204}Pb$, coupled with a negative correlation between $^{206}Pb/^{204}Pb$ and $^{87}Sr/^{86}Sr$, and between $^{208}Pb/^{204}Pb$ and $^{87}Sr/^{86}Sr$.

The origin of the carbonatitic and silico-carbonatitic rocks can be explained with a two-step model. Magma evolution started from a CO_2-bearing leucitite magma, which, after prolonged fractionation of olivine + clinopyroxene + Fe-Ti oxides ± melilite, evolved towards CO_2-enriched phonolite compositions. These melts experienced magma unmixing, with the separation of SiO_2-rich and CaO-CO_2-poor liquids (represented by syenites) and SiO_2-poor and CaO-CO_2-rich melts (represented by Ca-carbonatites). Silico-carbonatites are interpreted as the consequence of the entrapment of small portions of carbonate liquids in the strongly evolved silicate magma, during the unmixing process, whereas composite samples would represent the result of the mechanical mixing of the two unmixed melts.

Keywords: clinopyroxenite, oxygen fugacity, mantle.

Fossil subduction zones are key locations to study the deepest geochemical cycles of C, O, S and H. In non-cratonic areas C-bearing mantle rocks were reported for the orogenic peridotite massif of Beni Bousera - Moroccan Rif belt (Pearson et al., 1994), where graphite occurs in garnet pyroxenite layers as pseudomorphs after diamond. Montanini et al. (2010) found high-temperature graphite as flakes in garnet pyroxenite layers from the External Ligurides (Northern Apennine, Italy). Both sample sets show sulphides in equilibrium with carbon. These pyroxenite layers are proxies of deep recycling of subducted crust and may have formed by crystallisation of mafic melts induced by C-S-related redox processes. We analysed the redox state of garnets and clinopyroxenes associated with C and S, related to a liquid segregated from the melting of a recycled eclogite. Transmission Electron Microscopy coupled with Electron Energy-Loss Spectroscopy and synchrotron micro-Mossbauer analyses were performed to check the $Fe^{3+}/\Sigma Fe$ distribution heterogeneities, in relation to its partitioning among mineral phases and/or to the occurrence of fluid fluxes at different redox conditions.

Our results indicate a strong partitioning between garnet and clinopyroxene at high temperature in samples from Beni Bousera, with $Fe^{3+}/\Sigma Fe$ in clinopyroxene reaching up to 0.30, vs. garnets with values up to 0.07. Interestingly, graphite-bearing clinopyroxenites from External Ligurides show two generations of clinopyroxene. The first included in garnet has higher values of Fe^{3+}/SFe with respect to high temperature clinopyroxenes in the rock matrix (0.23-0.38 vs. max 0.08). Garnet shows homogeneous values (up to 0.07). This variation in clinopyroxenes may therefore records a variation of redox conditions, likely related to the interaction and evolution of C-S-bearing liquids, corresponding to an average ΔFMQ (Fayalite-Magnetite-Quartz buffer) from -0.25 to -5. These values correspond to redox conditions slightly above the CCO (Carbon-CO_2 buffer) to below the CCO, indicating a variation in the carbon speciation.

The Monte Pagliano Unit in the southern Dora-Maira Massif (Western Alps): a preliminary petrologic study

Maroni A.*, Miccoli A., Balestro G., Groppo C. & Castelli D.

Dipartimento di Scienze della Terra, Università di Torino.

Corresponding author email: andrea.maroni@edu.unito.it

Keywords: southern Dora-Maira Massif, petrologic investigations, forward thermodynamic modelling.

Located at the mouth of the Varaita and Maira valleys (Western Alps), a few km south-east of the worldwide renew ultra-high pressure Brossasco-Isasca Unit of the southern Dora-Maira Massif, the Monte Pagliano relief, is mostly unknown from a geological point of view, the most recent detailed study being dated to the end of the 19th century (Stella, 1899). However, understanding its geological-structural setting and its metamorphic evolution is crucial for interpreting the whole tectonic architecture of the southern Dora-Maira Massif.

In the study area, we have recognized a new tectonostratigraphic unit, named Monte Pagliano Unit (MPU), which is bounded at its bottom by a several hectometers thick shear zone (i.e., the Valmala Shear Zone, Balestro et al., 2020). Here we present the results of a detailed petrographic study aimed at recognizing the lithostratigraphic succession of the MPU and defining its peak metamorphic assemblages.

The monometamorphic metasedimentary succession of MPU consists of three lithological units: (i) chloritoid- and tourmaline-bearing graphitic micaschist at the bottom; (ii) kyanite- and chloritoid-bearing micaschist with meters-thick levels of paragneiss and metabasite; (iii) quartzitic micaschist at the top.

The paragneiss shows a peculiar mineral assemblage consisting of quartz, kyanite, chloritoid, muscovite, Fe-hydroxide and rutile. The preliminary petrologic investigation of this paragneiss allowed us to provide an estimate of the peak P-T conditions experienced during Alpine subduction.

The obtained results open new questions on the tectonic architecture of this portion of the Dora-Maira Massif and stimulate further petrologic investigations in the adjacent areas.

Chemistry of sulfides in the Earth's mantle: insights from magmas, mantle xenoliths and inclusions in diamonds

Marras G.* & Stagno V.

Dipartimento di Scienze della Terra, Sapienza Università di Roma.

Corresponding author email: giulia.marras@uniroma1.it

Keywords: sulfur, sulfide, mantle.

Sulfur (S) is one of the main volatile elements occurring on Earth, both in its reducing (S^{2-}) and oxidized (S^{2+}, S^{4+}, S^{6+}) form. The abundance of S in the bulk silicate Earth has been proposed to be 250 (±50 ppm; McDonough & Sun, 1995), whereas cosmochemical constrains indicates that more than 97% of the bulk Earth S is hosted in the core (Palme & O'Neill, 2003). As a chalcophile element, sulfur binds with Cu, Se, Cd, ln, Sn, Te, Pb and Hg as well as with siderophile elements like Ni, Au, Ag, Co and PGEs.

Sulfides are the main S-bearing minerals and are present as an accessory phase in the Earth's mantle (< 1% of bulk), often occurring as mineral inclusions in lithospheric diamonds. Interestingly, solidus curves of the principal sulfide end-members indicate that these are likely molten or partially molten in almost the mantle (Zhang & Hirschaman, 2016). Studies of natural mantle sulfides reveal significant heterogeneities in terms of both chemical composition and isotopic signatures. However, the reasons for these heterogeneities are not yet fully understood.

In this work, we review the chemistry of sulfides from mantle-derived samples including melts, peridotites, eclogites and inclusions in (sub-)lithospheric diamonds, metamorphic rocks and experimental works at the aim of shedding light on the controversy between the composition of sulfides in nature and those from quenched laboratory experiments with particular emphasis on the role of pressure, temperature and oxygen fugacity.

Keywords: New Caledonia ophiolite, forearc magmatism, subduction inception.

The New Caledonia peridotite nappe is crosscut by orthopyroxenites, amphibole-bearing websterites, clinoenstatite boninites and hornblende gabbro/diorite dykes intruded between 55.5 Ma and 50 Ma (U-Pb zircon and $^{40}Ar/^{39}Ar$ hornblende ages, Cluzel et al., 2024). Dolerite dikes with tholeiitic affinity were subsequently emplaced between ca. 50 and 47 Ma. Hornblende-gabbro/diorite-forming melts have a broad adakitic affinity, whereas contrasting parental melts with boninitic and Mg-adakitic composition may be inferred for the pyroxenite dikes. Production of slab melts was modelled by moderate degree (20-40%) of partial melting of the HT garnet amphibolites of the metamorphic sole. End-member compositions of the dikes, hornblendites and anorthosites, resulted from solid-state phase segregation of crystal mush within tectonically active magmatic conduits. Residual mantle source re-enriched by slab melt inputs during the Eocene subduction successively formed clinoenstatite-boninite magmas. The youngest magmas of tholeiitic affinity, appeared about 6 Ma after subduction inception when the cooler subducting slab plunged more steeply. Incipient slab retreat allowed corner flow, triggering low pressure hydrous melting of the uplifted asthenosphere. The early stages of forearc magmatism were closely associated with transcurrent shear zones, now testified by HT mylonitic deformation in the peridotites, which recorded oblique subduction inception. The lower Eocene tectonic and magmatic features of the New Caledonia ophiolite witness the existence of a north- or northeast-dipping hot (forced) subduction zone in the Southwest Pacific, which appears notably distinct from the slightly younger west-dipping Izu-Bonin-Mariana cold (spontaneous) subduction system (e.g. Reagan et al., 2013). Our results support the notion that compositional variability of the early forearc products may be a hallmark of subduction inception.

Keywords: anatexis, kyanite trace element zoning, thermodynamic modelling.

Trace element zoning in kyanite can preserve information about the growth history of this phase, particularly in anatectic metapelites (Kendrick & Indares, 2018; Phillips et al., 2023). There, kyanite can grow (i) at sub-solidus conditions through metamorphic reactions involving other aluminous phases as reactants (i.e., sub-solidus kyanite), (ii) through muscovite dehydration melting reaction (i.e., peritectic kyanite), and (iii) during cooling and melt crystallisation either through back-reactions between melt and solid phases (e.g., garnet, K-feldspar) or crystallising directly from the melt (i.e., back-reaction overgrowth or magmatic kyanite). Thermodynamic modelling successfully reproduces these reactions, allowing a more robust interpretation of the observed features based on predicted reactants and products.

In this study, we integrate cathodoluminescence (CL) microscopy (optical CL and SEM-CL), LA-ICP-MS mapping and forward thermodynamic modelling to unravel the anatectic history of biotite + kyanite + garnet migmatites from the Lower-Greater Himalayan Sequence exposed in eastern Nepal Himalaya. Changes in kyanite CL colour intensity appear mostly related to different concentrations of Fe, Cr and V (hundreds to thousands of ppm; Müller et al., 2016). Three main generations of kyanite revealed by CL and LA-ICP-MS maps have been identified, consistent with the three main kyanite-producing reactions predicted by forward thermodynamic modelling. Trace element zoning patterns and relative concentrations have been related to kyanite growth (i) at sub-solidus conditions, (ii) during the dehydration melting of muscovite and (iii) during the following decompression and cooling.

The major implications of this study concern the interpretation of the melt extraction processes in anatectic rocks and the understanding of the Cr and V partitioning between minerals and melt. On a broader perspective, our work highlights how minerals characterised by simple chemistry, investigated with a multi-methodological approach coupled with thermodynamic modelling, can reveal important information about metamorphic processes occurring during the evolution of continental crust undergoing partial melting.

Keywords: quality factor, statistical solution, Python script.

Forward thermodynamic modelling is ubiquitously used in modern metamorphic petrology. Phase diagrams calculated using this technique allow users to determine the pressure (P) and temperature (T) conditions of mineral assemblage formation for a given bulk composition (*X*). Traditionally, isopleth thermobarometry involves manually tracing the field of maximum isopleth overlap, which can be considered a qualitative method (Powell & Holland, 2008; Lanari & Duesterhoeft, 2019). In the last decade, several software solutions have provided more quantitative approaches where optimal P-T conditions can be calculated from a statistical point of view, resulting in a more accurate interpretation of forward model results (Lanari et al., 2017; Duesterhoeft & Lanari, 2020). However, these approaches are based on Theriak-Domino, and/or require quantitative compositional maps (e.g., Bingo-Antidote routine in XMapTools; Duesterhoeft & Lanari, 2020).

We present an application of statistical quantification of the quality of fit starting from the Perple_X WERAMI output, testing different statistical approaches: (i) a least squares approach, which minimises the difference between the observed and modelled compositions, referred to as the residue; (ii) a weighted least squares approach, which adds a weighting factor using analytical uncertainties (Lanari et al., 2017); and (iii) a quality factor approach, which assesses the quality of fit between the modelled and the observed compositions (Duesterhoeft & Lanari, 2020). The calculation shows that a quality factor approach, as implemented in Bingo-Antidote (Duesterhoeft & Lanari, 2020), can be applied to Perple_X results, allowing the propagation of uncertainties in the measured mineral composition. This work and the code will help to improve the quality of interpretation when using isopleth thermobarometry.

Keywords: mineral distribution, quantitative microstructural analysis, bulk rock composition.

Despite the rise of innovative approaches and high-resolution techniques in Earth Sciences, the reconstruction of the tectono-metamorphic history of crystalline basements is mostly based on a two-dimensional (2D) thin-section investigation. Forward thermodynamic modelling requires the definition of a bulk rock composition, which can be obtained from a three-dimensional (3D) rock volume by whole-rock geochemical analysis (e.g., X-ray fluorescence, XRF). Nevertheless, most petrological contributions consider a 2D local bulk rock composition (Palin et al., 2016; Lanari & Duesterhoeft, 2019), obtained by combining the modal abundance of phases with their chemical compositions (e.g., via a weighted calculation using different software, combining mineral proportion of a thin section with their representative compositions and densities). Similarly, textures, grain size, shape, and orientation of different mineral phases in polymineralic rocks are mostly investigated only in 2D, leading to a potential loss of information.

On the other hand, 3D investigations, despite being computationally intensive and requiring specialised tools and expertise, offer a more comprehensive and realistic representation of metamorphic features than traditional 2D thin-section observations (e.g., Corti et al., 2019). Different sample sectioning directions can influence the mineral modal proportions of strongly heterogeneous and anisotropic samples, and 2D thin-section observations risk to oversimplify complex textures. Thus, this work focuses on the comparison between 2D and 3D approaches to understand possible mismatches.

We compared microstructural evidence, modal abundances, local bulk rock compositions and thermodynamic modelling results using a 2D thin section and a 3D volume analysed through X-ray computerised axial microtomography (μCT). Moreover, three different cuts from the 3D volume have been extrapolated (XZ, YZ, XY planes of the finite strain ellipsoid of deformation), and results have been compared. Despite differences in the modal distribution in the 2D thin section, 3D volume, and different-oriented cuts, the mismatches in the local bulk rock composition estimates are very small, with no major implications for the derived thermodynamic modelling. We quantitatively corroborate the reliability of the thin section approach, still emphasising that 3D analysis is complementary for a complete understanding of microtextures and a better representation of the complex geological reality.

The origin of melilitites: an experimental study

Poli S.*[1] & Melluso L.[2]

Keywords: mantle, melilitite, carbonatite.

Melilitites are ultramafic magmas characterized by normative Ca_2SiO_4, larnite, high FeO* and TiO_2. Melilitite primitive lavas (Mg# 67-77) occurs in ocean island as well in alkaline volcanic districts on rifted continental crust. Liquids compositionally close to melilitites were experimentally reproduced in the model system CaO-MgO-Al_2O_3-SiO_2-CO_2 at 3.2-3.3 GPa, approx. 1500°C, at relatively high melt proportions. In complex compositions, MORB-eclogite derived, carbonated, partial melts reacted with a fertile peridotite were proposed at the origin of melilitites. The experimental reconstruction of phase relationships on the liquidus of carbonated natural melilitites reveal that clinopyroxene and olivine or garnet are stable phases, suggesting that carbonated wehrlites are potential sources for the genesis of melilitites.

Here, we explore phase relationships on the high pressure melting of a model wehrlite, initially composed of a mechanical mixture of San Carlos olivine, diopside, aegirine, dolomite, rutile and kyanite. Starting materials were loaded in graphite capsules, inserted in sealed platinum capsules. Vitreous carbon spheres and synthetic diamond grains were adopted for liquid traps.

A first set of experiments performed at 3.2 GPa from 950 to 1450°C reveal that the solidus for the model wehrlite composition is located at temperatures in the order of 1050°C. In all experiments, an orthopyroxene-rich layer, with polygonal microstructure, forms at contact with aggregates resulting from quenched liquids, its thickness increasing with increasing temperature, i.e., increasing melt fraction. Estimates of liquid composition are melilititic at 1150-1200°C, with TiO_2 approx. 2.5 wt.% on a volatile free basis.

A second set of sandwich experiments is devoted to verifying the modification and equilibration of liquids produced by a natural aphyric melilitite from Alaotra district (central-northern Madagascar) interbedded with wehrlite.

Currently available experiments suggest that the melting reaction producing a melilitite liquid is dolomite + olivine + clinopyroxene + garnet = orthopyroxene + liquid. This is feasible only if the primary phase field of orthopyroxene on the liquidus surface extends on the Ca-rich portion of the volume forsterite-enstatite-nepheline-larnite in the presence of CO_2.

Compositional variability of the oceanic crust as a function of spreading rates: insights from the ultra-slow spreading Gakkel Ridge (Arctic Ocean)

Scarani S.*[1], Sanfilippo A.[1], Basch V.[1], Genske F.[2] & Stracke A.[2]

[1] Dipartimento di Scienze della Terra e dell'Ambiente, Università di Pavia.
[2] Institut für Mineralogie, Universität Münster, Germany.

Keywords: mid ocean ridges, lower gabbroic crust, mineral chemistry.

Gakkel Ridge runs for ~1,800 km in the Artic Basin, and features a long spreading segment without transform faults, expanding nearly perpendicular to the North America-Eurasia opening. It is currently the slowest spreading ridge on Earth, its full spreading rate decreasing from 14.6 mm.yr-1 near the Lena Trough in the west to 6 mm.yr-1 towards the active rifting in the Laptev Sea in the east. The composition of Gakkel ridge lower gabbroic crust is undocumented to date. Bathymetric and gravity data display variation in crustal thickness, suggesting the occurrence of three distinct tectono-magmatic provinces along its length: i) the Western Volcanic Zone (WVZ), ii) the central Sparsely Magmatic Zone (SMZ), and iii) the Eastern Volcanic Zone (EVZ). Extensive sampling during the AMORE expedition in 2001 allowed for the recovery of gabbroic lower crustal rocks from all these provinces, therefore allowing for a detailed assessment of the composition of the lower gabbroic crust at the worldwide end-member of slow-spreading ridges. We here report the very first data of the petrography and mineral major and trace elements of the lower gabbroic lithotypes sampled during the HLY0102 and PS59 expeditions. The sampled gabbros show strong compositional variability, representing the whole crystallization sequence of oceanic melts, ranging from troctolites to oxide gabbros and felsic vein. Furthermore, gabbroic rocks from the central SMZ show widespread occurrence of Fe-Ti oxides and amphiboles even in the most primitive lithologies such as troctolites. Important textural differences characterise the lower gabbroic crust from the central SMZ and WVZ, where clinopyroxene presents habitus from vermicular to subequant and the olivine shows habitus from rounded anhedral to interstitial, respectively. On the other hand, the different gabbroic lithologies from the EVZ were mostly sampled as variably altered veins associated with basaltic intrusions and peridotites. As a whole, these lower gabbroic sections show a correlation between modal and chemical compositions, showing higher Mg-numbers in olivine and clinopyroxene and Anorthite contents in plagioclase in the most primitive lithotypes such as troctolites and troctolitic gabbro, and lower contents in the most evolved lithotypes such as gabbronorites and oxide gabbros, forming after progressive compositional evolution of the magmatic system. Low Anorthite contents are most likely correlated with minor extents of melting, suggesting that the lower oceanic crust of the Gakkel Ridge is compositionally distinct from that of the Mid-Atlantic Ridge. The systematic analysis of the compositions in major and trace elements of gabbroic lithologies from the Gakkel Ridge will allow us to broaden the compositional spectrum of oceanic ridges worldwide and provide better constraints between the composition of the oceanic crust and its spreading rate.

Quantitative analysis of sulfur volatile species generated from HP-HT experiments: a novel approach

Secchiari A.*, Toffolo L. & Tumiati S.

Dipartimento di Scienze della Terra "A. Desio", Università di Milano.

Corresponding author email: arianna.secchiari@unimi.it

Keywords: sulfur, HP-HT experiments, subduction zones.

Subduction zones serve as crucial sites for chemical exchanges between the Earth's surface and its deeper reservoirs. Within these zones, slab dehydration facilitates elemental transfers from the subducting slab to the mantle wedge, initiating hydrous melting and melt production. The introduction of slab-derived oxidizing material is often proposed to account for the higher oxidation state observed in arc magmas compared to magmas formed in other geological settings, such as mid-ocean ridges. However, the specific agents responsible for oxidation and the mechanisms underlying chemical transfer remain enigmatic, necessitating further exploration.

Among the most controversial components, sulfur plays a pivotal role in regulating mantle redox conditions. Diverse perspectives on sulfur behavior within subduction zones primarily stem from petrological analyses of mantle xenoliths, HP sulfide-bearing rocks, and thermodynamic models (Schwarzenbach et al., 2018; Piccoli et al., 2019). However, the lack of experimental works significantly limit our understanding of sulfur release and speciation in slab-derived fluids.

To bridge this knowledge gap, we have developed a novel methodology enabling accurate and high-sensitivity determination of sulfur volatile species (H_2S and SO_2) in HP-HT dehydration experiments. A series of experiments was performed at conditions of geological interest (P = 3 GPa and T = 700°C , ~ to subarc regions) under controlled oxygen fugacity and using different runtimes, from six hours to up one week. The volatiles produced were analyzed using a capsule-piercing device connected to a quadrupole mass spectrometer (Tiraboschi et al., 2016), using gas mixtures of known composition as calibration standards.

Our study not only validates predicted thermodynamic models but demonstrates for the first time that chemical equilibrium between the sulfide and fluid phase is reached quite quickly, typically within hours. Remarkably, the sulfide phase remains relatively inert even under relatively oxidizing conditions.

We expect that this technique will offer valuable insights into sulfur behavior within subduction settings. By identifying the predominant sulfur species under fixed pressure, temperature, and redox conditions, we will be able to gather crucial constraints into the role of sulfur as effective oxidizing agent of the mantle wedge.

[2] Geological Survey of Newfoundland and Labrador, Canada.

Corresponding author email: azam.soltanmohammadi@nrcan-rncan.gc.ca

Keywords: sulfide mineralization, lower crust, Bay of Islands Ophiolite.

The Bay of Islands Ophiolite Complex (BOIC) in southwestern Newfoundland has significant exposures of mafic-ultramafic rocks, both crust and mantle. Parts of the lower crust in North Arm Massif (NAM) contains sulfide concentrations. The ultimate origin of the sulfur remains unclear due to the complex nature of the BOIC crust. In order to better understand how Sulfur was transported and concentrated in lower crustal sections of the NAM, we analyzed siderophile elements from whole rocks and minerals. At NAM, lower crustal peridotitic and pyroxenitic intrusions of boninitic affinity intrude and assimilate host gabbros derived from the overlying tholeiitic crust, many of which were previously affected by greenschist-grade hydrothermal metamorphism and deposition of subordinate pyrite. Field evidence and mineral chemistry show that the feldspathic facies associated with gabbro-peridotite contacts are hybrid rocks, containing gabbroic xenoliths and xenocrysts. Cm-scale sulfide lenses are locally present, and the reaction zones show a wide range of siderophile element abundances, ranging up to 58,000 ppm S and up to 538 ppb ΣPGE. Enrichment of PGEs in feldspar peridotite and pyroxenite indicates high siderophile element concentrations associated with sulfide mineralization in hybrid rocks. Petrological indicators, such as sulfide inclusions in chromite, pyroxene and olivine, and drop-like pyrrhotite-pentlandite-chalcopyrite blebs, indicate that sulfides behaved immiscibly and concentrated chalcophile elements by high-temperature magmatic processes. This is consistent with in-situ laser ablation analyses from individual sulfide phases, which shows a magmatic range, comparable to the mantle range (~ 2000-6000 ppm). However, boninitic melts are generally poor in sulfur, and do not show sulfide immiscibility until very late in their crystallization history. One way to add sulfur and trigger early immiscibility is by assimilation of previously altered, sulfur-enriched, gabbroic host rocks. This is supported by the wide chalcogenic element variations observed, with S/Se varying from ≤ 2000 ppm up to 23000 ppm, the highest ratios being found at contact zones between peridotite and gabbro. This suggests that the Sulfur was previously concentrated by hydrothermal circulation in the deep gabbroic crust, and that assimilation of these S-enriched hosts triggered sulfide saturation in the intrusive boninite.

From cold to hot mantle: exploring new concepts for migration of alkaline melts and perspective on critical minerals

Soltanmohammadi A.*[1], Rabinowicz M.[2] & Fontaine JF.[3]

Keywords: volatile-rich alkaline melts, heterogeneous mantle, Hawaiian plume, critical minerals.

Alkaline melts and related volatile-rich melts are derived from a compositionally heterogeneous mantle. There is a long-standing debate not only about their composition, but also about migration of alkaline melts and their mantle temperature in different geological settings. Based on an integrated approach combining results from petrology, geophysics and modeling, we propose models to explain the origin of volatile-rich alkaline melts in the middle-Alpine-Himalayan orogenic belt and the Hawaiian plume, representing two contrasting cold and hot mantle temperatures, respectively. Our synthesis of recent seismic tomography images shows the presence of a large set of low-velocity, 100 km elliptical bodies called 'compaction pockets' in the middle Alpine-Himalayan orogenic belt (Soltanmohammadi et al., 2018). The compaction pocket model shows that the low velocities result from percolation and concentration of volatile-rich melts. The volatile-rich melts interact with a surrounding mantle that is 100°C cooler than the normal adiabatic mantle. It is argued that this leads to the precipitation of hydrated and carbonated mineral phases (at 8-6, 5 GPa and < 4 GPa, respectively). As the top of the compaction pocket successively crosses these critical depths, different types of alkaline melt extraction via dykes occur. In contrast, the hot mantle plume model is composed of four types of "filaments" as the main components (Soltanmohammadi et al., 2022). Our plume model shows that the filaments melt at depths ≥ 5 GPa. The mantle flow is split into two flow lines. Each line consists of different filaments. The dykes formed at the top of each type of cold and hot flow line carry different melt compositions, from tholeiitic picrite to kimberlite/carbonatite, respectively. The key is that alkaline melts are known as fertile melts that host critical minerals. Our primary synthesis shows that our models imply in world-class metallogeny domains hosting alkaline rocks. The fact offers new observation to track melt trajectories for a systematic investigation on critical minerals.

When modern petrology meets advanced microstructural analysis

Spiess R.*[1], Festa V.[2] & Tursi F.[3]

[1] Dipartimento di Geoscienze, Università di Padova. [2] Dipartimento di Scienze della Terra e Geoambientali, Università di Bari "Aldo Moro". [3] Dipartimento di Scienze della Terra, Università di Torino.

Corresponding author email: richard.spiess@unipd.it

Keywords: migmatites, clogged melt channels, garnet coalescence.

Petrology and microstructural analysis are inextricably linked together. The recent paper of Festa et al. (2024) on garnet growth to large ellipsoidal crystals by coalescence within residual migmatitic metapelites is a proof for the successful interaction of modern petrological modelling and advanced microstructural analysis. The whole set of data (phase equilibrium thermodynamic modelling, EBSD analysis, EDS and BEX mapping, micro-Raman analysis) obtained by this combined approach fit together like a puzzle. It defines a model showing that melt extraction in a dynamic system stops when melt channels become clogged by coalescence of peritectic phases carried along in anatectic melt migrating towards pull-apart structures, where the melt with entrained garnet pooled as it was progressively squeezed out. The importance of deformation for melt extraction is known since the basic work of Brown et al. (1995). The amount of decompression associated with formation of extensional sites within rocks undergoing ductile deformation has been documented quantitatively by Spiess et al. (2012).

Coalescence of garnet aggregates to large single crystals is invariably related to deformational rotation and surface energy reduction of individual grains (Spiess et al., 2001). Whether coalescence finally results in large single crystals or not depends on several factors. Of prime importance is the presence of a grain boundary wetting fluid/melt. Static experiments conducted in a piston cylinder apparatus at 3 GPa confining pressure and 1100°C show that any attempt to epitaxially grow single garnet crystals in platinum capsule, using a fine pyrope powder surrounding a polished pyrope rod acting as seed, fails. The absence of a fluid-saturated system prevents surface energy from becoming a driving force strong enough to crystallographically isorient the garnet crystals growing around the seed.

In the migmatite studied by Festa et al. (2024) rotation of coalescing garnet grains is documented by EBSD mapping. EBSD mapping also shows that during coalescence quartz did not activate dislocations that accommodated geometric incompatibility as a consequence of garnet rotation. Instead, quartz became dissolved in contact along melt decorated grain boundaries. Internal deformation within quartz during coalescence is essentially limited by activation of dauphiné twinning. This contrasts with local activation of dislocations in garnet along presumed boundaries of coalesced garnet grains. Activation of dislocations within garnet most reasonably happened once melt channels were clogged, and a rheological change accompanied ongoing deformation within the residual migmatites.

Potential mineral resources in historically dismissed volcanogenic massive sulfide (VMS) deposits of the Emilia Romagna region (Italy): petrological and geochemical study for Critical Raw Materials (CRMs) exploration and exploitation

Tagliacollo L.*, Bonadiman C., Saccani E., Bianchini G., Brombin V. & Tassinari R.

Dipartimento di Fisica e Scienze della Terra, Università di Ferrara.

Corresponding author email: tgllsi@unife.it

Keywords: critical raw materials, VMS deposits, Emilia Romagna ophiolites.

The last update on the Critical Raw Materials Act (2023) drawn up by the European Union identified 54 Critical Raw Materials (CRMs), i.e., minerals, elements, or materials that are fundamental to supply for technology and strategic for the green transition, but subjected to fickle supply, e.g., for the fragile geopolitical contest (Kiss et al., 2023). This led many European countries, including Italy, to focus on the metal recovery from dismissed mines, mine wastes, and landfills to accomplish the circular economy politics. Italy has more than 100 historically dismissed mining sites just in the North, and, among them, the ones in the Emilia Romagna region are now under investigation for the various volcanogenic massive sulfide (VMS) deposits (Zaccarini & Garuti, 2008). These are a type of metal sulfide ore deposits that occur as a result of underwater volcanic eruptions, associated with hydrothermal events in submarine environments, and are divided based on ore composition (Cu, Cu-Zn, Cu-Zn-Pb group) and environment formation (Cyprus, Kuroko, Besshi, as mentioned by Zaccarini & Garuti, 2008). In the Emilia Romagna region, these deposits occur as pods within small bodies of ophiolitic basalts cropping out as olistoliths in the Northern Apennine External Ligurian units and owe their origin to the metal-rich hydrothermal circulation which developed quartz-sulfide veins when mixed with seawater through a fissures network (Saccani, 2015; Kiss et al., 2023). These ophiolites represent Jurassic Alpine Tethys oceanic crust fragments obducted in the continental crust (Zaccarini & Garuti, 2008). The stratigraphy of the area is characterized by sequences of pillow lavas associated with serpentine and gabbro breccias, radiolarian cherts, limestones, and abundant serpentinized subcontinental mantle peridotites (Kiss et al., 2023). Basalts, then, show Ocean Continent Transition Zone (OCTZ) chemical features with transitional-MORB affinity and a garnet signature (Dyn/Yb0: 1.2-1.4, Saccani, 2015), in agreement with Cyprus-type VMS deposits (Zaccarini & Garuti, 2008). Major and trace elements bulk rock geochemical analyses were performed in a group of basalts of the Boccassuolo ophiolite and compared with the previous results (e.g., Barrie & Hannington, 1999; Zaccarini & Garuti, 2008; Kiss et al., 2023): the VMS deposits in the Emilia Romagna region belong to the Cu and Cu-Zn types (Cu up to 5818 ppm, 200 times Upper Continental Crust, UCC, composition; Zn up to 7941 ppm, 118*UCC), low to very low Pb contents (< 1 ppm, max. 0.42*UCC). These preliminary results provide the first relevant geochemical information to map trace metal enrichment distribution in the main rocks of the area. Radiogenic (Sr-Nd-Pb) and stable (S-C) isotopic analyses, as well as mineralogical and in-situ analyses, will provide additional information on the enrichment and distribution of VMS deposits in the Region.

Keywords: crust-mantle transition, ultramafic cumulates, thermodynamic modelling.

The Ivrea-Verbano Zone (IVZ, northwestern Italy) is recognised worldwide for exposing a complete section of a lower - and possibly its transition to the upper - continental crust. Along the Sesia river, the lower part of this section consists of a km-sized mantle peridotite body (i.e., Balmuccia peridotite) and a sequence of websterites, pegmatoid clinopyroxenites, cumulus peridotites and gabbros (Rivalenti et al., 1984). New detailed field mapping and petrography have revealed a previously unrecognised presence of garnet, together with spinel and plagioclase, within the pegmatoid pyroxenitic bodies. Here we present the first results and observations on this unusual garnet-bearing ultramafic lithology.

Petrography and scanning electron microscope analyses showed a main magmatic assemblage consisting of pegmatoid clinopyroxenes with variable occurrence of exsolution lamellae of orthopyroxene ± garnet ± spinel ± plagioclase. A secondary assemblage made of garnet, plagioclase, spinel, and ortho ± clinopyroxenes, occurs as veins and pockets within the main pegmatoid texture.

Pegmatoid clinopyroxenes are augites with 7.4 to 8.1 wt.% Al_2O_3 and 0.86 to 0.87 Mg#. Garnets in the exsolution lamellae contain 22.1 to 22.9 wt.% Al_2O_3 and 0.45 to 0.49 Mg#. In the secondary assemblages, garnets are geochemically similar to those in the exolution lamellae, orthopyroxenes contain 2.9 to 7.2 wt.% Al_2O_3 and Mg# from 0.76 to 0.80, while An content in plagioclase varies from 61 to 83.

The initial results suggest that the secondary assemblage might have formed from the percolation of melts within the pre-existing pegmatoid pyroxenite. The texture of the garnets in this secondary assemblage suggests a metamorphic origin and may be related to high bulk aluminium content or high equilibration pressure, or a combination of both. Further work is being devoted to the garnet-bearing exsolution lamellae in the pegmatoid clinopyroxenes, as these will potentially provide insights into the P-T path that the original assemblage has undergone. We are investigating these aspects through phase equilibrium calculations using a set of bulk compositions assumed to represent the original pegmatoid clinopyroxenite and the secondary assemblage. We use the thermocalc software (Powell & Holland, 1985) and an internally consistent thermodynamic model (Holland et al., 2018) to generate pseudosections for each calculated bulk composition. Altogether, the results are aimed to shed light on the petrological history of this pegmatoid clinopyroxenite and bring new insights into the geothermal evolution of IVZ.

Investigating isotopic signatures of CO_2 produced by coccolithophore algae in subduction zones: experimental insights and modeling approach

Tumiati S.*[1], Faucher G.[2], Monzillo A.[1], Ferrari E.[1], Toffolo L.[1], Erba E.[1] & Poli S.[1]

Keywords: carbon stable isotopes, arc volcanism, high pressure.

This experimental study investigates the isotopic signature of CO_2 emissions from coccolithophore algae within subduction zones, elucidating the complex isotopic exchange mechanisms among CO_2, $CaCO_3$, and graphite. Coccolithophore algae, characterized by their calcium carbonate plates, serve as a dual source of organic and inorganic carbon, significantly impacting the isotopic composition of volcanic arc CO_2. The research aims to unravel the influence of subducted oceanic sediments on the isotopic signature of volcanic arcs.

High-pressure and temperature experiments were conducted (T = 700°C and P = 3 GPa), simulating conditions conducive to peak CO_2 production resulting from the oxidative dissolution of graphite in subduction zones. Cultivated coccolithophore algae were utilized as starting materials, supplemented with green algae or ooze sediment to modulate the graphite/$CaCO_3$ ratio across a spectrum of organic matter percentages.

Chemical and isotopic analyses, facilitated by a capsule-piercing device coupled with a quadropole mass spectrometer and other Isotope Ratio Mass Spectrometers (IRMS), quantified CO_2 in the experimental fluid phase and $\delta^{13}C$ values of CO_2, $CaCO_3$ and organic matter/graphite. Experimental findings were compared with the model proposed by Tumiati et al. (2022), correlating $\delta^{13}C$ CO_2 with experimentally determined CO_2/$CaCO_3$ ratios, while considering the isotopic signature of starting materials.

Results underscored the recrystallization of coccolithophore calcite into aragonite and the graphitization of organic matter. Isotopically, $\delta^{13}C$ values of CO_2 and $CaCO_3$ exhibited convergence with model predictions, particularly evident for experiments with low CO_2/$CaCO_3$ ratios. Conversely, experiments with high CO_2/$CaCO_3$ ratios demonstrated a notable divergence, likely due to kinetic issues when carbonate is present in minor or trace amounts.

Experimental observations highlighted the exclusive association of CO_2 isotopic signatures with the CO_2/$CaCO_3$ ratio under consistent pressure-temperature-oxygen fugacity conditions, aligning with previous research demonstrating similar dependencies in ^{13}C-doped systems. Graphite emerged as the primary source of aqueous CO_2 through oxidation, with isotopic exchange occurring solely between CO_2 and $CaCO_3$ during dissolution and reprecipitation processes. This sheds light on the isotopic dynamics of CO_2 emissions from coccolithophore algae within subduction zones, providing crucial insights into the isotopic evolution of volcanic arcs influenced by subducted oceanic sediments.

It's getting hot, depleted, dense and dry: evolution of garnet-sillimanite restites from Catena Costiera (northern Calabria, Italy)

Tursi F.*[1], Godard G.[2], Braga R.[3] & Piluso E.[4]

[1] Dipartimento di Scienze della Terra, Università di Torino. [2] Institut de Physique du Globe de Paris, University of Paris-Cité, France. [3] Dipartimento di Scienze Biologiche, Geologiche e Ambientali, Università di Bologna.

Keywords: restites, extraction of melt entraining peritectic minerals, chemical potentials.

In granulite-facies terranes, rocks of the middle-lower crust undergo different degrees of partial melting, depending on their fusibility. It is well known that pelites, after greywackes, are the most prone lithologies to melt, producing anatectic magmas of granitic composition. These anatectic magmas are mainly produced by incongruent melting reactions that continuously take place and involve hydrous minerals, forming peritectic minerals and melt. At this point, there is a fork in the road: (i) melt production exceeds melt extraction rates or (ii) melt with entrained peritectic and residual minerals is extracted from the source, leaving behind a depleted, dense and dry residue. The Variscan garnet-sillimanite residue from Catena Costiera (northern Calabria), which is the subject of this contribution, is derived from migmatitic metapelites that followed the second route, experiencing high degrees of partial melting and melt extraction. Garnet in the residue exceeds 50 vol.%, the rest of the mineral assemblage consisting of sillimanite and ilmenite and very little quartz, with complex cordierite-spinel-corundum symplectites occurring between garnet and sillimanite. Inclusions of biotite, rutile, quartz and sillimanite are found in the garnet, indicating that the garnet-sillimanite residue resulted from biotite dehydration melting. K-feldspar was not found in the residual mineral assemblage and the reaction is thus unbalanced. We show, supported by phase equilibrium thermodynamic modelling, that melt entraining K-feldspar (and possibly some reactants) was extracted from the source during heating up to ~930°C at 0.90-1.05 GPa. The A/AFM ratio of the residue obtained from modelling extraction of melt entraining peritectic K-feldspar is indeed more adherent to that measured when compared to the A/AFM obtained by simply modelling melt extraction at the melt connectivity threshold. Finally, the dry residue underwent a progressive shrinkage of the equilibration volume and an increase in the μFeO, μMgO and μSiO_2 chemical potential gradients, leading to the formation of cordierite-spinel-corundum symplectites during cooling from peak temperature conditions at 0.5-0.6 GPa. Our results allow refinement of the commonly used method for modelling melt extraction in open systems and illustrate the microstructural evolution of the equilibration volume during cooling of residual rocks.

Neoproterozoic serpentinites from the Bou Azzer ophiolite (Central Anti-Atlas - Morocco): exploring the geodynamic changes and mantle processes beneath the boundaries of the West African Craton

Wafik A.[1], Visalli R.*[2], Punturo R.[2-3], Conte A.M.[3], Guglietta D.[3], Ben Massoude M.[1], El Aouad N.[1], Mabika N.N.[1] & Cirrincione R.[2]

Keywords: partial melting, ultramafic massifs, Inguijem-Aït Ahmane.

The West African Craton (WAC) originated during the Archean period and underwent significant development around 2 billion years ago during the Paleoproterozoic Eburnean orogeny (Ennih & Liégeois, 2008). Following this, a relatively quiet period during the Mesoproterozoic era, approximately 1.7-1.0 billion years ago, marked the beginning of craton formation. In the early Neoproterozoic, the WAC experienced widespread extension, suggesting the potential fragmentation into separate continents, followed by convergence towards the end of the Neoproterozoic. Around 760 to 660 million years ago, the WAC was involved in the accretion of island arcs along its northern and eastern margins (e.g., the Moroccan Anti-Atlas) (Hefferan et al., 2014). Subsequently, during the primary Pan-African orogeny, the WAC encountered convergence along all its boundaries, leading to the subduction of Pan-African oceanic crust beneath various oceanic arcs. These collision events induced partial mobilization of other craton regions within the peri-Gondwanan terranes, resulting in the recycling of water and volatile-rich fluids. This process led to subsequent melting, metasomatism, and serpentinization of mantle peridotites (Wafik et al., 2015). Understanding the alterations in peridotites and their mineral compositions is crucial for interpreting the extent of melting and metasomatic influences within the mantle. Chromite minerals, commonly found in chromitites or serpentinites within ophiolites, are significant indicators of their origin. Being the first mineral to crystallize from ultramafic magma and highly sensitive to the primary magma's composition, chromite serves as a valuable petrogenetic marker (Kang et al., 2022). Moreover, residual Cr-spinel minerals are often used to estimate the melt rate in upper mantle peridotites due to their resistance to alteration compared to early-formed olivine and pyroxene. During partial melting, Cr-spinel minerals become depleted in Al and enriched in Cr. This geochemical tool is increasingly utilized to reconstruct the magmatic and geodynamic context of depleted ophiolites formed in supra-subduction zones (SSZ) as a result of partial melting processes and rock-fluid interactions.

In this contribution, we focus on the Inguijem-Aït Ahmane ultramafic complex situated in the central region of the Bou Azzer inlier (Moroccan Anti-Atlas). We aim to offer fresh insights derived from petrological, mineral chemistry, and geochemical analyses, aiming to characterize the processes of mantle melting and enrichment during the Neoproterozoic era. This is to gain a better understanding of the evolutionary dynamics of the Neoproterozoic mantle beneath the West African Craton (WAC) and to enhance the analysis of how this mantle reservoir influenced the Neoproterozoic geochemical cycle.

The continental Moho from a geobarometric perspective

Ziberna L.*[1-2], Beltrame M.[1], De Min A.[1], McCammon C.[3], Masotta M.[4], Del Rio M.[1], Narduzzi F.[1], Černok A.[1], Terranova K.[1] & Venier M.[1]

Keywords: pressure, crust-mantle transition, peridotites.

Understanding the structure and composition of the Moho transition zone continues to be a long-standing goal in Earth science. Regarding anorogenic continental settings, there is no general consensus whether direct evidence of this transition can be obtained through surface sampling or drilling. A possible case could be the Ivrea-Verbano Zone (IVZ), Southern Alps, in which peridotitic bodies of mantle origin crop out in contact with lower crustal lithologies of Permian age. Another possible way to investigate the petrology of this transition is through the study of crustal and mantle xenoliths brought to the surface by alkaline magmas. Xenoliths are sporadic and cannot provide continuous sampling of the lithosphere. Yet, they can be used to get as much information as possible about the pathway(s) through which the magmas reached the surface, including the possible petrological and geophysical transitions of the lithosphere. In order to use xenoliths to constrain these transitions, we need good estimates of the depth of provenance, and therefore we need good geobarometers. This is easy to say, but difficult to put in practice. What is a good geobarometer for these settings? The uppermost mantle in continental settings is made up of spinel peridotites, and methods to retrieve accurate and precise pressure estimates are not available. Even when they might appear to be available (i.e., Ca-in-olivine barometry), they have strong temperature (T) dependence, and T cannot be determined with accuracy. An even more basic aspect is the need to determine when the accuracy becomes good enough to make the geobarometer useful to reconstruct the lithological structure of the lithosphere. This contribution will show some case studies with applications to xenolith suites, comparisons with the IVZ crustal section and the results of a new experimental and theoretical approach to quantify the limits of geobarometry for spinel peridotites.

Keywords: micrometeorites, CuAl alloy, natural quasicrystals.

Recently, two remarkable extraterrestrial fragments, named FB-A1 and FB-A2 respectively, have been found at Monte Gariglione (Catanzaro, Italy). FB-A1 consists of a scoriaceous, elongated-, subspherical-shaped micrometeorite of about 400 μm in diameter, while FB-A2 is an irregular fragment of about the same size.

Preliminary non-destructive investigation, using micro-computed X-ray tomography and scanning electron microscopy, revealed that both particles exhibit extraterrestrial features, including forsteritic olivine crystals in a porous matrix of silicates, Fe-Ni metals, Fe-Ni sulfides, oxides and disseminated exotic CuAl alloys with variable stoichiometric ratios. This finding represents the third independent discovery of naturally occurring intermetallic Al-Cu alloys in meteorites, after the Russian Khatyrka meteorite (MacPherson et al., 2013) and the Sudan KT01 spherule (Suttle et al., 2019; Ma et al., 2023).

FB-A1 was yet deeply investigated by EPMA and EBSD and the analyses revealed that this micrometeorite contains naturally occurring quasicrystals. This is the second finding of quasicrystalline material, after Khatyrka meteorite, and the first case of quasicrystal with composition $Al_{52}Cu_{31}Fe_{10}Si_7$ (Agrosì et al., 2024).

The study of FB-A2 is currently in progress. Preliminary results reveal that the second fragment is quite different from FB-A1; actually, the irregular shape is associated to a different texture. The fragment can be described as composed of two main regions. The first consists of relict olivines, with forsteritic core and Fe-rich rim, orthopyroxenes (enstatite), clinopyroxenes with pigeonitic composition, oxides and sulfides disseminated in the silicate glass. Locally, intergrowths of partially melted olivines and pyroxenes are visible. The porosity is very low. The second region shows a high porosity and consists mainly of silicatic glass. In this region there is a big portion of Fe-poor AlCu-alloy. These alloys consist of worm-like intergrowths of nearly pure Al in khatyrkite ($CuAl_2$) and stolperite (CuAl). Sub-spherical Fe-Ni alloys of few micrometers in diameter are visible on the surface of the fragment at the contact between the CuAl alloy and the silicatic matrix. The presence of voids in the core suggests that these Fe-Ni bubbles represent the residual part of melting and degassing of precursor grains of sulfides.

Further studies of this fragment, and the comparison with data acquired on FB-A1, will be very helpful to shed light on the origin of these micrometeorites and to try to decipher the source of these materials and their growth conditions.

Keywords: martian rock, X-ray micro-computed tomography, SEM-EDS analyses.

Returning sample missions have gained increasing attention in the last decades since the only way to know the planetary surface's composition and reconstruct the history of geological processes is to analyse samples using Earth-ground laboratory-based techniques.

In order to be ready to receive samples from returning missions (see https://science.nasa.gov/mission/osiris-rex/, https://science.nasa.gov/mission/mars-sample-return/, and https://global.jaxa.jp/projects/sas/hayabusa2/), the scientific community is working on protocols to carry out a comprehensive characterization, avoiding at first stages, methodologies that implies the sample modification and contamination.

With this aim, we are studying some unclassified chips of a supposed Martian rock sent to us in 2017 from Dr Abdeltif Mechaouguen, a Moroccan meteorite collector and dealer. To obtain the major amount of information on extraterrestrial materials following a non-destructive or minimally destructive protocol, we decided to use these chips as analogues of returned samples to test the methodology and the protocol to follow.

The samples (less than 0.5 cm in size and no fusion crust) characterized by a typical microstructure of basaltic shergottites with pyroxene laths in a transparent glassy-looking matrix are studied by X-ray micro-computed tomography (μ-CT) combined with chemo-mineralogical analyses by SEM-EDS. The results confirmed the typical internal microstructure of shergottite, which consists of intergrown laths of crystals with a high attenuation coefficient and grains characterized by a smaller absorption coefficient.

A preliminary non-destructive characterization of Tarda meteorite

Agrosì G.[1], Mele D.[1] & Manzari P.*[2]

[1] Dipartimento di Scienze della Terra e Geoambientali, Università di Bari "Aldo Moro".
[2] Agenzia Spaziale Italiana, Matera.

Corresponding author email: paola.manzari@asi.it

Keywords: Tarda, carbonacoues asteroids, returned samples.

The Tarda meteorite is a carbonaceous chondrite fallen in the locality of Tarda in Morocco on August 25th, 2020 (Chennaoui Aoudjehane, 2021). Since it was readily collected after the fall, it was exposed to desert weathering for very little time (few days) and therefore it should have preserved its original composition.

It consists of a bulk composition of clay minerals, plus chondrules, anhydrous silicates, Fe bearing sulphides, carbonates and amoeboid olivine aggregates. On the basis of the mineral chemistry, this meteorite shows a petrologic type 2 (Chennaoui Aoudjehane, 2021). Moreover, oxygen isotopic analyses plot this meteorite in two fields of carbonaceous chondrites corresponding to CI and CY. All these peculiarities are also typical of only one another meteorite similar in bulk mineralogy and oxygen isotopes, the Tagish Lake, also classified as a C2 ungrouped. Both meteorites could be from the parent body: the type D asteroid (Marrocchi et al., 2021; Hiroi et al., 2022). In the view of a comparison with the returned samples from another very similar carbonaceous asteroid, Bennu, thanks to the Osiris-REX NASA's mission, we are exploring the composition and structure of this kind very friable and light material using non-destructive techniques.

In this conference, we will show some preliminary results acquired combining multimethod non-destructive investigations of a crusted sample of Tarda. Chemical and mineralogical analyses by SEM-EDS, chemical mapping and SEM-BSE images were compared with 3D reconstruction by X-ray micro-computed tomography (μ-CT), a technique used to explore the whole sample without any manipulation.

The purpose of this investigation is the study of mineralogical composition with a particular attention to the rare phases, mineral distribution and association, texture and microstructures in order to provide further information on origin and evolution of this meteorite. The results obtained will be subjected to a comparison with same investigations carried out on Bennu fragment, to deeply investigate the similarity observed and to deduce further information about the parent body.

Keywords: Mars, CRISM, Python.

Remotely sensed hyperspectral data provide essential information on the composition of rocks on planetary surfaces. On Mars, these data types are provided by the CRISM instrument (Compact Reconnaissance Imaging Spectrometer for Mars) (Murchie et al., 2007), a hyperspectral camera that operated onboard the MRO (Mars Reconnaissance Orbiter) probe that collected more than 10 Tb of data. CRISM covers a spectral range going from 400 to 4000 nm, with a spectral resolution of 6.55 nm/channel and a spatial resolution of 18.4 m/px, from 300 km altitude. The most advanced CRISM data products are the MTRDRs (Map-Projected Target Reduced Data Records) (Seelos et al., 2016). These data are re-projected onto the Martian surface and are cleaned from the so-called ”bad bands”, noisy stripes. The two main CRISM MTRDR subproducts are the hyperspectral datacube and the spectral parameter datacube. The first contains the detected reflectance spectra, while the second is composed of 60 different spectral parameters, as defined in Viviano-Beck et al. (2014), usually to produce RGB maps emphasizing specific minerals within the scene. Usually, the creation of the RGB maps and the spectral analysis are conducted using the commercial software ENVI©, software not specifically meant for these dataset and which inherently implies some costs for the user. Here we present a free open-source tool completely written in Python called FRESCO (Flexible RGB Extraction and Spectra Comparison for Observations), which allows the use of CRISM MTRDR data. The software can create RGB maps and select Regions Of Interest (ROI) from which the user can extract and further analyze the spectral data available from the chosen CRISM scene. The possible types of analysis that FRESCO supports range from simple descriptive statistics (to obtain, for example, mean spectra of a ROI), and spectra-related pre-processing methods like continuum removal and/or smoothing, to analysis through more complex techniques, like machine learning for automatic detection of the absorption lines or ML-driven Multi Gaussian Models (MGM) for spectral unmixing. The machine learning models implemented are programmed as transparent as possible, to ensure that the performed analyses are as much reproducible and interpretable as possible (white-box). Moreover, with FRESCO it is possible to georeference the RGB maps, export them to ArcGIS©/QGIS software and to confront the processed and confront the processed spectra with either laboratory or other CRISM reference spectra. In support of the effectiveness of FRESCO, we also present a case study conducted on the CRISM target FRT00009B5A that covers the northern portion of Kai crater, located in Meridiani Planum. The choice of this particular case study is motivated by the morphological and compositional complexity shown by this specific target (Baschetti et al., 2023), demonstrating that FRESCO can be useful especially in complex scenarios that require a detailed analysis of the geological context, evolution, and processes.

Are there more out there? The possible prevalence of quasicrystals in the Universe

Bindi L.*

Dipartimento di Scienze della Terra, Università di Firenze.

Corresponding author email: luca.bindi@unifi.it

Keywords: quasicrystals, meteorite, CuAl-alloys.

Until 2009, the only known quasicrystals - materials with a structure that is ordered but not periodic - were synthetic, having been formed exclusively in highly controlled laboratory experiments. Plausibly, the only quasicrystals in the Milky Way Galaxy or perhaps even in the Universe, are the ones manufactured by humans, or so it seemed. Then came the report that an icosahedral AlCuFe-quasicrystal had been discovered inside a small rock fragment from a remote stream in far eastern Russia. Later studies proved the rock to be extraterrestrial, a piece of a rare CV3 carbonaceous chondrite (known as Khatyrka). Few years later, a new quasicrystal was discovered in an Italian micrometeorite and few other occurrences of CuAl-alloys were described in other extraterrestrial bodies.

At present, only few examples of natural quasicrystals have been discovered. Does that mean that these exotic materials must be extremely rare in the Universe? During this talk, the author will accompany the audience on a cosmic-scale excursion going from presolar materials, through nuclear tests debris to recently formed fulgurites. Several reasons will be presented indicating that quasicrystals may prove to be among the most ubiquitous minerals found in the Universe.

Furthermore, based on the mineralogical and petrographic evidence as well as the triple oxygen isotope measurements on the silicates of all the CuAl-bearing objects, possible hypotheses about the provenance of these exotic alloys will be presented, including the fascinating scenario that they could come from another planetary system.

The author will also discuss how quasicrystals are an example of how sometimes being too uncritical of conventional wisdom may hinder research and progress in understanding the marvels of this world and beyond.

Geomicrobiology of the concretions of the Makgadikgadi pans (Botswana): an astrobiological perspective

Bokanda F.[1], Cavalazzi B.[2] & Franchi F.*[3]

[1] Department of Mineral Resources, School of Earth Sciences and Engineering, Botswana International University of Science and Technology, Palapye, Botswana. Corresponding author email: fulvio.franchi@uniba.it

Keywords: Mars analogues, astrobiology, silica.

The Makgadikgadi Basin of central Botswana hosts one of the largest salt lakes (pans) system on Earth. These pans are characterized by strong evaporation rate, high salinity and pH and high UV radiation. For this reason, they are considered 'extreme environments' and analogues to playa environments on Mars. Playa environments on Mars, such as Meridiani Planum, present layered sedimentary deposits and hydrated minerals and opaline silica. These Martian deposits, for their direct link with liquid water, became targets for ongoing and future astrobiological missions.

Three types of concretions were identified in the Makgadikgadi pans: silica concretions, silcrete, with opal as primary cement; carbonate concretion, calcrete, with calcite as primary cement; gypcrete, with gypsum as cementing material. Here the focus is on the role of microbial organisms (e.g. extremophiles) in the precipitation of minerals within the silica concretions in the Makgadikgadi pans. The aim is to decipher microbe-mineral interactions and constraints the biomineralization processes in this extreme environment.

Most of the silcretes are quartzarenites and/or quarzitic breccias cemented by a complex paragenesis of quartz and calcite. Lithoclasts of flint, sand-sized quartz grains and ostracods are cemented by microcrystalline quartz (brown opal) and pore-filling spatic (coarse crystals) quartz cement. The fractures and larger pore space are filled by spherulitic chalcedony: fibrous microcrystalline quartz with botryoidal habit and characteristic wavy-extinction. The remaining pore space and the spherules are cemented by microcrystalline, isopachous carbonates(probably calcite) as a late product of pan diagenesis.

The silcretes are formed through direct precipitation of silica from groundwater within the pan system resulting in distinct silcrete morphologies e.g. nodules, massive, sub-outcrop, "scatter" or ellipsoidal. The complex paragenesis reflects fluctuation in the pH and water chemistry. It remains to be proven if the formation process was purely abiogenic or if there was also a biogenic component. In order to achieve this goal SEM analysis, looking for microbial fossils, and Raman spectroscopy, for identification of organic matter and biomarkers, will integrate the petrographic analysis of the Makgadikgadi silcretes.

This work, although at its preliminary stage, is bound to teach us how microbial communities of extremophiles interact with diagenetic products and what is the astrobiological potential of the Makgadikgadi silcretes.

Landslides on solid bodies in the Solar System

Brunetti M.T.* & Peruccacci S.

Istituto di Ricerca per la Protezione Idrogeologica, CNR, Perugia.

Corresponding author email: mariateresa.brunetti@cnr.it

Keywords: landslides, Solar System, extraterrestrial bodies.

Landslides affect almost all solid bodies in the Solar System, including planets, moons, asteroids and comets (Brunetti & Peruccacci, 2023). The rocky and icy surfaces of Solar System bodies are modified by a variety of processes, including tectonics, volcanism, impact craters, weathering and erosion, which overlap and interact to predispose slopes to landslides or to trigger landslides.

As on Earth, landslides observed in the Solar System are classified according to the mechanism of mass displacement and the material involved. This can be rock or soil (or both) mixed with water or ice. The types of movement are falling, toppling, sliding, spreading or flowing, and possible combination of these. Variability in landslide characteristics is reflected in their magnitudes (e.g., area, volume, fall height, length) that may vary by orders of magnitude. The effects of specific body properties such as surface gravity, atmospheric pressure (if present) or the presence of water (in different physical states) on the initiation and propagation of landslides can be deduced by comparing the observed mass movements of different bodies. This can be very important for manned and unmanned missions involving landings.

This contribution provides a brief overview of landslides observed in the extraterrestrial environment. The landslides are grouped by solid body type, including terrestrial planets, planetary moons, dwarf planets, asteroids and comets. For example, for the terrestrial planets, an inventory of large rockfalls in impact craters has been made on the Moon using high-resolution images from the Lunar Reconnaissance Orbiter (LRO) (Brunetti et al., 2015). On Mars, the giant landslides of the Valles Marineris (VM) canyon system have been mapped and classified using data from the Mars Reconnaissance Orbiter (MRO). Mass movements have been collected in a comprehensive geomorphological inventory (Brunetti et al., 2014). A global inventory of the planet's landslides was produced a few years later (Crosta et al., 2018). On the airless surface of Mercury, large rock slides in impact craters have been identified and mapped using images from the MESSENGER spacecraft (Brunetti et al., 2015).

This overview shows that landslides occur throughout the Solar System. They are evidence of the continuous dynamic evolution of the surface of solid bodies. Landslides are also one of the most interesting geological features because they expose fresh material, making it possible to study the subsurface composition of extraterrestrial bodies.

Comparative studies on Martian landslides found in Craters of Noachian highlands: new perspectives for mass wasting phenomena

Caramanico A.*, Lanci L. & Francioni M.

Dipartimento di Scienze Pure e Applicate, Università di Urbino "Carlo Bo".

Corresponding author email: a.caramanico1@campus.uniurb.it

Keywords: Mars, landslides, impact craters.

Noachian highland terrains on Mars preserve a large record of unnamed impact craters, representing the perfect study area to perform a new quantitative analysis on Martian landslides occurred within impact basins. The steepness of crater walls and the multiple weakness planes and fractures developed on the surroundings of the crater rim after a meteoritic impact could be the starting points for the generation of mass wasting phenomena (Crosta et al., 2018; Guimpier et al., 2021). The characterization and correlation of different landslides within impact craters located at different latitudes can help understanding the Martian climate and the underground conditions at the time of their formation (Guimpier et al., 2021). A comparative study between the nature of landslides found in impact craters has not been performed yet. Only a small percentage of the total amount of Martian landslides have been studied in detail (Valles Marineris, Tharsis region) (Roback & Ehlmann, 2020; Guimpier et al., 2021), thus it can be interesting to expand the knowledge about this topic through the analysis of landslides with size comparable with terrestrial analogs, to unveil new hints for constraining trigger mechanisms (still debated in many case studies).

A good satellite data coverage is mandatory to perform the research, and heavily influenced the selection of the targets. The workflow to perform the research can be divided into three main phases: i) the reconstruction of the geological frameworks in which landslides occurred (CTX, THEMIS, CRISM dataset), ii) formulation of reasonable hypotheses regarding their formation mechanism based on detailed quantitative analyses (HiRISE dataset), 3D models based on CTX-derived DEMs and comparisons with data on the literature, and iii) trace correlations between the selected landslides in terms of planetary evolution.

All the information collected during the research, including the total number and classification of proposed crater candidates and landslides, are summarize in a general catalog.

The expected results will give new perspectives and quantitative data to investigate the causes triggering Martian landslides in well-defined, specific environments (impact craters in Noachian highlands). This aspect could also support the study of terrestrial landslides through remote sensing techniques (Sosio et al., 2013). Moreover, the occurrence of a landslide, considered one of the active geological processes on the surface of Mars, can show geomorphological features potentially interesting even from the astrobiological point of view.

Keywords: ordinary chondrites, porosity, asteroid analogues.

Meteorites, together with return mission samples, represent unique tools to investigate Solar System bodies. Unfortunately, planetary surface sampling is rarely possible and the attribution of a meteorite to a planetary body is tentatively done using reflectance spectroscopy techniques. Double asteroid 65803 Didymos/Dimorphos, supposed to be formed by stony material chemically affine to L/LL ordinary chondrites, was the object of the DART (Double Asteroid Redirection Test) mission (Michel et al., 2018), and it is planned to be visited by the next HERA mission, to investigate the subsurface and interior properties of impact site outcome materials exposed by the kinetic DART impactor. To support the HERA mission scientific activity, we have investigated 9 ordinary chondrites, i.e., Aba Panu (L3), Bruderheim (L6), Gueltat Zemmour (L4), Kheneg Ljouad (LL5/6), Loro (L6), Ouadangou (L6), Vinales (L6), Aldsworth (LL5) and Rio Negro (L4), which VNIR (visible and near-infrared) spectroscopic characteristics make them the best asteroid surface analogues. Usual petrographic and mineralogical characterization using SEM-EDS and EMPA allowed us to determine the exact modal mineralogy and mineral phase compositions necessary for a correct VIS-NIR-MidIR reflectance spectroscopy interpretation of the analysed materials. Alongside petro-mineralogical analyses, we obtained physical properties like bulk density and porosity. Using a structured light 3D scanner, we have calculated volume samples and mean bulk densities, resulting in the 3.21-3.33 gr/cm^3 range, in agreement with the literature data (Wilkinson et al., 2003). Only Gueltat Zemmour showed a lower density of 3.01 gr/cm^3, inferred by the high porosity found through SEM-EDS modal maps. The use of an X-ray microtomographer (µCT) allowed us to better constrain its high porosity value (15.8 vol%), while the remaining sample showed much lower porosity (less than 2-3 vol%). Forthcoming analyses will expand our samples dataset, and we will also perform nano-indentation tests using the AFM (Atomic Force Microscopy) technique, with the possibility to investigate in situ physical properties like Young's modulus, hardness and rigidity at the level of a single mineral grain, as already done for some grains sampled from the surface of the asteroid 25143 Itokawa (Tanbakouei et al., 2019). In addition to Young's modulus, hardness, and rigidity, it will also be possible to evaluate the cohesion forces, which, together with porosity, are the most important properties for modeling the mechanical/dynamic behavior of the regolith on the Dimorphos surface in microgravity (Stickle et al., 2023).

Keywords: drainage networks, AI, statistics.

This work introduces an innovative approach to river hydrographic basins classification within the River Zoo Survey project. Main goal of this project is to perform a statistical evaluation of the classification of terrestrial and extraterrestrial drainage networks by human experts to be subsequently used as base of knowledge to train supervised AI methods.

The idea is to analyze the degree of reliability of class assignment to drainage samples, driven domain expert decisions, based on visual inspection of images and the identification of the right pattern type. Through the analysis of Earth, Mars and Titan's rivers, experts were asked to classify rivers into one of ten distinct patterns, further categorized into two macro-classes: dendritic and non-dendritic.

The purpose of this study is to establish an objective classification system for rivers, improving the understanding of terrestrial and extra-terrestrial rivers drainage networks. Through the use of statistical techniques, the study explores methods to reduce noise in human based classification, thus providing a robust classification system for the automatic processing of river data with a detail much better (10 classes) than the current two class classification systems (dendritic and non-dendritic).

This work focuses on the methodology and objectives of the research, highlighting its interdisciplinary nature and potential contributions to a better comprehension of river morphologies across different planetary bodies.

Three-dimensional probabilistic slope stability analysis in lunar South Pole region

Ermini A.*[1-2] & Salvini R.[2]

Keywords: lunar south pole region, landslide, slope stability, 3D numerical modeling.

Landslides stand out as significant geomorphic events driving morphological changes across mountainous and hilly landscapes. These impactful phenomena, often occurring on steep slopes, have received extensive study on Earth, both in terrestrial and submarine environments. Similarly, various gravitational events have been observed on celestial bodies such as the Moon. This work aims to enhance our understanding of landslide on lunar surface, focusing on the lunar south pole region (LSPR) that has garnered increasing attention due to its geological features, including permanently shadowed regions (PSRs) and volatile deposits such as water ice. The study of slope stability in the LSPR is useful for the success of forthcoming space exploration missions such as NASA's Artemis planning to land the first woman and man near the Moon's south pole in 2024. In view of this and with the aim of contributing to ensure the safety of personnel and equipment, this study proposes a probabilistic three-dimensional slope stability analysis of LSPR using the RocscienceTM Slide3 software. Morphological data as 3D mesh, crucial for understanding the intricate lunar topography, was extrapolated using lunar orbiter laser altimeter (LOLA) digital elevation model (DEM), providing a detailed representation of LSPR surface. Geomechanical characteristics of lunar regolith, like unit weight, cohesion, and friction angle, was statistical analysed to determine their distribution and uncertainty. The statistical analysis was conducted by collecting data from various researches containing data from past different lunar missions (Huang et al., 2024). Differently from a deterministic analysis, where the above parameters are typically kept fixed and a single factor of safety (FoS) is provided, a probabilistic analysis was carried out yielding multiple FoS. This approach offered a more comprehensive view of lunar slope stability. In order to consider both, static and dynamic conditions, a contribution of seismic event produced by lobate thrust fault scarps movement, as proposed by Mishra & Kumar (2022) and Watters et al. (2024) was implemented. Specifically focusing on the LSPR, the analysis allowed to identify critical areas susceptible of potential instability phenomena and engineering-geological parameters which mostly influence the slope stability. Results from this research may be used for the formulation of strategic risk mitigation measures and meticulous planning of future lunar missions. This study effectively demonstrated the efficacy of employing three-dimensional numerical modelling techniques in addressing the unique geotechnical challenges inherent to the lunar environment. Furthermore, it underlined the critical importance of adopting a probabilistic approach to ensure safety and successful execution of future space exploration endeavours.

Keywords: reflectance, ammonium-bearing minerals, icy bodies.

Ammonium-bearing minerals have been observed on icy planetary bodies such as Comet 67/CG and Ceres (e.g. De Sanctis, 2016; Poch et al., 2020). The presence of NH^{4+}-minerals could be associated with upwelling of ice from possible subsurface oceans (e.g. Cruikshank, 2019). Given the presence of surface roughness, topography and variations in morphology, the surface reflectance spectra of all Solar System bodies are affected by observation geometries. In this work we analyse the effects of viewing geometry variations on the near-infrared reflectance spectra of mascagnite-$(NH_4)_2SO_4$ and salammoniac-NH_4Cl powder samples (Fastelli et al., 2023). These two samples could represent some of the most promising candidates as ammonium-bearing minerals on icy bodies. Bi-directional reflectance spectra are collected in the 1-4.2 µm range considering a set of 3 incidence (*i*) angles ($i = 0°$; 30°; 60°) and 9 emergence (*e*) angles between -70° and 70° at room temperature. The reflectance spectra analysed in this study were collected using the custom-made bidirectional reflectance spectro-goniometers SHINE (SpectropHotometer with variable INcidence and Emergence) at the Cold Surface Spectroscopy facility (CSS) of the IPAG laboratory (https://cold-spectro.sshade.eu) in the frame of the Trans-National Access program, project number 20-EPN2-081, of Europlanet 2024. The NH^{4+} absorption bands located at ~ 1.09, 1.32, 1.62, 2.04, 2.2 and 3.05 µm are experimentally investigated. Changing observation geometry, the absorption bands parameters (area, depth and FWHM), reflectance values and spectral slope show important variations in the bidirectional reflectance spectra. Bands' area and depth parameters show the highest variability for $i \geq 30°$ and *e* greater than ±40°. The area and depth parameters of these bands show a dual behaviour: (1) the weak to medium absorption bands below 2 µm have their area and depth that decrease as the phase angle increases, (2) however, the stronger absorption bands above 2 µm have their areas and depth that increase only at phase angles above 90°, but also at low phase angles for high incidences, $i \geq 30°$. We observe an important dependence of band depth and area on the incidence angle, up to 60°, compared to moderate variation with emergence angles. Furthermore, the ~3 µm absorption band becomes less saturated at ± 70° emergence angles. A general trend of spectral bluing with change in observation geometry is observed. The dataset reported here represents a contribution in the framework of present and future space missions focused on understanding the nature and quantification of NH^{4+}-bearing minerals on icy bodies. The NH^{4+}-minerals identification has a strong impact on understanding their thermal evolution and the construction of geophysical internal models providing information on ocean/brine compositions, possible explanations of geological phenomena, like cryovolcanism, and implications for biological activity.

Keywords: aubrites, enstatite achondrites, Mercury's surface.

Compositional and spectroscopic data acquired by the NASA's MESSENGER (Mercury Surface, Space Environment, Geochemistry and Ranging) mission led to the hypothesis that planet Mercury formed from highly reduced materials, such as the asteroidal parent bodies of enstatite chondrite meteorites. The mineralogy of the planet surface is thought to be dominated by FeO-poor pyroxene and olivine, Na-rich plagioclase and Mg-Ca-Fe sulphides assemblage (Nittler & Weider, 2019). These characteristics suggest that the best analogues of the planet surface currently at our disposal are represented by highly reduced meteorites, in particular aubrites (Burbine et al., 2002) and enstatite chondrite impact melts (Udry et al., 2019).

We are conducting a minero-petrological and spectroscopic investigation on ten highly reduced meteorites: Rantila, Tiglit, NWA 14185, Peña Blanca Spring and Norton County (aubrites), Itqiy (EH7-an), Zakłodzie (enstatite achondrite ungrouped), NWA 13266 (enstatite achondrite), NWA 13210 (EL-melt rock) and NWA 4945 (EL6). The texture and modal mineralogy of every sample were investigated through SEM-BSE and SEM-EDS mapping and the mineral chemistry of the detected phases was obtained with EPMA analysis.

The samples, belonging to different meteorites groups originated by various processes, show some differences in their texture and modal mineralogy, while their mineral chemistry is quite similar. The main mineralogical phase (60-90%) in every sample is nearly FeO-free enstatite ($En_{96.9-99.8}Wo_{0.2-1.7}Fs_{0.0-0.6}$). Nearly FeO-free forsterite ($Fo_{99.6-99.9}$) and diopside ($En_{53.7-61.3}Wo_{38.7-46.0}Fs_{0.0-0.3}$) are present only in the five aubrite samples (up to 17% and 13%, respectively). Plagioclase covers a wide compositional range ($Ab_{60.3-97.2}Or_{0.2-13.8}An_{0.1-40.4}$) and is a minor constituent in the aubrites (max 5%) while it is more abundant in the other samples (up to 14%). Sulphides and metals are much more abundant in enstatite achondrites and melts (up to 19%) than in aubrites (max 2%). Metals are mostly represented by kamacite with variable Si content (max 0.4% in aubrites and up to 3% in enstatite achondrites and melts). The detected sulphides are: troilite, daubréelite/zolenskyite, alabandite, niningerite, keilite, oldhamite, heideite. Glass with albitic composition is found in some of the samples.

Reflectance spectra in the VNIR range show features typical of highly reduced materials (Burbine et al., 2002) with very weak absorption bands in spectra related to silicates and sharper absorption related to sulphides. The correlation between mineralogical data and VNIR reflectance spectra enable to have a complete suite of information about highly reduced materials that could be useful for future comparison with Mercury's surface data expected to arrive from SIMBIO-SYS/VIHI spectrometer onboard ESA's BepiColombo mission (Cremonese et al., 2020).

Keywords: asteroids, meteorites, NEOs.

The taxonomic classification of asteroids is important to gain insights on their composition and texture of their surfaces for those asteroids never explored by space missions. Nevertheless, a large number of interesting Near-Earth Objects (NEOs), such as Atiras, Earth co-orbitals and Earth Trojans, have orbital dynamics that limit their observability by ground-based telescopes only during challenging twilight conditions. These objects hold clues to the dynamical history of the inner solar system, as well as the physical evolution of asteroids in extreme environments.

For this reason, since 2021, a project is under way collecting data by using the Large Binocular Camera (LBC) at Large Binocular Telescope (LBT) in evening and morning astronomical twilight time to discover and physically characterize NEOs in the low solar elongation region using multiband photometry in g, r, i and z Sloan band (Giunta et al., 2021). The resulting data of these measurements will be used to allow the taxonomic classification of these objects, following the methodology described in DeMeo & Carry (2013) according to which strict boundaries in the overall spectral gri slope and depth of the one-micron band (i-z) are used to classify the targets into ten broad classes.

With the aim to address the problem of the gap in the mapping of Atira classification to meteorite groups, and trying to identify a possible parent body for those meteorites for which is still not clear the planetary bodies they may come, we are testing the approach that get “synthetic” Sloan values from reflectance spectra of meteorites and terrestrial analogues of planetary surfaces.

Keywords: planetary geology, Moon, structural geology.

Tectonics on the Moon is expressed by two types of contractional landforms: the lobate scarps, which are surface-breaking thrust faults characterized by a global distribution and the wrinkle ridges, thrust propagating folds, both present in the lunar maria (Hauber et al., 2018).

The wrinkle ridges can follow: (i) a concentric distribution pattern related to the presence of thick sequences of mare basalts, which induced subsidence and flexure of the elastic lithosphere (Freed et al., 2001) or (ii) a non-concentric preferred orientation, the origin of which is still a matter of debate within the scientific community.

Not only the origin, but other aspects are investigated in this work such as: (i) the complex stress field behind their formation which is presumably a result of a combination of different factors (secular heating, cooling and orbital despinning); (ii) how the deformation of wrinkle ridges in a certain lunar basin is related to the volcanic and thermal evolution of the basin; (iii) the décollement depths of such structures which is in turn related to (iv) the mechanical layering of the crust.

Oceanus Procellarum is the largest mare basin on the Moon and it is located on the western lunar nearside. The study area of this work is located within this basin, between two big shield volcanoes: the Marius Hills complex and the Aristarchus plateau.

The best products to identify thrust faults and wrinkle ridges are Digital Elevation Models (DEM). We used the "High-resolution Lunar Topography (SLDEM2015)", with a vertical accuracy between 3 and 4 meters, and the SLN Terrain Camera DTM Map V2.0 (TCDTMM), with a vertical accuracy of 5 meters. In addition, we used KAGUYA (SELENE) TC Derived Data, SLN Terrain Camera Ortho Map Seamless V2.0 (TCORTS).

To perform this study, we used the following software: QGIS Desktop 3.28.1, Minitab, Microsoft Excel, and MATLAB. QGIS was used to map the wrinkle ridges within the study area and to calculate the maximum displacement (Dmax). For better constraining the dip of the thrusts, we followed the method developed by Galluzzi et al. (2015). This method uses displaced crater to calculate the fault geometries and kinematics. It is based on the assumption of a perfect- circular shape and constant rim elevation of the initial crater. Accordingly, from the present-day topography the displacement and fault dip can be derived. Subsequently we estimated the shortening and through a MATLAB code even the décollement depth of each mapped fault (Karagoz et al., 2022).

The results on the décollement depths and the Dmax/L values (maximum displacement-length) are in agreement with previous local scale studies, but here are expanded at the basin scale proving multiple weak layers within the basin.

Keywords: late Quaternary, alluvial fan, dunes.

Luminescence dating could be a reliable method to date the recent climate and sedimentological changes active, and that have been active, in the recent past on Mars. Luminescence dating uses the properties of quartz and k-feldspar to absorb and entrap radiation when buried from the sun light. The presence of k-feldspar minerals, derived from basalt alteration, has been documented on Mars, rising luminescence as potential suitable dating methodology. Moreover, the recent improving technology has been capable to realize a portable instrument to date with luminescence in the field. This could be eventually installed on a rover and remotely driven from Earth. To test this potentiality it is necessary to select a Martian analogue where validate luminescence dating protocols applicable to date the Martian recent sediments.

Lanzarote (Canary Island) has been chosen as the best Martian analogue where to perform the test. The geological features and climatic conditions are very similar to those occurring on Mars: basaltic surface, low quartz and k-feldspar concentrations, dry weather, and very low vegetation.

Aim of the work has been to reconstruct the late Pleistocene geological and evolution of the El Jable Basin pointing out which have been the different depositional changes through time. The basin is the remnant of a Miocene caldera which flanks are made of basalts. On these colluvial deposits, similar to the gravity driven present at the rim and floor of a Martian impact craters, are forming. Moreover, the ephemeral streams associated with the basin border form a suite of colluvial gravity driven fans eventually evolving in alluvial fans alternating with aeolian deposits. Dunes become the dominant sedimentary feature in the more distal part of the basin. This dune system can easily be correlated to those forming inside some Martian craters where the colluvial deposits lose their character.

Selected luminescence protocol has been the pIRIR200 applied to fine-grained polymineral k-feldspar. Derived ages span form 132±12.3 to 13.3±2.6; that is, from the late Marine Isotope Stage (MIS) 6 to the late MIS 2.

From a sedimentary perspective, this study successfully reconstructed the evolution of the El Jable basin. This reconstruction enabled the correlation of deposits with different climatic periods, distinguishing between dry and humid conditions. During dry conditions, dunes dominated the deposition, whereas during wet alluvial fan systems developed. However, it does not seem that deposition followed a simple trend wet-and dry, but that minor climatic oscillation influenced and occasionally changed the normal deposition in the basin.

The ability to discern climatic oscillations recorded in terrestrial analogue provides a framework for interpreting past Martian climates and deciphering the planet recent geological evolution. By focusing on active deposits such as dunes or gravity driven, we can overcome the limitations posed by the age of ancient Martian alluvial-fluvial deposits and expand our understanding of the planet dynamic surface processes.

Geochemical characteristics of a newly discovered Vigarano chondrite fragment (CV3) - Study of redox conditions with unconventional Mössbauer spectroscopy

Permunian G.[1], Tagliacollo L.*[1], Bonadiman C.[1], Nodari L.[2], Brombin V.[1] & Tassinari R.[1]

[1] Dipartimento di Fisica e Scienze della Terra, Università di Ferrara.
[2] Istituto di Chimica della Materia Condensata e di Tecnologie per l'Energia, CNR, Padova.

Corresponding author email: tgllsi@unife.it

Keywords: Vigarano meteorite, carbonaceous chondrite, Mössbauer spectroscopy.

The Vigarano meteorite fell in 1910 in the province of Ferrara, Italy, and, after the impact, was divided into two blocks, "Cariani" and "Morandi", respectively, named after the owners of the farms where they were recovered (Trevisani, 2011 and reference therein). A new series of debris was found in a storehouse near the impact site at the beginning of the XXI century and was classified as part of the Cariani stone (Trevisani, 2011). This meteorite has been widely studied and represents the reference type of the reduced CV3 carbonaceous chondrite group (McSween, 1977). Notwithstanding it is worth noticing that the main contribution to the nature and origin of this meteorite is from fragments of the Morandi block, while knowledge on the other block is scarce.

This work aimed to characterize one of these newly discovered fragments to confirm its belonging to the Vigarano meteorite, with both bulk (XRF, and ICP-MS), in-situ (EMPA) major and trace element contents, and C-S elemental and isotopic (EA-IRMS) analyses. EMPA and petrographic thin section analyses did not identify phyllosilicates and carbonates, which were determined in the literature dealing with the Morandi block (McSween, 1977). Therefore, additional Mössbauer spectroscopy analyses were conducted to investigate iron speciation and possibly to determine the formation system's redox conditions and volatile elements circulation in the planetary body. Both XRF and ICP-MS analyses showed a composition in agreement with the literature data (McSween, 1977; Dauphas & Pourmand, 2015), confirming at first, that the recovered unnamed meteorite fragments belonged to the Vigarano meteorite, even though the fragment had no CAIs evidence, and, for major elements, a higher Mg/Si (1.43 versus 0.94) and Fe/Si (1.59 versus 1.46) and lower Ca/Al rate (0.71 versus 1.09). Slightly differences between the two blocks were also observed for trace element contents: the newly found fragment had a lower Eu (0.09 versus 0.11 ppm), Gd (0.29 versus 0.40 ppm), Dy (0.40 versus 0.53 ppm), Er (0.25 versus 0.30 ppm), Lu (0.04 versus 0.05 ppm) contents than what found in the well-studied Morandi block (Dauphas & Pourmand, 2015).

Due to a lack of carbonates and less sulfides presence, carbon and sulfur elemental contents (0.92±0.05, 1.38±0.05 wt.%) and isotopic ratios (δ^{13}CPDB: -17.8 PDB, δ^{34}SCDT: +0.3 CDT) were lower compared with literature CV3 values (e.g., McSween, 1977).

The iron speciation determined with Mössbauer analyses led to an Iron Oxidation Index (IOI), whose results increase with increasing oxidized iron to the total iron content, with a value of 2.13, consistent with the 2.12 shown in the classification of reduced CV3 group (Garenne et al., 2019). The sample contained 17% Fe^{3+}, attributable to incipient thermal metamorphism that tends to form magnetite and oxidize Fe in silicates and matrices. The fragment is more oxidized when comparing the IOI with the literature value (Garenne et al., 2019).

Keywords: analogs, laboratory, spectroscopy.

Silicates dominate volcanic terrains across the Solar System's terrestrial planets. Earth's volcanic landscapes consist of lava flows and pyroclasts with a predominantly glassy texture. Understanding how the glass/crystal ratio influences the spectral response of volcanic rocks is crucial for planetary interpreting remote sensing data from Mars and other rocky bodies. In the Petro Vulcanology Research Group (PVRG) labs, mafic volcanic materials were synthesized to mimic the composition of Nakhlite meteorites. A homogeneous silicate glass (Nglass) was created and then used to produce three samples by melting at 1500°C and gradually cooling to subliquidus temperatures of ~1200°C (N12), ~1100°C (N11), and ~1000°C (N10). Analysis revealed varying degrees of crystallinity, with N11 and N10 exhibiting similar mineralogical compositions, while N12 showed intermediate crystal content. X-ray powder diffraction (XRPD) coupled with Rietveld method for quantitative phase analysis, X-ray fluorescence (XRF) and scanning electron microscope (SEM) analyses were performed to assess type, degree of crystallinity and glass content. Reflectance spectra were collected at room temperature in the 1-4.2 μm range considering a set of 3 incidence (i = 0°; 30°; 60°) and emergence angles between -70° and 70° using the custom-made bidirectional reflectance spectro-goniometers SHINE (SpectropHotometer with variable INcidence and Emergence) at the Cold Surface Spectroscopy (CSS) facility laboratory at the Institut de Planétologie et d'Astrophysique (IPAG) (project number 21-EPN-FT1-025 Europlanet 2024). The spectral features of the single mineral phases are barely distinguishable for N10 and N11, due to the presence of magnetite that probably flattened the spectra, whereas the spectral signature of Fe in augite is distinguishable for N12 located at ~0.9 and ~1.15 μm. Spectral shifts from positive slopes for glasses to flat-negative slopes for crystalline materials were observed in the Visible and Near-Infrared range as crystallinity increased. Changing observation geometry, reflectance values and spectral slope show important variations while the bands position remains unchanged. We observe important dependence of band and slope in correspondence of low phase (< 30°) angle and high phase angle (> 100°). Principal component analysis (PCA) identified four distinct clusters corresponding to the four samples, particularly for glass-bearing materials. These findings offer additional insights into the spectral characteristics of synthesized rock samples, particularly those containing glass materials. Such information is valuable for accurately modelling the spectral signatures observed from rocky bodies within the Solar system.

Keywords: geological map, depositional environments, Mars.

Geological mapping of planetary surfaces has some intrinsic peculiarities when compared to Earth. Among the many (and body-specific) issues, the main ones are that the scales are instrument-dependent, and the remote sensing approach can be rarely tied with groundtruth. Still, while lithology has limited or no constraints, often landforms are preserved in the deep geological time, thus marking a considerable (and somewhat also philosophically significant) difference with Earth.

In this framework, the sedimentary deposits of Mars are particularly tricky because landforms are the result of a succession of depositional and erosional events which complicates a straightforward geomorphological interpretation. In order to address these issues, classical geological maps and associated stratigraphic reconstruction can be associated with a 3D geological model in order to strengthen and constrain the genetic interpretation of the landforms.

The Eberswalde contributing basin - delta - basin system (delta centered 23.8°S/-33.3°W) represents an ideal geological setting to test this approach and evaluate the good practices that might become the basis to standardize the detailed (i.e., CTX to HiRISE scale) geological and geomorphological mapping of Martian sedimentary deposits. This area is characterized in fact by pristine morphologies, exposed stratigraphy, data quantity, and quality, including compositional and topographic ones (e.g., Malin & Edgett, 2003; Pondrelli et al., 2008; Mangold et al., 2012; Hughes et al., 2023).

The contributing basin consists of about 6890 km^2, the delta of about 130 km^2, and the basin of roughly 950 km^2. Sedimentary deposits related to the fluvio-lacustrine phase consist of light-toned layered deposits (LTDs) placed unconformably on top of a Noachian substratum and disconformably covered by recent cover units. Within the delta LTDs occur in correspondence with a distinctive morphological assemblage, including delta plain, delta front, and prodelta morphofacies, found in different deltaic lobes. Depositional elements can be distinguished to further detail depositional processes. These deltaic lobes correspond to different water levels within the basin, suggesting an external control (possibly climatic) on sedimentary deposition, although intrinsic controls (e.g., erosion of the contributing basin/crater rim) are also present.

We attempted a source to sink-to-sink and time-related reconstruction by unraveling the depositional architecture of the depositional system.

The increase of complexity and number of planetary exploration missions, make geological maps a fundamental resource both concerning safety, planning of surface operations, scientific objective's location and prioritization, in situ resource identification and planetary protection. Any future planetary exploration framework which does not envisage production and use of geological maps is prone to failure. These require a careful planning that come in large part from geologic maps including hazard analysis. Currently, only the United State Geological Survey the only institute able to produce such maps on a regular basis while Europe have fostered the production of planetary maps firstly with the European PLANMAP project and then with the GMAP action within the EUROPLANET infrastructure. Both these activities are led by the Department of Geoscience of the University of Padua around which different institutions are gathered to form a European network of planetary mapping experts. A pivotal aim of the network is to prepare the next generation of planetary scientists to face the challenges of future planetary missions. As the missions increase in number and complexity, also the technical and scientific skills in geological mapping are evolving at a fast pace, so that the teaching strategy need to be continuously renewed and re-focused. The 4th Geology and Planetary Mapping Winter School 2024 took place from 22nd to 26th of January 2024 with more than 600 subscribers spanned all over the world in 75 countries in all time zones, continuing to the most recent outcomes and techniques on the production of planetary geological mapping, fostering a large international network and community of mappers with in mind the newly announced missions to Venus and the recently launched Missions to the Jupiter Icy satellites. The previous editions - held in February 2023, February 2021 and 2022 - share similar outstanding numbers (over 200 hundred participants in the first edition and over 300 in the second and 400 in the third with a similar number of instructors). The objectives of the 2024 were partly common to the previous ones, adding each time a relevant sub topic (i.e. from the first edition 3D geologic mapping, landing sites selection). The main topics covered are listed here:

- processing techniques for planetary data handling and basemaps creation;
- production geological maps of selected areas embedding traditional geological mapping with crater chronology;
- spectral and compositional data handling;
- insights on SAR data for Venus volcano-tectonic mapping;
- Vesta;
- Ganymede structural mapping;
- Irregular small bodies mapping (67P comet).

Due to the high number of online participants spread over diverse time zones, like in previous editions, we have provided live lectures, hands-on and seminars in a format that can be also followed asynchronously with the possibility to download lesson materials from Zenodo or alike, as well as, datasets for exercises and recorded lessons over a 5 days winter school duration. Al the 4 Winter School editions are still available in asynchronous format for long-term exploitation through the website planetarymapping.eu.

Mankind cannot stay in the cradle forever. The Space It Up project

Pratesi G.*

Dipartimento di Scienze della Terra, Università di Firenze.

Corresponding author email: giovanni.pratesi@unifi.it

Keywords: PE15, Space It Up, planetary sciences.

This presentation serves as an introduction to the Space It Up project, with a specific focus on the geo-mineralogical activities that will be at the heart of our research.

Space It Up – The Italian Partnership for Space Science and Engineering was conceived within the Extended Partnership 15 (PE15) and subsequently developed as an autonomous project financed by the Italian Space Agency (ASI) and the Ministry of the University and Research (MUR) for 80 million euros.

The project will last 36 months and involves 33 partners (13 universities, 10 research centers, and 10 enterprises) representing the best available science in Italy regarding space exploration and research. Space It Up will hire hundreds of Ph.D. students and researchers to work on nine Spokes and some 45 work packages. Spokes 1 to 4 focus on models and technologies for Space science and engineering, including satellite systems, system engineering and digital twins, and remote imaging and non-imaging sensing. Spokes 5 to 7 focus on Earth observation, whereas Spokes 8 and 9 on extraterrestrial observation.

The main Space It Up goals are (i) extending the fundamental knowledge on exploration and exploitation of space, (ii) fostering sustainable technologies to preserve the Earth and space for future generations, and (iii) ensuring long-term human permanence in extraterrestrial environments. On this latter point, the contribution of geosciences will be of fundamental importance in advancing the body of knowledge regarding extraterrestrial exploration, resource exploitation, mining, in situ manufacturing, and circular solutions for life adaptation to the space environment.

Spoke 8 and Spoke 9 deal with the following activities requiring geo-mineralogical knowledge and expertise: experimental research for advanced space exploration; identification and characterization of potential extraterrestrial habitats; laboratory and in situ analyses of planetary resources; resource mapping.

In particular, geological, mineralogical, petrologic, geochemical and geotechnical studies will be performed on lunar, martian, and asteroidal meteorites to increase the knowledge of these bodies and to evaluate their potential as in-situ resource (ISRU) valuable for human settlements. Methods and instrumentations for surface and subsurface exploration will be also developed for exploitation and mining the volatiles. Moreover, terrestrial analogs will be investigated to test mission methodologies, protocols, and technologies/instrumentations useful to train astronauts and scientists. Finally,mineralogical, compositional and lithological mapping from global to local scales will be obtained by using available datasets and developing new portable instruments for in situ investigations.

In conclusion, the Space It Up project aims to develop innovative ideas and solutions that will strengthen Italy's role as a leading country in space science and exploration. The synergies between universities, research institutions, industries, and small and medium enterprises will be strategic for the scientific, economic, and cultural systems, thus promoting the establishment of a comprehensive Italian space ecosystem. In this framework, geosciences will have a key role in achieving these ambitious goals and creating new professional opportunities within and outside academia.

"Chirfa" meteorite: the largest specimen from Mars

Shehaj X.*[1-2-3], Ammannito E.[2] & Pratesi G.[3-4]

[1] Dipartimento di Fisica, Università di Trento. [2] Agenzia Spaziale Italiana, Matera.
[3] Dipartimento di Scienze della Terra, Università di Firenze.[4] Istituto di Geoscienze e Georisorse, CNR, Pisa.

Keywords: Mars, meteorite, petrography.

The Martian meteorites (MMs) are peculiar igneous rocks distinguished from other achondrite meteorites based on their different petrography, mineralogy, mineral-chemistry, major and trace elements, and isotopic compositions. To date, MMs are classified into three main groups: Shergottites (basalts), Nakhlites (clinopyroxenites), and Chassignite (dunite). In addition, two unique types of meteorites have been found: ALH84001 (orthopyroxenite) and NWA 7034 (and the related pairs) regolith breccias. The basaltic shergottites, the most abundant MMs (about 90% of the total MMs), can be further subdivided into the following subgroups: basaltic (45%), olivine-phyric (30%), poikilitic (18%), gabbroic (5.5%), augite-rich (0.9%) and pigeonite-rich NWA 10414 (0.5%). In this work, we present the preliminary petrographic results of a new MM found on 18th November 2023 in the Sahara desert near Chirfa, Niger (coordinate: 21°05'12.72"N, 11°26'07.76"E). It represents the largest individual Martian sample hitherto described in the Meteorite Bulletin database - total weight of ~ 24.6 kg. A centimeter-size fragment has been embedded and polished for petrographic investigations. Backscattered images were acquired by scanning electron microscopy (SEM) at the Centro di Servizi di Microscopia Elettronica e Microanalisi (MEMA) of the Università degli Studi di Firenze, Italy. Quantitative analyses were obtained by electron microprobe (EMPA-WDS) at the same center. Backscattered images show a coarse-grained texture, with crystals ranging from tens to hundreds of microns, dominated by pyroxene, olivine, and plagioclase (possibly maskelinite). Large elongated prismatic pyroxene (up to 2.1 mm) and olivine (up to 2.5 mm) crystals may also occur. Oxides, phosphates, and sulfides are present as accessory phases. Pyroxenes are subhedral to euhedral with total abundance of about 66 total vol%. They also occurring with a lath-like and, generally, show low-Ca cores (average $En_{68}Fs_2Wo_5$) surrounded by more Ca-rich rims (average $En_{49}Fe_{38}Wo_{13}$), although complex zoning patterns are commonly observed However, a poikilitic texture containing olivine chadacrysts (~100 μm) enclosed by pyroxene oikocrysts (mm-size) is also present. Olivine grains are both subhedral and euhedral and generally show normal zoning from the Fo_{65} core to the Fo_{34} rim (about 16 total vol%). The Fe/Mn ratio ranges from 50.4 to 55.5 and from 27.8 to 36.3 for olivine and pyroxene grains, respectively. Maskelinite mainly occurs in both lath-like and interstitial textures (about 15 total vol%). The size ranges from ~100 μm up to 1mm, and the average composition is about $An_{50}Ab_{48}Or_2$. Tiny veins (~50 μm in thickness) mainly composed of granular calcite are present. Olivine gabbroic shergottite, proposed as a link between gabbroic and poikilitic shergottites (Benaroya et al., 2022), are coarse-grained igneous rocks predominantly composed of pyroxene, olivine and maskelinite. Likewise, the poikilitic shergottites contain poikilitic olivine set in a groundmass of smaller olivine, pyroxene, and maskelinite. The coarse grained and poikilitic texture, and the abundance of maskelinite (>10 vol%) found in the "Chirfa" meteorite, suggest more affinities to olivine gabbroic shergottite rather than poikilitic, or other shergottite subtypes. In conclusion, we propose that "Chirfa" meteorite, the largest martian specimen, is an olivine gabbroic shergottite. We believe this meteorite worthy, and further investigations such as petrographic, petrologic, and geochemical analyses will be carried out. The "Chirfa" meteorite could indeed improve our understanding of the Martian geological processes.

Benaroya S. et al. (2022) - Olivine-Gabbroic Shergottite Northwest Africa (NWA) 13227: A Link Between Gabbroic and Poikilitic Shergottites? 53rd LPSC, 2678, 1175.

Experimental alteration of volcanic bedrock: a terrestrial analogue for Mars

Tangari A.C.*[1-2], Marinangeli L.[1], Scarciglia F.[3], Pompilio L.[1] & Piluso E.[3]

Keywords: Mars, clay minerals, basaltic rock.

The study of the alteration of mineral assemblages, produced under a different range of conditions (i.e., pH, temperature, and time), can provide information on the reconstruction of the environmental conditions that occurred or may still occur on Mars. Specifically, Clay minerals have been detected on Mars to outcrop mainly as alteration of ancient bedrock, and secondarily, as deposition from aqueous environments or interlayered with evaporitic deposits on Mars. The main goal of this work is to better understand and constrain the conditions required for the formation of clay minerals as alteration of volcanic bedrocks on Mars, using laboratory experiments carried out on terrestrial analogues. We reproduced experimentally at lab scale the alteration of a fresh alkaline basaltic rock collected at Etna Mount. We selected Etna Mount as a Martian analogue for the following reasons: (i) the basalts are compositionally similar to those identified in differerent areas of the Martian; (ii) the volcanic morphologies such as basaltic channels, caves and lava tubes are widely exposed on the Etna active volcano and are very similar to those observed on Mars. Previous works considered only volcanic glass or single mineral, but this may not reflect the full environmental conditions. The novelty of this work is to experimentally simulate the alteration considering a powdered bulk composition of the fresh holocrystalline Etnean alkali-basalt as starting material and without acidic sulphates solution as catalyst. In particular, we simply mixing the basaltic fresh bulk powder with an acidic aqueous solution of HCl at pH 5.0 and 3.5, after exposure at low to moderate temperature, between 80°C and 250°C and investigate the alteration patina on single parent crystal for each stage. We observed that under acidic aqueous solution (pH ~ 3.5-5.0) and moderate temperature (~ 150-175°C), produced the formation of coatings with "honeycomb" morphology typical of smectite (as Fe-Mg saponite) on the surface of clinopyroxene and plagioclase crystals, just in a few days. The cations mobilization from the crystal to the patina indicates the development of coatings faster and more efficient on clinopyroxene than plagioclase where the formation of analcime (zeolite) occurs. Furthermore, temperature above 175°C seems to favor the formation of oxides rather than clays, regardless the pH. The results of our work suggest that on Mars, environmental conditions to produce clays can be reached in, a limited range of T and pH with acidic fluids (probably deriving from the volcanic activity in a warm and humid climate or by oxidation of the groundwater on the surface), and the alteration of the basaltic bedrock can occur at shallow depth if a source of heat (volcanic or impact) is close enough to reach the optimum temperature range. Finally, this work demonstrates that the basaltic rocks of Etna can be considered as a good Martian analogue to model the alteration processes.

Application of CHyM hydrological model on Mars surface: clues of drainage patterns on Jezero crater

Verdecchia M.*[1], Pedone M.[2], Tomasetti B.[3], Manzari P.[4], Lombardi A.[1] & Colaiuda V.[5]

Keywords: Mars, hydrology, drainage.

In our Solar System, the diversity in surface topographic features is observed. On Earth, plate tectonics has extensively shaped its topography; instead, on other less tectonically active rocky bodies, as Mars, as well as, on the ice bodies, the history of the observed surface topography are different and, in some cases, unknown.

Inside inner Solar System, fluid runoff has shaped the surfaces of Earth and Mars in the form of liquid water. On Mars, large-scale topography was established more than 3.5 billion years ago (Ga) in the wake of the formation of Borealis Basin and the growth of the Tharsis volcanic rise. Most fluvial activity likely occurred early in the planet's history (Black et al., 2017 and references therein). Some clues of past drainage patterns could be "seen" on Mars surface; however, some of them could be masked from impacts occurred.

Surface liquid water may also imply that environmental conditions appropriate to sustain prebiotic chemistry were present on Mars. In this context, Jezero crater (coordinates 18.38° N - 77.58° E) is the chosen (among other candidates) target for the programme Mars Sample Return (Grant et al., 2018; NASA Science Mars 2020 mission, https://mars.nasa.gov/mars2020/mission/science/landing-site/) which will allow the scientific community to receive (in 2033) and study the martian samples, possibly having biosignatures.

In this work, the Cetemps Hydrological Model (CHyM), already tested in different domains of the Earth surface (Coppola et al., 2006), is used to characterize a possible drainage pattern on Mars. Analysis derived by using CHyM model have been carried out in several areas of Mars (Jezero, Eridania, Ismenius), and preliminary results show that it may plausible to speculate that some areas on Mars have been covered by water body similar to the lakes on Earth. Moreover, the boundaries between the drained and not-drained areas seem to be characterized by a high slope.

Structural setting and tectonic evolution of the Central Matese Fault System, Southern Apennines: preliminary observations

Bacchiani A.*, Ferranti L., Iezzi F. & Pavano F.

Dipartimento di Scienze della Terra, dell'Ambiente e delle Risorse, Università degli Studi di Napoli "Federico II".

Corresponding author email: alberto.bacchiani@unina.it

Keywords: Central Matese Fault System, faulted Pleistocene breccia, left-lateral shear zone.

The central part of the Matese Massif is crossed by a major fault system, the Central Matese Fault System (CMFS), which is associated to several intramontane basins developed through to the interaction of karst and tectonics processes. To date, the tectonic evolution of the CMFS is poorly constrained due to a lack of detailed structural and chronological data. Nevertheless, the fault system is often considered active (e.g. Valente et al., 2019) and included in the ITHACA database of capable faults (ITHACA Working Group, 2019).

A geological-structural field survey was conducted in order to constrain the geometry of the fault system and to map the associated Quaternary deposits. Additionally, a morphological analysis was performed using the 1-m resolution LIDAR DTM provided by the Ministero dell'Ambiente of Italy and the 5-m resolution Carte Tecniche Regionali provided by Regione Campania.

The survey revealed that the main basin-bounding faults have dominant ~ E-W and ~ NW-SE strikes and a dip ranging from ~ 60° to vertical. In few cases, kinematic indicators were collected on the fault planes to carry out a strain inversion. We mapped stratiform breccia deposits covering the Mesozoic carbonate bedrock, consisting of carbonate clasts sourced from the bedrock, embedded in a clayey reddish matrix and frequently exhibiting channel-like features. Noteworthy, the attitude and geometric pattern of the breccias are not consistent with the current mountain slope. Based on facies and mineral analysis, these breccia deposits can be referred to the "Brecce Mortadella", a well-known continental deposit that outcrop in several mountain localities of Central and locally Southern Italy and is thought to have a Lower Pleistocene age (D'Agostino et al.,1997).

Locally, NW-SE striking high-angle faults with a marked reverse component thrust the Mesozoic carbonates above the breccias, often tilting them up to 55° and creating fault damage zones with thickness of several meters in the carbonate bedrock. Moreover, the CMFS includes E-W striking normal faults, such as the Letino, the Gallo Matese and the Cusano Mutri faults, show few hundred meters of geological throw between the Mesozoic carbonate in the footwall and the Upper Miocene siliciclastic flysch in the hanging-wall.

The high-angle reverse faults can be interpreted as formed within restraining bends of the CMFS, which is thus interpreted as a major NW-SE striking shear zone with a dominant left-lateral displacement. Similarly, the E-W striking normal faults could have formed within releasing bends of the shear zone. Although no evidence of a recent extensional displacement on the NW-SE main faults was found, further investigations will explore whether these faults are active in the current tectonic setting of the region, which is dominated by NE-SW extension.

Addressing fault structural complexity and geometric interference in seismic hazard assessment for railways design

Bonini S.*[1], Asti R.[1], Viola G.[1], Tartaglia G.[2], Rodani S.[2], Benedetti G.[2] & Vignaroli G.[1]

Keywords: active and capable faults, seismic hazard, railways.

Active and Capable Faults (ACFs) represent a threat to crucial infrastructures, as they may generate substantial permanent deformation of the topographic surface. This geohazard is more relevant for railway lines that, unlike punctual infrastructures such as dams or nuclear installations, span hundreds of kilometers and potentially cross complex structural features belonging to distinct tectonic contexts. In this regard, the Italian territory shows several interference situations because of the intricate tangle of railway lines and ACFs.

ACFs are generally described by fault attributes, namely its geometry, kinematics, and temporal constraints on its activity. Unfortunately, the structural complexity commonly associated with internal architecture of fault zones does not readily translate to uniform hazard values, as it can lead to significant variability in fault parameters both along and across the fault. This could be related to the growth mechanisms of such tectonic structures and to the modes of deformation localization and partitioning, potentially resulting in the development of a specific fault aspect rather than others.

We propose a new structural geology-based methodological approach to assess seismic hazard related to ACFs specifically for railway planning purposes, identifying four key geometric interference cases between faults and railway line: fault-crossing, fault-parallel, near-fault tip, and transfer zone-crossing railways. For each case, we determined: a) the key fault parameters to be estimated, and b) the most suitable investigations to obtain deterministic structural input data respecting the main fault element to be detected with higher priority specifically for planning purposes. Also, the incidence angle is an essential factor to consider as the impacted zone tends to grow if the railways cross the ACF with lower angles. Hence, we suggest that the potential impact of seismic fault-related effects can be distinguished based on the way ACFs geometrically interact and physically interfere with the railway infrastructure.

Our proposed workflow and the results thereof provide novel insights into the full parametrization of a fault zone to be used to support probabilistic fault displacement hazard analysis scenarios and finally lead to the development of mitigation strategies to minimize infrastructure vulnerability.

First comparison of instrumental European Ground Motion Service by Copernicus Data with short and long-term geological vertical movements for the Italian Coasts

Keywords: InSAR data, coastal tectonics, vertical deformation.

A deep comprehension of ground motion is essential for assessing seismic and volcanic hazards, geological interpretations, and geotechnical applications. This study addresses the imperative of conducting a thorough first comparison between vertical ground motion (InSAR) data from the European Ground Motion Service (EGMS) released by Copernicus (https://egms.land.copernicus.eu/) and geological vertical movements along the Italian coasts across various time scales, including the MIS 5e (Late Pleistocene), the Holocene, and the very short term (2015-2022) data. Anchored to the European Terrestrial Reference Frame 2014 (ETRF2014), EGMS level 3 data, covering both horizontal and vertical ground deformation (Costantini et al., 2021, 2022), facilitates a precise geodetic comparison. With a focus on discerning areas affected by tectonic, volcanism, and sediment compaction crucial for geological risk assessment, our research evaluates the reliability of EGMS data. This review study provides valuable insights for seismic hazard assessments, environmental applications, and an enhanced understanding of geological processes. Our findings disclose a promising alignment between EGMS data and geological observations in stable areas like Sardinia, affirming the efficacy of EGMS for monitoring ground stability. In areas with fault-related activities, such as the Pontina Plain and Volsci Range, EGMS data reveal differential subsidence, underscoring its capability to detect localized ground motion phenomena, possibly related to a combination of compaction and tectonic activity. In volcanic regions, particularly in Campi Flegrei and Mt. Etna, observed short-term data are the most sensitive for EGMS applications, as long-term observations are unrelated to them. The study also illustrates that the smaller disparities between EGMS and GPS data in active tectonic zones emphasize the intricate nature of short-term and long-term deformation interactions, highlighting the significance of local-scale geo-structural analysis. These insights contribute to a nuanced understanding of ground motion dynamics, crucial for informed hazard assessments and environmental planning.

Keywords: earthquake energy, graviquake, elastoquake.

Faults are passive features mobilized by the dissipation of the energy and shear stress accumulated in the crustal volume surrounding them. However, the energy in the volume differs from the tectonic setting, i.e., it is gravitational in extensional tectonic settings, whereas it is elastic in strike-slip and contractional tectonic environments. In extensional settings, below 1 km the horizontal tensile stress is overwhelmed by the confining pressure of the lithostatic load. Therefore, the motion pro-gravity of the crustal volume is provided by the lithostatic load that is the vertical maximum principal stress. The elastic energy is rather accumulated by the maximum horizontal principal stresses, i.e., iso-gravity in transcurrent settings and counter-gravity in contractional tectonic settings. The different relation with the gravitational force in the different tectonic settings generates several relevant differences in the three main tectonic environments. The pro-gravity movements, or graviquakes, determine i) lower energy and lower differential stress to activate faults with respect to the other tectonic settings; ii) lower maximum earthquake magnitude than the other tectonic environments; iii) a larger number of low magnitude earthquakes in extensional settings because the crust moves downward as soon as it can move, whereas contractional settings require larger accumulation of energy to move counter-gravity; iv) therefore, the b-value of the Gutenberg-Richter is higher than 1 and the aftershocks are more numerous and last longer in extensional settings; v) the downward motion of the hangingwall determines more diffuse cataclastic deformation with respect to the other tectonic settings because the lithostatic load works everywhere, whereas in the other tectonic settings is concentrated where the elastic energy accumulates; vi) in extensional settings the volume dimension is determined by thickness of the brittle layer, and its length is about three times the seismogenic thickness, whereas in the strike-slip and contractional settings, where the elastic energy dominates (elastoquakes) the volume may be ten to thirty times longer, being its size proportional both to the brittle thickness and the relative speed of plates. These differences characterize the seismic cycle of graviquakes with respect to the elastoquakes. The bigger the volume, the wider the seismogenic fault in all tectonic settings. The interplay between the horizontal tectonic forces and the lithostatic load, which is ubiquitous, varies in the three main tectonic settings, generating different seismotectonic styles and an increase of seismic energy as the effect of the vertical gravitational force becomes minority.

The continuous GNSS network of Salina Island in the framework of CAVEAT project

Keywords: GEodesy, Aeolian Islands.

CAVEAT (Central-southern Aeolian islands: Volcanism and tEAring in the Tyrrhenian subduction system) aims to study the active dynamics of the Central-Southern Aeolian Islands (CSAI) in the framework of the ring-volcanism and the subduction of the Ionian plate under the Calabrian Arc. CSAI, formed by Salina, Lipari and Vulcano islands, is considered as a volcanic ridge located at the intersection of the WNW-ESE Sisifo-Alicudi fault system to the west, and the NNW-SSE Aeolian-Tindari-Letojanni fault system to southeast. To properly detect the geodetic transients over CSAI area, recently we established a new GNSS network on Salina Island. The new local GNSS network, SalinaNet, consists of five stations that monitor by June 2023 and equipped with STONEX SC600+ GNSS receiver and antenna SA1200 GNSS. All raw GNSS observations acquired during first year are processed by using the GAMIT/GLOBK 10.71 software (Herring et al., 2018). The installation of these stations will significant improve the resolution of regional velocity field and the associated strain rate map. We present time-series and the preliminary results.

Geodetic velocity constraints on fault strain accumulation in southern Italy

Keywords: geodetic strain accumulation, active faults, Southern Italy.

We provide updated rates of geodetic strain accumulation on faults and deformation zones in southern Italy (from Molise to northern Calabria) by using a dense geodetic network derived from a combination of continuous (2001–2024) and episodic (1995–2013) GNSS observations. The continuous GNSS sites are part of several networks; the episodic sites belong to the PTGA network (Ferranti et al., 2008). For this analysis, the estimated GNSS velocities were aligned to a fixed Central Eurasia reference frame and successively to a local reference frame, whose Euler pole was estimated by using GNSS sites located in southern Apulia and eastern Lucania regions.

We refine previous estimations presented in Ferranti et al. (2014) using a new fault model derived by combining seismogenic sources of the INGV-DISS catalogue, faults inferred to be active in literature from the ITHACA database, and newly defined sources. The faults were modelled using a rectangular hull embedded in an elastic half-space. Computed geodetic rates for each modelled fault were compared with geological displacement estimates using Pleistocene or Holocene offset markers, where available.

Our analysis supports previous inferences that active deformation in southern Italy is accommodated by faults with low–moderate slip rates distributed in two distinct domains. A western domain of extension along the axis of the Apennines include faults with mainly extensional geodetic strain. Conversely, mostly blind, geodetically active strike-slip faults are found in an eastern domain encompassing the frontal Apennines, the Apulia foreland and eastern Calabria.

A longitudinal gradient in extension rate is observed for the axial fault array, with two sectors of higher strain accumulation (~0.8–1.7 mm/yr for individual faults). The modelled extensional faults do not form a continuous array, rather they show recurrent en-echelon patterns and strike changes that closely follows structural highs in the Apulian belt underneath the Apennines outlined in the map by Nicolai & Gambini (2007). This result is consistent with geological observations and supports the notion that extension occurs in discrete patches and is controlled by the inherited orogenic structure buried beneath the mountain belt.

Faults of the eastern domain have lower (few 0.1 to ~1.2 mm/yr) strike–slip rates and locally both extensional and contractional components. Noteworthy, significant geodetic displacement is detected in areas of the eastern domain lacking clear geological evidence of activity.

The pattern of strain accumulation in southern Italy appears strongly influenced by a combination of processes including mantle upwelling, and exploitation of intra-plate crustal anisotropy, which are not immediately related to plate boundary forces.

Keywords: L'Aquila 2009 seismic sequence, machine-learning seismic catalog.

Nowadays the use of neural networks and artificial intelligence in seismology provides high-resolution seismic catalogs including very small magnitude events that remained undetected by human analysts and standard monitoring procedures. Here, we test the performance of two new machine-learning (ML) modules that provide P- and S- wave arrival times (i.e. PhaseNet from Zhu & Beroza, 2019) and seismic waves association (i.e. GaMMA from Zhu et al., 2022) for their reliability in the high-seismic hazard area of the Central Apennines, Italy. In this work, we build a new earthquake catalog for the Mw6.1 L'Aquila 2009 seismic sequence using all the permanent and temporary seismic stations that operated in the epicentral area for a period of one year. After applying the combination of PhaseNet and GaMMA to the entire 2009, we obtained a new ML-based earthquake catalog composed of 407,229 seismic events with at least 3 P- and S- arrival times per event. The availability of a large-scale high-resolution catalog (about 63,000 earthquakes) for the L'Aquila seismic sequence (Valoroso et al., 2013), computed using semi-automatic picking and detection methods (Aldersons et al., 2009), permits testing the performance of the ML technique. In our new ML-based catalog, we found 62,492 common seismic events (about 99%) with the existing high-resolution catalog, demonstrating how powerful the ML techniques are to deliver a huge seismic catalog. The deep neural network PhaseNet recognizes more P- and S-wave arrival times than the semi-automatic algorithm, providing a decrease in the hypocentral horizontal and vertical error in the locations of the earthquakes. As a final step, we test the use of the newly developed ML earthquake catalog to compute 3D Vp and Vp/Vs velocity models that we compare with those obtained by using the MannekenPix procedure. Our final goal is to use this application to the L'Aquila 2009 seismic sequence as a test-case to validate whether this new ML- approach could be used for real-time monitoring during a future seismic sequence in Italy.

Keywords: block modelling, Calabria, active faults.

Extensional faults in Southern Calabria (Italy) have been widely studied for their capability to generate high magnitude earthquakes (Mw 7-7.2). An example is the historical seismic sequence of the 1783 (Jacques et al., 2001), which caused numerous fatalities near the villages located along the largest fault structures of this region, the Cittanova the Serre faults. In this area, the low strain rates and the high seismic moment release observed over time represent an open problem and raise a continuous interest of the scientific community.

In this work, we estimate the seismic potential of the Serre and Cittanova faults by a kinematic block modelling approach (McAffrey, 2002). We used the BLOCKS MATLAB code (Meade & Loveless, 2009) to divide the study area into rigid blocks bounded by faults and GNSS data of both campaign and permanent stations. Our results indicate that both faults are accommodating the extensional velocity gradient (~ 1 mm/yr), with long-term slip rates (~ 2 mm/yr).

Then, we estimate the spatial variability of the back-slip on fault planes (Savage, 1983) generating a 3D mesh with triangular dislocation elements (TDEs). We also compute the corresponding interseismic coupling degree for the studied faults and investigate the resolution capability related to GPS network geometry. This approach allowed us to distinguish the fault areas where elastic seismic rupture is more likely to happen from those affected by aseismic creeping behaviour. The obtained interseismic coupling distribution shows a good agreement with the relocated microseismicity of the area, concentrated mainly in the fault portions of low coupling degree. Moreover, the highest values of coupling are concentrated near the shallow portion of the fault planes and near the southern tip of the Cittanova fault.

The obtained results allowed us to propose a possible sets of rupture scenarios in southern Calabria by estimating the coupled area of the faults for each coupling increment, the related moment magnitude (Mw) and recurrence intervals. Moreover, geodetically constrained slip deficit rates, allowed us to estimate an overall interseismic moment accumulation rate of 4.05´1015 Nm/yr, larger than the average rate of the moment release (~1.19´1015 Nm/yr,) for the studied area.

Keywords: active faults, geophysical investigation, structural geology.

Understanding the architecture of active faults is crucial to assess their seismic hazard, in both terms of ground motion and coseismic fault displacement. This is important especially when active faults are located in geologically complex areas, characterized by the overprinting of preexisting and newly formed fault splays. An example of this is provided by the NW-SE striking, NE dipping Northern Matese Fault System, Southern Apennines (Italy), a main normal fault formed by numerous fault strands with both along- and across strike arrangements. The fault is thought to be responsible of destructive historical earthquakes (e.g. Galli et al., 2017) and it is included in the Italian catalogues of seismogenic sources and capable faults. Although the general fault geometry, segmentation pattern and kinematics are relatively well understood (e.g. Ferrarini et al., 2017), accurate definition of fault arrangements, detailed measurements of slip-rates, and high-resolution subsurface images are lacking.

We combined remote sensing analysis through high resolution Digital Terrain Model (DTM), structural mapping and high-resolution geophysical investigations to reconstruct the complex architecture of the northern sector of the Northern Matese Fault System. Our study provides (1) new evidence of a WNW-SSE fault strand characterized by an overall large (up to ~25 m high) fault scarp of likely Late Pleistocene-Holocene age along the NE flank of the Mt. Patalecchia, and (2) a detailed mapping of the fault strand bounding the "Il Lago" plain, where the only paleoseismological trench to date was carried along the fault system (Blumetti et al., 2002). The linkage between these two main strands occurs through a relay ramp affected by a series of newly mapped antithetic and synthetic faults that accommodate the transfer of the deformation along the fault system.

In addition, we investigated the subsurface structure of the "Il Lago" plain by acquiring two high-resolution seismic reflection profiles. The strong reflection at the interface between the carbonate bedrock and the sedimentary fill shows an overall deepening of the bedrock towards SW, and a maximum thickness of the infilling of about 100 m. Although the profiles did not reach the main fault at the border of the basin, we imaged multiple synthetic and antithetic fault strands that affect the buried bedrock underneath the plain. Future investigations will allow us to verify whether the buried faults cut the sedimentary infilling and to determine a possible age of the infilling.

Keywords: active tectonics, GNSS geodesy, Iberian Peninsula.

Geodetic measurements from GNSS networks are vital for quantifying active tectonic processes. Their combination with seismological and structural studies of active faults allows for the characterization of fault parameters (e.g. long-term and short-term slip-rate, seismic release, dimension), leading to an improved picture of seismic hazard of the study region. Iberia was the westernmost microplate situated between the Eurasian and Nubian plates, affected by the Alpine-Himalayan orogeny. In the north, the Iberian margin was mainly deformed during the Oligocene-Eocene collision with Eurasia. At present, geodetic deformations are not very high. The largest, N-S extension of up to 2 mm/yr, is concentrated in the western Pyrenean Cordillera. In turn, seismicity in the Pyrenees is mainly associated with extensional contexts (Rigo et al., 2015). Currently, the 4-6 mm/yr convergence between Nubia and Eurasia mainly affects the southern and southeastern margins of Iberia, resulting in the development of the Betic Cordillera, which, along with the Rif and the Alboran Sea basin, composes the Gibraltar Arc. Moreover, the southern Iberian and Nubian margins are deformed due to the 3-5 mm/yr westward migration of the Gibraltar Arc (González-Castillo et al., 2015). These frameworks make it the region with the highest deformation and affected by the most seismicity in Iberia (www.ign.es). The interior of the Iberian microplate was deformed, inverting all previously rifted regions, and producing intraplate mountain ranges. Nowadays, the intraplate region is affected by recurrent low-magnitude seismicity in the Iberian Cordillera and the Galician-North Portugal region where no main relative velocity changes are registered. In this work, we present a new 3D velocity model obtained from nearly 500 public continuous stations throughout the Iberian Peninsula and adjacent mountain belts. The data cover a time span of almost 25 years from 1999.00 to 2024.00. Overall, they improve previous models of Iberia (Palano et al., 2015) with new 100 stations and 9 years of measurements. These data have been processed using GAMIT/GLOBK (www-gpsg.mit.edu) following the process described in Palano et al. (2020). Achieved results are referred to the ITRF2014 reference frame. To improve the detail of the geodetic velocity field over the studied area, we perform a rigorous integration of our solutions with those reported in recent literature. The final velocity field has been used as input to compute a novel strain-rate field at the scale of the whole Iberia. The new velocity and strain fields will improve the knowledge of active deformation around Iberia and surrounding mountain belts and combined with seismology and active faults databases would be an important tool for hazard assessment.

Keywords: Italian seismicity, seismic bulletin, Open Access Data.

The activity of the Italian Seismic Bulletin (BSI) is addressed to the scientific community and the public with the objective of publishing a seismic bulletin and accurate information on Italian seismicity. The analysts of the BSI routinely review data recorded by the Italian National Seismic Network managed by the Istituto Nazionale di Geofisica e Vulcanologia (INGV), and other permanent networks operated by Italian and European institutions (Margheriti et al., 2021). Arrival time readings of local and regional P and S waves, as well as polarities and ground motion amplitudes, are manually revised to compute earthquake hypocenter locations, magnitude and focal mechanisms. BSI datasets are released every 4 months and integrated into the International Seismological Center (ISC) bulletin. Since 2015, the BSI working group rapidly revises events of magnitude ML ≥ 3.5 releasing parameters and focal mechanisms of earthquakes in 24 to 72 hours (BSI Working Group, 2015).

Recently, the BSI activity is focused on developing a new website where data and other products including reports, publications and conference presentations, will be accessible to the public and the scientific community. The website presents an intuitive navigation. The homepage displays an interactive map where users can explore earthquakes of magnitude ML ≥ 3.5 that occurred in the last 12 months. For each event, users can view hypocenter parameters and, if available, the beachball representing the double-couple focal mechanism calculated with first-arrival polarities. The "History" section is dedicated to the historical observatories and their seismic bulletins that led to the formation and evolution of the BSI Working Group. The "Data Archive" section currently allows users to download data that was previously available on the websites terremoti.ingv.it/bsi (2015 to present) and bollettinosismico.rm.ingv.it(2002 to 2012). In the future, a data access point will be created for the whole BSI catalog, from 1985 to the present. Data of four-month bulletins from 2015 are available both in QuakeML and in text file formats commonly used by the scientific community. The "Seismicity in Italy" section displays the list of earthquakes with ML ≥ 3.5 recorded in the past 12 months and rapidly reviewed. For each earthquake, the first-polarity focal mechanisms are released if available (Ciaccio et al., 2021). In the near future, we plan to enhance the website by incorporating in-depth studies of the main Italian seismic sequences analyzed by the BSI working group.

Identifying and studying active faults is crucial for assessing seismic hazards and implementing measures to mitigate earthquake risks in areas prone to seismic activity. The region of South-East France is found in an tectonic domain where seismic activity is low to moderate and crustal deformation is slow, nevertheless about one magnitude 6 earthquake is recorded per century (Bertrand et al., 2007). Social vulnerability to seismic hazard in South-East France is noticeble, specifically due to the presence of urban agglomerations, chemical industries and most importantly, nuclear facilities.

Today's seismic activity in this region is of transtensional behaviour and is dominated by the ongoing tectonics of the post-alpine orogen and gravitational isostatic adjustments (Sue et al., 2007). However, the near future location and magnitude of this activity is not well constrained due to the relatively small time windows of seismic records and GPS data aquisition in respect to the seismic cycle of a slow deformation domain. The available knowledge on potentially active structures which determine the location of events is low, affirmed after the unexpected 4.9 Mw Teil earthquake in 2019 (Cornou et al., 2021). The geomorphic evidence of faults is weak as the seismic cycle is slower than erosional processes, difficulting the identification of recent fault activity. Moreover, the possible activity of faults with no neotectonic activity evidence under today's tectonic stress fields is ignored.

My work aims to analyse all major tectonic structures in the South-East of France and re-evaluate their near future rupture probability in accordance to the instrumental and historical seismicity and the stress field. The characterisation of potentially active faults in a slow deformation domain is a complex task which requires the determination of uncertainty levels for the defined data. For this, a methodology of estimation of fault activity and information reliability is proposed. The resulting fault dataset from this study will then be applied for the construction of a multidisciplinary and complex source model which considers all possible ruptures for a PSHA study of the area.

Keywords: Afar, rift linkage, numerical modeling.

Detailed understanding on how propagating rifts connect is crucial to fully capture the dynamics of continental break-up and the onset of seafloor spreading. The Afar rift is a classic natural laboratory where we can directly observe tectonic processes related to the ongoing deformation between the Red Sea and Gulf of Aden rifts. While there have been several geophysical studies conducted in the region, we know surprisingly little about the mechanism of connection between the two rifts. Earlier studies suggest that the two rifts form an overlap zone within which crustal blocks rotate in a clockwise sense. In contrast, geodetic data indicate a direct linkage via a zone of extension with dextral shearing at the lateral tips of the zone of extension and minimal vertical axis block rotation. Here we combine high-resolution 3D lithospheric scale geodynamic models and strain rate derived from geodesy to fully capture the evolution of deformation between the Red Sea and Gulf of Aden rifts as they evolve. The results demonstrate that the two rifts initially overlap and crustal blocks within the overlap rotate in a clockwise sense before direct linkage forms. We argue that the discrepancy between the proposed models for the Red Sea and Gulf of Aden rift connection can be reconciled when considering the spatial and temporal evolution of the rifts.

DInSAR coseismic surface deformation of the 2023 Mw 6.8 Al Haouz earthquake (High Atlas Mountains, Morocco)

Keywords: earthquake, DInSAR, tectonics.

On 8th September 2023, the Al Haouz province in Morocco was struck by a strong earthquake of 6.8 Mw. The mainshock was generated by a reverse fault with an ENE-WSW orientation, as suggested by the derived focal mechanism. To obtain preliminary information of a seismic event, and to characterize the associated seismotectonic framework, in the last decades, the combination of field geology with satellite observations is becoming gradually more frequent. In particular, the DInSAR technique can be a powerful method of analysis to have an initial detailed information on the deformation field produced by the earthquake. In the present study, to understand the deformation field induced by the event and the structures involved, the DInSAR technique has been applied to obtain displacement maps in LOS, vertical, and horizontal (E-W) directions. On these maps, the geological meaning of both the vertical and horizontal displacement components is interpreted in the framework of the known tectonic structures of the Western High Atlas Belt. The inferred coseismic deformation along its vertical component shows a wide antiform characterized by an overall E-W trend and a slight southward vergence. On the other side, the horizontal (E-W) component of the deformation seems to be affected by the flexuring of the antiform flanks. Integrating the retrieved DInSAR maps with published geological observations and preliminary seismological data, it is possible to demonstrate how the coseismic deformation pattern may be affected not only by a possible activity of the main Tizi n'test fault but also by the far western High Atlas frontal thrust and by possible blind faults, better oriented to the vertical deformation field.

Geodetic and seismological constraints for the intra-orogenic normal Lakes Fault (Sila, Calabria, southern Italy)

Keywords: geodesy, seismic data, modelling.

The Calabrian Orogenic Arc is affected by active extensional and strike-slip tectonics as largely documented by the presence of N-S and NE-SW trending intra-montane basins bordered by faults, whose slip has caused many destructive earthquakes during the last millennium. Here we collected a new set of geodetic and seismological observation related to the central sector of the Calabrian Orogenic Arc, i.e. the Sila Massif. By analyzing these novel datasets, we observed some relevant differences (e.g. seismic activity and hypocentral depths, faulting style, geodetic strain, vertical rates) between the western and eastern sectors of the Sila Massif. The transition between the two sectors occurs in the area of the Lakes Fault, a NW-SE striking and west-dipping fault indicated as the causative source of the 8 June 1638 M 6.8 earthquake. By modelling of the available geodetic data, we inferred a dislocation plane whose geometry and kinematics (a prevalent dip-slip component coupled with minor left-lateral strike-slip) is compatible with the real fault reported in literature. This fault only accounts for a small amount of the deformation across northern Calabrian Orogenic Arc and divides the seismically more active western sector from its eastern counterpart with appreciable geodetic strain and moderate seismicity. Achieved results (Palano et al., 2023) are encouraging and suggests that a similar approach can help in other regions where surface evidences of active faults are rare or non-existing and field geological investigations are hence difficult.

Crustal deformation along the Dead Sea fault system

Palano M.*[1-2-3], Parrino N.[1], Madarieta-Txurruka A.[4-1], Pietrolungo F.[2], Sparacino F.[2] & Sulli A.[1-2]

[1] Dipartimento di Scienze della Terra e del Mare, Università di Palermo. [2] Istituto Nazionale di Geofisica e Vulcanologia. [3] Istituto di Geologia Ambientale e Geoingegneria, CNR.

Keywords: GNSS velocity, geodetic strain, natural strain markers.

The Dead Sea fault system (DSFS) represents the ~1000-km-long left-lateral transform boundary between the Arabian plate and the Sinai sub-plate, stretching from the Red Sea in the south, to the Hatay triple junction in the north, where it joins with the East Anatolian fault and the Bitlis-Zagros continental collision zone. The DSFS is characterized by a significant natural hazard due to its substantial seismic activity documented by historical records (Ambraseys, 2009). Although most seismic events along this fault are of small magnitude, typically less than Mw 4, there have been two significant earthquakes during the instrumental period. The first, theroughly Mw 6.3 Jericho earthquake in 1927 and the second event, the Mw 7.3, 1995 Nuweiba earthquake, a nearly pure strike-slip mechanism with approximately 1.6 m of left-lateral slip along an 80 km fault segment oriented about N20E (e.g. Klinger et al., 2000 and references therein). Such a persistent seismic activity can cause extensive damage to infrastructure and homes and pose significant safety risks to populations. Consequently, understanding and monitoring this fault is essential for earthquake preparedness and risk management in the affected regions. Both continuous and episodic GNSS networks, established in the last 2 decades along the DSFS, have allowed to infer the main slip-rates of the major fault segments (Li et al., 2024). Here we propose a new GNSS-based horizontal velocity field for DSFS by taking into account novel observations as well as literature solutions. By using as input this unified velocity field we computed both the strain-rate field and the slip-rate distribution along the entire DSFS. Furthermore, we have identified areas within the DSFS where river basins exhibit more significant rotations by utilizing them as natural strain markers for tectonically active regions (e.g., Goren et al., 2015), aiming to understand the spatial variations of long-term tectonic deformation across the fault system. Finally, achieved results have been framed into the general seismotectonic setting of the study area.

A method for the determination of the orientation of fault plane from the analysis of seismograms in the time domain

Perrucci F.* & de Lorenzo S.

Dipartimento di Scienze della Terra e Geoambientali, Università di Bari "Aldo Moro".

Corresponding author email: f.perrucci5@studenti.uniba.it

Keywords: focal mechanism, directivity, rise time.

During the last decades, many studies (i.e., Sato & Hirasawa in 1973; de Lorenzo & Zollo in 2003) have tried to solve the problem of the ambiguity of the solution of the focal mechanisms of earthquakes by modeling the directivity source effect.

The directivity effect is the changing in shape and amplitude of the body wave pulses, varying the position between the source and the stations. Directivity effect is linked to the shape of the source (unilateral, circular or complex), so, in order to create a model of directivity, it's important to define *a priori* a source model.

Starting from the limits of the work by Filippucci et al. (2006), a method has been developed to better costrain the fault plane solution.

In this work a circular-crack source model with constant rupture velocity and a fixed 0.9 ratio between ν (rupture velocity) and β (S-wave velocity) has been used (Model by Sato & Hirasawa, 1973).

In this study the measurement of the rise times at a regional scale has been carried out for 21 earthquakes of the Amatrice-Visso-Norcia Seismic Sequence (2016). This dataset is composed of ML 3 to 4 earthquakes, with depths varying between 8 and 13 km, which focal mechanisms have been determined by previous studies.

The proposed method explaines the differences between observed and theoretical source rise times as due to local attenuation site effect or to an additional station Q. In this way the limiting assumption (constant Q for all the seismic stations) of the previous method is now overcome.

Data analysis and data plotting have been carried out through csh procedures, Fortran based softwares and Matlab scripts.

[1] Dipartimento di Scienze Psicologiche, della Salute e del Territorio, Università "G. d'Annunzio", Chieti. [2] Istituto Nazionale di Geofisica e Vulcanologia, INGV. [3] Dipartimento di Ingegneria Civile e Meccanica, Università di Cassino e del Lazio meridionale.

Corresponding author email: alberto.pizzi@unich.it

Keywords: paleoseismology, seismic hazard, Central Apennines.

The Mt. Morrone active normal Fault (MMF) and the related Sulmona intermountain hanging wall basin constitute one of the most characteristic examples of the extensional tectonic landscape carving the central Apennines of Italy. Above the SW-dipping MMF, extending for more than 22 km in a mean NW-SE direction, concentrates a population of several tens thousands of inhabitants with a thriving industrial and commercial reality, as well as a historical and cultural heritage of great significance documented by archaeological and architectural elements. According to the current knowledge, the last activation event of the whole MMF occurred approximately 2000 years ago (Ceccaroni et al., 2009) and the maximum expected magnitude from fault activation is approximately M 6.6-7 (Gori et al., 2009). Thus, the MMF today constitutes one of the most problematic structures in the central Apennine seismotectonic setting in terms of large magnitude earthquake probability. However, despite this, information on the activity of the MMF rare presently relatively few, both as for associated historical seismicity and paleoseismological data. To strengthen these knowledge weaknesses, we performed new extensive paleoseismological analyses (by means of four trenches dug across the MMF) in the central sector of the fault, specifically in the Roccacasale village area. Our goal was to supplement the limited existing dataset, primarily comprised of a single paleoseismological study (Galli et al., 2015) on evidence of coseismic faulting (situated close to the northwestern tip of the fault). Additionally, we aimed to incorporate findings from a pair of studies focused on archaeoseismological and speleoseismological secondary evidence (Di Domenica & Pizzi, 2017). Through these analyses, we unveiled three significant surface rupture events of the MMF occurred over the past 6000 years Before the Present (BP). Specifically, as for the youngest displacement event (Eq1) that we identified, it occurred after 3.6-3.5 kyr BP, being thus chronologically consistent with the previous paleoseismological and archaeosesismological information that dated the event at 2nd century CE; a penultimate event (Eq2) occurred after 4.4 kyrs BP; a previous event (Eq3) occurred after 5.4-5.3 kyr BP, presumably between 4.8 kyr and 4.6 kyr BP; and the oldest event (Eq4) took place after 9-8.9 kyr and (presumably) before 5.8-5.7 kyr BP. Considering that the cumulative minimum vertical displacement (minimum because we lacked correlative stratigraphic markers in the fault footwall as to define the actual cumulative offset), estimated encompassing the last three events, is approximately 140 cm, that metre-scale large ground chasms opened during these events, and based on the length of the fault at the surface, we can confirm that earthquakes with M 6.6-7.0 may be expected from the activation of the MMF with an inferred average recurrence interval not longer than 1800 years over the last ca. 5500 years.

Keywords: seismo-tectonics, active faults, seismic sequences.

One of the most seismically active areas in Central Italy is located within the Pre-Apennine Umbria region, between the Tiber Valley, the town of Gubbio and the northern sector of the Umbria-Marche Apennine Mountain chain. The main geological structure of the area is the Alto-Tiberina fault (ATF), a 60 km long low angle normal fault active since the Late Pliocene-Early Pleistocene and characterized by a high rate of micro-seismicity (Ml < 3.0) nucleating along the fault plane. A considerable number of synthetic and antithetic faults are located within the ATF hanging wall; among them, the 20 km long Gubbio normal fault produced historical and more recent earthquakes of moderate magnitude (e.g., MW 5.1 1984 Gubbio earthquake). Our study focuses on 5 major seismic sequences occurred from 2010 to 2023 at the hanging-wall of the ATF, located and published in the Database of the Central Eastern Italy Seismometric Network (ReSIICO) (Cattaneo et al., 2019). They are characterized by mainshocks of moderate magnitude up to 4.5 and not associated to any previous mapped fault on the field (Mw= 3.6 - Pietralunga 2010, Mw= 3.6 - Città di Castello 2013, Mw = 3.9 - Gubbio 2021, Mw = 4.5 - Umbertide 2023). We aim to investigate the concept of "on-fault" vs "distributed" seismicity (Collettini et al., 2022) in areas where earthquakes of moderate magnitude occurred without rupturing any major fault at the surface. In this case, we don't know if the seismic clusters trace the rupture along a single segment of a larger fault or if the seismicity is distributed within a "seismic volume" characterized by smaller sub-parallel faults. Our research questions, relevant for seismic hazard definition at a local scale, are the following: first, whether the mechanical stratigraphy of the crust controls the seismicity distribution and second, whether these seismic sequences can be associated to minor faults with a seismic expression. To investigate the first aspect, we performed statistical analysis on seismicity distribution with respect to the four main geological units of the area (starting from the bottom: the acoustic basement, the evaporitic, carbonatic and turbiditic layers). To explore the presence of other minor faults we developed a revised detailed interpretation of a set of 2D-sesimic reflection profiles, acquired in the 80s for hydrocarbon exploration purposes and used in previous works to study the subsurface geology at a regional scale (Mirabella et al., 2011). To improve the correlation between seismicity and geological structures atepth, we relocated the 2010-2023 seismic catalogue using a 3D velocity model derived from geological data (Latorre et al., 2016), integrated with the innovative Markov chain Monte Carlo location algorithm. By combining interpretation of active seismic data with innovative strategies of earthquake re-location and statistical analysis, our study proposes as a significant experience for seismo-tectonic interpretation of low-magnitude seismic sequences.

Keywords: L'Aquila seismic sequence, fault zone structure, seismicity distribution.

The integration of structural geology with high-resolution earthquake location is a fundamental approach to build a comprehensive reconstruction of fault zone structure that is a prerequisite for understanding the time-space evolution of a seismic sequence. As faults accumulate displacement, their length and degree of maturity increase (Cowie & Scholz, 1992) influencing earthquake rupture dynamics and crustal scale fluid flow. Our study focuses on the 2009 seismic sequence, when a mainshock of Mw 6.1 struck the city of L'Aquila in the central region of Italy, activating the Paganica-San Demetrio fault system (PSDFS). This fault system involves multiple sub-parallel N133°E-trending active faults forming a complex structure with an overall length of 20 km. We constructed a series of geological cross-sections that we used to characterize the long-term fault throw and the degree of fault segment interaction. The fault throw profile highlights two main fault segments that merge in a zone characterized by relatively low throw that is partitioned along different small fault segments, resulting in a zone of soft linkage (e. g. Walsh et al., 2003). The PSDFS has also been studied via 2 km-spaced seismological cross-sections normal to the fault system. In each section, aftershock distribution illuminates the earthquake fault represented by <1 km wide zone of earthquake alignment along a SW-dipping structure together with antithetic faults. Furthermore, at shallow depth (1-4 km) the seismicity distribution highlights a sub-horizontal cluster of aftershocks. Within the cluster, the seismicity rate is characterized by a bimodal distribution, with a typical Omori decay followed by a further increase of the seismicity rate at about 15 days after the mainshock. This second pulse of seismicity is associated with a temporal increase of Vp/Vs ratio occurring in the same time window (Chiarabba et al., 2022). Because this cluster is located in correspondence with the fault soft linkage detected by our structural geology analysis, we interpret that this zone of structural complexities represents a preferential path for fluid flow promoting post mainshock fluid migration and favoring the observed clustered seismicity at shallow crustal depth.

Our results suggest that fault zone structure and associated structural complexities can play a primary role in seismicity distribution and crustal scale fluid flow.

Keywords: GNSS geodesy, seismology, hazard.

Over the past three decades, the worldwide growth of continuous and episodic GNSS stations as well as more dense seismic networks allowed the acquisition of extensive geodetic and seismological datasets. This resulted in more reliable applications for comparing geodetic and seismic strain-rates at the scale of regional fault systems. Studies focusing on this topic have provided new insights on the partitioning between fault slip and bulk lithosphere permanent strain. The fundamental notion underlying these studies is that, for a given region, the moment released by earthquakes mirrors the rate of tectonic deformation. Achieved results have allowed us to identify regions in Italy where the crustal deformation budget appears entirely released by seismicity but also regions where the excess deformation could be potentially released either as aseismic slip or through large future earthquakes.In this study we present an analysis of the Seismic Coupling Coefficient (SCC) for Italy by adopting the same structure and input data of the current seismic hazard map MPS04, on which seismic building code provisions are based. The computation of SCC is based on the seismic source zone model ZS9 (Meletti et al., 2008), the earthquake catalogue CPTI04 (Gruppo di lavoro CPTI, 2004) and the related Gutenberg-Richter parameters, expected maximum magnitude and seismogenic thickness, that are used to estimate the seismic moment-rates. Finally, the geodetic moment-rates are calculated from the GNSS velocity field (1995-2022 time interval) available for the Italian territory (EUREF, https://www.epncb.oma.be/; ASI, https://www.asi.it/; RING, http://ring.gm.ingv.it/; and other networks). The SCC analysis has been performed following the Kostrov (1974) approach.

Keywords: Adriatic Sea, seismogenic buried faults, rupture model.

On 9 November 2022, a Mw 5.5 earthquake struck approximately 30 km offshore the city of Pesaro in the Adriatic Sea (Italy), followed by several M4+ earthquakes and numerous minor aftershocks. The tectonic activity in the region is poorly constrained. The area falls in the NE-verging composite seismogenic source ITCS106 (DISS Working Group, 2021), but its seismic activity has been debated due to the absence of historical earthquakes (before 2022) and the lack of evidence of active tectonics in high-resolution bathymetric and seismic data.

Given the proximity of the seismic sequence to the densely populated coastline of the area, accurately characterizing the activated fault and the associated rupture history assumes great importance for a comprehensive seismic risk assessment and for a proper evaluation of the related tsunamigenic hazards.

Exploring seismogenic faults in offshore regions presents various challenges, particularly in delineating their geometry and kinematics. Geological data from deep-sea exploration and geophysical surveys are commonly used to characterize offshore active faults and earthquake hypocentral locations. Nevertheless, limitations in data availability and quality may affect the creation of precise 3D models. Furthermore, the relocation of offshore seismic events, especially in the depth domain, is challenging due to the limited azimuthal coverage and the minimum station-event distance. For these reasons, an interdisciplinary approach that combines geological, seismological, and geodetic methodologies represents an essential workflow for defining seismogenic sources and constructing a comprehensive rupture model in offshore areas.

In this study, we defined the structural setting of the area involved in the Pesaro offshore seismic sequence through the interpretation of 38 seismic reflection profiles and well data acquired over the past decades, provided by oil companies, which integrate several publicly available seismic and geological data.

The interpretation of the seismic profiles enabled an accurate delineation of the principal stratigraphic markers and the thrusts geometry focusing on their relationship with inherited structures. Starting from the reconstructed geometry of the activated fault, strong motion data and continuous GNSS stations, located both onshore (within storage centers) and offshore (on seabed-anchored hydrocarbon platforms), were jointly inverted to reconstruct the coseismic rupture history of the Mw 5.5 event and to precisely delineate the activated portion of the fault plane.

Open questions on the Likva locality K-Pg boundary bed on the Adriatic carbonate platform

Španiček J.* & Korbar T.

Department of Geology, Croatian Geological Survey, Zagreb.

Corresponding author email: jspanicek@hgi-cgs.hr

Keywords: K/Pg boundary, event bed, stratigraphy.

While the K-Pg boundary hiatus is common across much of the Adriatic carbonate platform, exceptions exist, particularly in the southwestern part (present-day Dalmatian archipelago). Here, continuous K-Pg successions and unique deposits at the boundary suggest a possibility of a major event-bed (tsunamite?) related to the Chicxulub asteroid impact. Simulations suggest the impact cratering may have triggered a near-global tsunami, potentially underestimated due to seismic shock-induced collapses along the Yucatan and Cuban carbonate platforms. Submarine landslides along the southeastern North American margin could have further propagated a trans-Atlantic mega tsunami, influencing the K-Pg boundary neritic sedimentation in Europe and Africa (Korbar, 2019).

While Hvar and Brač island yield the evidence of the K-Pg event (Korbar, 2019), additional evidence from a site over 300 km northwest (Karso/Kras) corroborates the existence of a widespread Adriatic carbonate platform tsunami, although precise correlation with the K-Pg boundary and the Chicxulub impact awaits further evidence. Strontium isotope stratigraphy could provide better resolution of Maastrichtian deposits, while the foraminifera could ascertain the supposed Paleocene age of the overlaying deposits.

Likva section (Brač island) provide the strongest evidence of the K-Pg event on the platform), although some researcher argued for firmground (Cvetko Tešović et al., 2020) or even hardground (Font et al., 2017) within the event-bed, suggesting a hiatus in the deposition around the K-Pg boundary. However, as pointed out by Korbar (2019), sedimentological evidence strongly supports the event-bed deposition. With the aim to found further evidence on the origin of the debated K-Pg boundary bed, we analysed the deposit in details and found further evidence on its specific origin.

Diversity of Early Cretaceous carbonate facies around the OAE1a on Adriatic carbonate platform

Španiček J.*[1], Korbar T.[1], Fuček L.[1] & Steuber T.[2]

[1] Department of Geology, Croatian Geological Survey, Zagreb.
[2] Earth Science Department, Khalifa University of Science and Technology, Abu Dhabi.

Corresponding author email: jspanicek@hgi-cgs.hr

Keywords: carbonate platform, Aptian, OAE 1a.

The Early Cretaceous was a period of relatively high temperatures, marked by the occurrence of several Oceanic Anoxic Events (OAEs). Significant is the early Aptian OAE-1a, one of the extreme occurrences triggered by the initiation of volcanic activity within large igneous provinces, leading to a substantial release of CO_2 into the atmosphere, either directly or indirectly. The resultant greenhouse gas emissions set off a series of environmental repercussions. This case study is an example how a tropical carbonate platform responded to the disruptions associated with the OAE1a.

During the Lower Cretaceous, the Adriatic carbonate platform was a subtropical isolated carbonate platform, which existed for most of the Mesozoic. At the beginning of the mid-Cretaceous environmental perturbations, the Adriatic carbonate platform was characterized by subtidal, more open environments characterized by *Lithocodium-Bacinella* (L-B) oncoliths or rudists rich facies, as described from Istria and Dalmatian islands (Husinec & Sokač, 2006; Huck et al., 2010), recognized as the Kanfanar formation. On the island of Vis (central Adriatic, Croatia), deposits underlying and overlaying the supposed OAE1a succession are characterized by monotonous peritidal cycles, while the relatively thick Lower Aptian succession is characterized by significant facies diversifications, recognized as the Barjaška formation.

The base is a thick-bedded dolomite with L-B oncoliths, resembling Kanfanar formation. They are followed by the distinct sub-units stacked one atop another: a) thinly bedded marly limestones - skeletal-peloidal W-P with orbitolinids; b) laterally variously thick sedimentary bodies rich in various rudist and chondrodont shells topped by chondrodont and orbitolinid tempestites; c) bioturbated limestones containing chert nodules with the last occurrence of *Palorbitolina lenticularis* (Blumenbach, 1805); d) *Salpingoporella* unit, representing the shallowing of the depositional environment, characterized in its lower part by layers of M-P rich in oriented *dinaricas* – indicating a shallow, restrictive environment with increased freshwater influence, followed by skeletal W-P with small miliolids and textularids – indicating a re-establishment of marine conditions, and skeletal-peloidal M-W with shell fragments and L-B oncoliths at the topmost part.

Formation ends with layers of marls interpreted as a regional Aptian-Albian emergence. Above succession contains micritic limestones with subaerial exposure evidence and increases fresh water influence alternating with layers of peloid-skeletal P-G with benthic foraminifera, *Mesorbitolina* sp.

Integrated bio- and chemostratigraphy indicate the Early Aptian age of the investigated deposits. Significant facies diversification is observed, partly related to sea level changes partly to changing environmental conditions, but for deposition of about 60 meters of deposits the influence of synsedimentary tectonics is also needed.

The record of the Early Cretaceous Oceanic Anoxic Events (OAE) in the Apennine carbonate platform: insight from the geological mapping of the Sheet 390 - Frosinone (CARG project)

Artegiani F.*[1], Cipollari P.[1], Cosentino D.[1], Rabiee A.[1], Rossetti F.[1], Cipriani A.[2] & Fabbi S.[3]

[1] Dipartimento di Scienze, Università di Roma Tre. [2] Dipartimento per il Servizio Geologico d'Italia, ISPRA.
[3] Dipartimento di Scienze della Terra, Sapienza Università di Roma.

Corresponding author email: federico.artegiani@uniroma3.it

Keywords: oceanic anossic events, Ernici mountains, shallow-water carbonate platform.

The ongoing CARG project gives us the opportunity to investigate with renewed perspectives and different approaches the multiple geological facets of the central Apennines. Here we present the preliminary results of a study related to the geological mapping of the sheet 390 – Frosinone, aimed at the identification and description of the perturbation induced in the Latium-Abruzzi Carbonate Platform by the well-known Early Cretaceous Oceanic Anoxic Events (OAEs).

In the examined area, located in the Ernici Mts., a shallow-water carbonate platform succession, ranging from Late Triassic/Early Jurassic to Late Cretaceous, crops out (Cosentino et al., 2010; Fabbi et al., 2023). This study is focused on the "calcari ciclotemici a gasteropodi" (CCG - Berriasian *p.p.* - lower Aptian *p.p.*) and the "calcari e marne a *Salpingoporella dinarica* e carophyta" (CMS - lower Aptian *p.p.*). A layer of black dolostones, about ten centimeters thick, was observed at the same stratigraphic position in several outcrops of the dolomitic lithofacies (CCGa) of the CCG unit. Moreover, black shales, a few centimeters thick, were observed within the thin CMS unit.

Chemical composition variations on whitish and blackish dolostones (CCGa) were investigated in *situ* using the laser ablation inductively coupled plasma mass spectrometry (LA-IC-MS) facility at Roma Tre University. Results show significant increase of elemental concentration of P, Fe, Zn, As, Ba, Pb, and U, as well as in the Fe/Al ratio in the blackish layers, which are generally considered as redox sensitive proxies associated with anoxic paleoenvironments (Bodin et al., 2007; Craigie, 2018).

Biostratigraphic calibration performed on the samples has shown an Hauterivian *p.p.* age for the CCGa levels and lower Aptian *p.p.* age for the CMS calcareous beds. A preliminary attempt was carried out for U-Pb dating of the CCGa dolomite through the LA-ICP-MS technique. In the Tera-Wasserburg diagram the measured, uncorrected, compositions of CCGa dolomite yielded a lower intercept age of 123.8 ± 3.2 Ma (MSWD=1.6; N=19;). These promising results allow us to hypothesize a correlation between the black dolostones levels in CCGa with the Faraoni event. For the black shales within the CMS, a correlation with the Selli event is likely. Future investigations will aim to consolidate this hypothesis by taking advantage of a multidisciplinary approach between field work, bio-lithostratigraphic correlations and chemostratigraphical analyses.

Soft-sediment deformation structures and Neptunian dykes across a carbonate system: Evidence for an earthquake-related origin (Norian, Dolomia Principale, Southern Alps, Italy)

Berra F.*

Dipartimento di Scienze della Terra "A. Desio", Università di Milano.

Corresponding author email: fabrizio.berra@unimi.it

Keywords: soft-sediment deformation structures, carbonate platform, Triassic.

Identification of the processes producing soft–sediment deformation structures, common in siliciclastic deposits and less abundant in carbonate successions, is complex, because different processes may produce similar structures. Thus, interpreting the origin of these structures may be challenging: it requires both a detailed sedimentological study and the knowledge of the depositional environment and stratigraphic evolution, in order to provide hints to identify the processes affecting sediments after deposition. Among the potential causes of the formation of soft–sediment deformation structures, seismic shock is one of the possibilities, but their origin could be also related to other triggering mechanisms, such as volcanic activity, sediment loading, salt tectonics, fluid expulsion, meteorite impacts and mass movements. Although it is a plausible option, the interpretation of these structures as 'seismites' is not obvious: it must be supported by different lines of evidence, considering that the correct interpretation of soft–sediment deformation structures as a consequence of seismic shocks acquires important implications in palaeoseismology studies The possibility to study and interpret the origin of soft-sediment deformation structures in carbonate successions is favoured when diverse structures are preserved in different subenvironments of the same depositional system. A favourable situation is represented by the Norian carbonate system in the Southern Alps of Italy, where different soft-sediment deformation structures occur in different carbonate facies. Sedimentological analyses provide the chance to characterize different types of soft–sediment deformation structures along a platform–to–basin depositional profile. Presence of pseudonodules in basinal resedimented limestone, sedimentary dykes and clinostratified breccias with unlithified clasts in slope settings and liquefaction of inner platform facies at the platform top testify to an origin compatible with multiple seismic shocks, repetitively affecting the same stratigraphic intervals. This interpretation fits with the evidence of extensional syndepositional tectonics documented for this succession by rapid thickness changes and by the development of strongly-subsiding intraplatform basins within the inner platform domain. The diverse types of soft–sediment deformation structures in the studied carbonate system provide a rich catalogue of structures related to seismic shocks, representing a possible reference for other similar settings, especially for carbonate succession where the preservation and identification of diverse and associated soft-sediment deformation structures is less common with respect to siliciclastic successions.

The drowning of the Trento Platform: facies characterization and depositional changes across the San Vigilio Oolite - Rosso Ammonitico Veronese transition (Lower-Middle Jurassic, Venetian Southern Alps, N Italy)

Coccia N.*, Della Porta G., Berra F. & Marini M.

Dipartimento di Scienze della Terra "A. Desio", Università di Milano.

Corresponding author email: niccolo.coccia@unimi.it

Keywords: Trento platform, drowning, Southern Alps.

The drowning of Jurassic shallow-water carbonate platforms is a widespread phenomenon across the Tethys realm in a context of extensional tectonics manifested with the deposition of red colour, hemi-pelagic nodular limestone, rich in ammonites. The study of the facies deposited during the stages preceding and following platform drowning contributes to the understanding of the causes, modes and timing of carbonate platform demise. The Lower-Middle Jurassic carbonate succession of the Trento Platform (Venetian Southern Alps, N Italy) is a field laboratory for studying the sedimentary record of the onset of platform drowning and demise of a carbonate platform consisting of peritidal facies (Monte Zugna Formation, 120 m thick; Hettangian-Sinemurian), high-energy ooidal grainstone (Loppio Oolitic Limestone, 40 m thick; Sinemurian) and low-energy subtidal lagoon (Rotzo Formation, 200 m thick; Sinemurian-Pliensbachian). The San Vigilio Oolite (10 m thick; Toarcian-lower Aalenian) represents the last shallow and high-energy deposit before drowning and consists of oolitic grainstone with intraclasts and peloids deposited above fair-weather wave base. The upper portion of the San Vigilio lithostratigraphic unit is devoid of ooidal grainstone (20 m thick) and consists, from base to top, of: 1) bioclastic packstone with lithistid sponges, oncoids and coated grains, 2) oncoidal packstone-rudstone with coated grains and bioclasts, 3) coated grain skeletal packstone-grainstone. The abundance of siliceous sponges and crinoids, the lack of ooids and the reddish colour of the upper San Vigilio unit are indicative of a gradual deepening of the depositional environment, compatible with the onset of carbonate platform drowning. A regional drowning unconformity marked by an erosional surface and a hardground composed of mm to cm thick Fe-Mn nodules separates the San Vigilio Oolite from the overlying hemi-pelagic Rosso Ammonitico Veronese (upper Bajocian-Tithonian). The hardground consists of mm to cm thick Fe-Mn polymetallic nodules favoured by low sedimentation rates, enhanced by the sweeping action of bottom currents, removing fine sediment and oxygenating the seafloor. The lower Rosso Ammonitico Veronese (5-11 m thick) overlying the hardground consists of superimposed: 1) skeletal packstone with protoglobigerinids and peloids, 2) bioclastic packstone with *Bositra* thin-shelled bivalves and peloids, 3) intraclastic packstone with bioclasts. This facies superposition demonstrates a gradual deepening of depositional environments from above (San Vigilio Oolite) to below fair-weather wave base (sponges and echinoderms rich deposits; upper San Vigilio) followed by the abrupt reduction in sedimentation rate (hardground polymetallic nodules) and by the establishment of a hemi-pelagic sedimentation (drowning succession; Rosso Ammonitico Veronese) on bioturbated oxygenated seafloors below the photic zone, as confirmed by a drop in the benthic faunal diversity.

Unveiling the architecture and geological significance of mesophotic oyster reefs on the Apulian Continental Shelf: a multiscale approach

de Luca A.*[1], Lisco S.[1], De Giosa F.[2], Gimenez G.A.[3], Pierri C.[3], Acquafredda P.[1], Corriero G.[3] & Moretti M.[1]

[1] Dipartimento di Scienze della Terra e Geoambientali, Università di Bari "Aldo Moro". [2] Environmental Survey, s.r.l.

Corresponding author email: alessia.deluca@uniba.it

Keywords: marine bioconstructions, mesophotic reef, Apulia shelf.

The Apulian continental shelf in the Southern Adriatic Sea is a unique geological region characterized by the formation of various biogenic facies at depths ranging from 20 to 80 meters. These facies result in persistent structures that provide habitats for diverse marine communities and contribute to the complexity of the seafloor topography.

Three distinct biogenic facies have been identified in this region: coralligenous, mesophotic coral reef, and mesophotic oyster reef. The mesophotic oyster reefs of Monopoli have been the subject of several studies in recent years. These studies have documented the distribution, structure, and composition of the reefs, as well as their ecological importance.

The present study provides a detailed analysis of the mesophotic oyster reefs of Monopoli, focusing on their structure, composition, and relationship with the underlying substrate. A multiscale approach was employed, combining field observations, bathymetric data, and laboratory analyses of rock samples. The mesophotic oyster reefs of Monopoli are characterized by a peculiar pinnacular morphology, with oysters - *Neopycnodonte cochlear* (Poli, 1795) - encrusting rocky outcrops and creating complex three-dimensional structures and oysters are typically arranged in "*bouquets*".

The present study provides, using thin sections and image analysis, new insights into the structure, composition, and relationship of the mesophotic oyster reefs of Monopoli with the substrate. The findings of this study have important implications for the conservation and management of these reefs.

The lateral-vertical relationships in facies distribution have been studied to document sea-level rise during the Holocene, providing a framework for understanding past dynamics and predicting future trends in the evolution of shelf communities. The current distribution of these temperate biogenic facies on the shelf contributes to the complexity of the seafloor topography, promoting diverse communities that enhance biodiversity. This work highlights the importance of the Apulian continental shelf as a unique geological region with significant ecological value.

Carbonate platforms: what can still be learned from outcrops?

Della Porta G.*[1], Wright V.P.[2], Samankassou E.[3], Preto N.[4] & Morsilli M.[5]

Keywords: carbonate platforms, outcrops, carbonate factories.

Outcrop studies are the foundation of sedimentary geology notwithstanding the advanced laboratory and digital techniques necessary for the in-depth analyses of collected field data. Exceptionally exposed carbonate platform outcrops of different geological ages and settings (Wright & Della Porta, 2021) provide a unique record of the secular changes and evolution of carbonate systems and the compelling evidence that the present-day carbonate deposits are not necessarily a key to the past for the geological record of carbonate platforms and carbonate-producing factories.

Carbonate sediments and rocks are inherently varied, especially because their constituents are mainly the remains of calcareous animals and algae, as well as the product of physico-chemical and microbially mediated carbonate precipitation. As a result, the distribution, abundance (productivity) and composition (biological, mineralogical and textural) of carbonates reflect ecologic controls, not simply physical processes. Add to that the fact that biological evolution, large scale global climatic, palaeoceanographic and environmental changes, and extinction events have altered the biological make up of seas and oceans over geologic time. Hence, it is little wonder that the resulting nature of carbonate sediments has changed so much. The sedimentary record of carbonate successions, through their composition, geometry and stratigraphic architecture, is an irreplaceable archive of past biological, environmental, accommodation, oceanographic, tectonic and climate changes.

A major theme in understanding carbonate deposition has been that of the carbonate factory and its interaction with accommodation changes and physical processes. Carbonate factories are the sites of formation of biogenic (skeletal, microbial, biologically induced and influenced) and abiogenic (inorganic, chemogenic or physico-chemical) carbonates; and mixtures of these components are found in most carbonate successions. In the Phanerozoic geological record, the microbial carbonate factory represents an opportunistic mode of carbonate production taking over when substrates become available following biotic crises. Carbonate sediments, rocks and platforms have varied through time as their originators and carbonate factories have responded to intrinsic and extrinsic factors linked to global climate change, geodynamics and macroevolutionary changes.

This review comprises carbonate platform systems well-exposed in continuous outcrops from the platform top interior to slope and adjacent basin from the late Paleozoic to the Cenozoic cropping out in Northern to Southern Italy, France, Spain, Morocco, Oman, China and USA. This compilation is intended to provide a means to facilitate other researchers to access outcrops which, while limited in number, illustrate key aspects of carbonate facies character, architecture and controlling factors through time and space.

An unusual rhodolith bed as a record of human activities in Mar Piccolo (Taranto)

Fracchiolla T.*[1], Lisco S.[1], Ravisato M.[2], Pierri C.[2], de Luca A.[1], D'Abbicco V.[1], Lazic T.[2], Acquafredda P.[1] & Moretti M.[1]

[2] Dipartimento di Bioscienze, Biotecnologie e Ambiente, Università di Bari "Aldo Moro".

Corresponding author email: teresa.fracchiolla@uniba.it

Keywords: rhodolith bed, Mar Piccolo, anthropic impact.

Rhodoliths are free-living rocks living on seafloor at various depths. The aggregation of several single rhodoliths forms a unique habitat called Rhodolith Bed (RB). RBs are typically found at depths ranging between 30 and 100 meters; only a small percentage of these habitats are located 25 meters below sea level. Due to their complex structural characteristics, RBs represent a perfect environment for housing various fish species and are crucial marine ecosystems associated with a rich variety of flora and fauna. In the Mar Piccolo basin, a part of marine sector of Taranto city, a RB with an extension of 1.5 km was recently discovered at a depth range from 0.5 m to 2 m (Pierri et al., 2024).

Mar Piccolo is a unique environment due to its exclusive morphology, which defines its temperature, salinity and hydrodynamics features. All these parameters influence RB development and the characteristics of individual nodules.

Rhodoliths were studied describing the outer and inner features of each nodule. Our study characterized rhodoliths development environment and nodules morphological parameters as a product of environment peculiarity. The nuclei discovered in the rhodolith nodules are classified into three main categories: bioclastic nucleus, lithic nucleus and anthropic nucleus. Chemical analyses were performed on anthropogenic nuclei to determine their origin and nature.

In Taranto city, numerous industries and factories are responsible for the high level of pollution in air, water and soils. In this context, marine environments are the final sinks of various human materials and chemical pollutants.

Mar Piccolo rhodoliths are very interesting because: 1. they develop in a very shallow depth range. In the Mediterranean Sea, only two others have been discovered with these features, one in Îles Kuriat in Tunisia (CAR/ASP-PNUE/PAM, 2011) and the second one in Stagnone di Marsala, Trapani, Italy (Mazzola & Vizzini, 2005); 2. Red algae have the ability to isolate and separate any type of material from the surrounding environment. This ability allows them to reduce the dispersion of pollutants from anthropogenic materials and to promote an increase of biodiversity.

The Cassian Dolomite demise: basinal insights on the carbonate platforms' agony (Dolomites, Late Triassic)

Gianolla P.*[1], Caggiati M.[1], Alverà G.[1], Dal Corso J.[2], Riva A.[1] & Aldrighetti E.[1]

[1] Dipartimento di Fisica e Scienze della Terra, Università di Ferrara.
[2] State Key Laboratory of Biogeology and Environmental Geology, China University of Geosciences, Wuhan, China.

Corresponding author email: piero.gianolla@unife.it

Keywords: carbonate platform demise, Carnian Pluvial Episode, paleoclimate.

In the Early Carnian a perturbation of the carbon cycle marked a worldwide biological and climate crisis known as Carnian Pluvial Episode (CPE) (234-232 Ma).The large injection of light CO_2 in the atmosphere-ocean system caused several environmental changes: a general global warming, a transition to more humid climatic conditions, demonstrated by weathering indexes, and a consequent intensification of the hydrological cycle with the arrival of large quantities of siliciclastic material in the basins. One of the major consequences of this climatic perturbation is the global crisis of the Early Carnian carbonate systems. A well known example in the Western Tethys is the demise of the Cassian high-relief, rimmed carbonate platforms and their gradual transition from a microbial dominated carbonate factory to a skeletal dominated one. To clarify the complex dynamics and the interweaving factors that ultimately led to these platforms demise a basinal perspective may be helpful. The basinal deposits of the lower Carnian are represented by the S. Cassiano Fm, coeval with the Cassian platforms, and the Heiligkreuz Fm, which lies above. The crisis of the platforms, synchronous with the first NCIE (upper T. aonoides zone/A. austriacum ammonite zones boundary) of the CPE, is lithologically testified by the gradual disappearance of bio-calcarenite intercalations which also marks the transition between the two formations. The basal part of the Heiligkreuz Fm, represented by the Alpe di Specie mb, reflects the evolution of the platform demise, during which the microbial production was not totally wiped out but mainly moved towards the slopes, where numerous small mounds nucleated. After this critical period a transition from the microbial component of the high-relief carbonate systems to a skeletal component of homoclinal ramp is testified by the platform debris shed in the basin. Following upwards, a relatively thick interval of hybrid arenites and sandstones attests to a strong terrigenous input (A. austriacum zone, Borca Mb). The sharp transition is strictly linked to a significant relative sea-level fall, occurred in a short time span, which also exposed the Cassian platform top, developing karst surfaces.

The performed high resolution stratigraphic study on the available Carnian basinal sections of the Dolomite's region allowed us to better discriminate the stages of these platform-basin systems complex evolution.

Facies analysis of a Cretaceous peritidal carbonate succession cropping out at Cava Porcili (Minervino Murge, southern Italy)

Lippolis E.*, Spalluto L. & Tropeano M.

Dipartimento di Scienze della Terra e Geoambientali, Università di Bari "Aldo Moro".

Corresponding author email: elio.lippolis@uniba.it

Keywords: Cretaceous, carbonate platform, cyclic sedimentation.

Cava Porcili is a limestone quarry located south of the town of Minervino Murge in the western Murge area (Apulian foreland, southern Italy). It is one of the most important quarry in Puglia, due to the discovery of six well-preserved karst caves. Despite its relevant geological importance, it remains quite underexplored for stratigraphic and sedimentological topics. In order to fill this gap, the preliminary results of the stratigraphic and sedimentological study are shown.

The succession cropping out along the quarry wall formed in the inner sector of the Apulia Carbonate Platform that, during the Cretaceous, was situated at a palaeolatitude of 20 to 25° N, along the southern margin of the Tethys Ocean, and was part of the continental Adria Plate. It is about 90 m, consists of well-bedded peritidal and shallow subtidal carbonate lithofacies associations, and belongs to the Calcare di Bari Fm. Although facies analysis testifies that this succession formed in protected shallow-water environments, the occurrence of continental silty clays, interbedded with carbonates, suggests that carbonate sedimentation suffered periods of temporary interruption due to subaerial exposure. Moreover, the vertical organization of lithofacies in beds and bedsets shows a clear cyclic recurrence of both depositional and early diagenetic features. This stratigraphic architecture suggests that relative sea-level changes were probably the main controlling factor of carbonate sedimentation.

This succession is preliminary referred to the upper Albian-lower Cenomanian based on the existing literature (Iannone et al., 1979).

Iannone et al. (1979) - Considerazioni stratigrafiche, sedimentologiche e micropaleontologiche su una successione cenomaniana del "Calcare di Bari" (Murge occidentali). Studi Geol. e Morf. sulla Reg. Pugliese, Ist. Geol. Paleont. Univ. Bari, 9, 28 pp.

The Eocene carbonate deposits of the Gargano Promontory and Tremiti Islands (southern Italy)

Morabito C.* & Morsilli M.

Dipartimento di Scienze dell'Ambiente e della Prevenzione, Università di Ferrara.

Corresponding author email: mrbcld@unife.it

Keywords: Eocene, Gargano Promontory, Tremiti Islands.

The stratigraphic framework of the Eocene deposits of the Gargano Promontory and Tremiti Islands, belonging to the Apulia Carbonate Platform (ACP), has been previously described in literature in numerous works since the late18th century (e.g. Tellini, 1890). These deposits are located in three clearly distinct sectors respectively in the south-eastern Gargano, south of Mattinata (Monte Saraceno), in the north-eastern Gargano, along the coast between Peschici and Vieste, in the Tremiti and Pianosa Islands (Morsilli et al., 2021 and references therein). In particular, previous stratigraphic studies, combined with recent findings on the carbonate factory change occurred during the middle to late Eocene epoch, highlight that this area represents an important stratigraphic archive comparable to worldwide coeval systems (Morabito et al., 2024).

The northern sector, characterised by the Peschici Formation, has been interpreted as a more distal setting. It consists predominantly of alternations, often affected by slumping, of pelagic mudstones with planktonic foraminifera and resedimented deposits, such as calciturbidites and breccia bodies with abundant Larger Benthic Foraminifera (LBF) and clasts with corals and rudists, resulting from the dismantling of Cretaceous and Eocene units.

In the southern sector, on the other hand, the shallow-water to basinal deposits belonged to the Monte Saraceno Sequence are spectacularly exposed and well documented. In particular, the upper intervals of the succession, which are characterised by a sharp transition from nummulitic clinoforms to coral facies, have recently been studied in order to explain their palaeoecological and palaeoclimatic significance (Morabito et al., 2024).

Furthermore, the Tremiti Islands, situated 20 km north of the Gargano Promontory, are mostly characterized by shallow-water settings with abundant larger benthic foraminifera covered by coral-rich facies. Unlike the upper intervals of the Monte Saraceno Sequence, corals in this area exhibit high variability in species and morphology (Morsilli, 2004).

Hence, the exposed Eocene formations on the Gargano Promontory and the Tremiti-Pianosa Islands offer insights into a range of depositional environments, spanning from shallow-water to slope-basin settings, constituting a valuable stratigraphic archive. The objective of this study is to reassess the interpretations of these diverse deposits and to explore their geological significance.

Unraveling the evolution of the Apulia Carbonate Platform and its sedimentary dynamics

Morsilli M.*

Dipartimento di Fisica e Scienze della Terra, Università di Ferrara.

Corresponding author email: mrh@unife.it

Keywords: Apulia Carbonate Platform, carbonate systems, sedimentology, stratigraphy.

The Apulia Carbonate Platform (ACP) stands out as one of the enduring carbonate platforms within the Tethys realm, persisting over an extensive period from the Triassic to the Miocene, punctuated by some hiatuses. Its outcropping succession, spanning from the Upper Jurassic to the Miocene, observable across the transect from Maiella to Salento, along with its submerged portion in the Adriatic offshore, offers a window into the platform's evolutionary history (Bosellini et al., 1999; Bernoulli, 2001).

This platform underwent varied growth dynamics, including progradation, aggradation, and retrogradation, alongside significant shifts in profile driven by evolving biota, environmental changes such as Oceanic Anoxic Events (OAEs), and regional or local factors. These transformations led to notable fluctuations in sediment deposition patterns, bypassing, and erosion along the slope, resulting in a diverse array of inner-platform, margin, and deep-water resedimented carbonate facies, each reflecting unique stratal architectures (Eberli et al., 1993; Morsilli et al., 2021).

The ACP was only partially affected by the orogenic phases that have characterized the broader region, allowing for the direct observation of original geometric relationships and various facies from the inner platform to contemporaneous basin deposits. Furthermore, the eastern margin visible only in Maiella and Gargano, along with the seismic profiles available along the Adriatic offshore, facilitates the reconstruction of the platform's physiography and its spatio-temporal evolution.

In contrast, the western margin of the platform is currently buried beneath the allochthonous elements of the Apennine chain, and limited knowledge stems from intense petroleum exploration leading to the discovery of the Val D'Agri fields. The western extent of the platform and its relationships with the Lagonegro-Molisan basin and the adjacent Apennine Carbonate Platform are not entirely understood.

The main goal of this study is to provide a comprehensive review of the development and evolution of the Apulia Carbonate Platform, focusing on its stratigraphic and sedimentological attributes from outcrops to seismic profiles along the Adriatic offshore. The intricate interplay of factors influencing its development, ranging from biotic evolution to environmental changes, emphasizes the necessity for further investigation to fully understand the complexities of this long-lasting carbonate system.

Lower Messinian *Halimeda* bioherms from the Mediterranean area: new insights on the controlling factors

Passaseo C.* & Morsilli M.

Dipartimento di Fisica e Scienze della Terra, Università di Ferrara.

Corresponding author email: psschr1@unife.it

Keywords: Halimeda bioherms, Messinian, Mediterranean.

Halimeda bioherms are gaining increasing attention in the scientific community due to their significance as carbonate producers and as a stratigraphic and paleoecological archive. Currently, the genus *Halimeda* thrives in both tropical and temperate environments, significantly contributing to carbonate sediment production due to its rapid calcification processes. *Halimeda* can form localized or extensive multi-kilometric bioherms, exemplified by those observed in the northwestern part of the Australian Great Barrier Reef and other tropical areas in the Caribbean and Indian Ocean.

Despite their prevalence in today's oceans, the documentation about *Halimeda* bioherms is scarce during the Cenozoic, showing a discontinuous stratigraphic distribution. Specifically, these bioherms are primarily described in carbonate Messinian pre-evaporitic successions in a few locations around the Mediterranean Sea, even though their first occurrence as reef builders dates back to the Oligocene period (Fournier et al., 2024).

Here we present a comparison of data carried out from stratigraphic and sedimentological analysis conducted on *Halimeda*-rich deposits from three significant sites within the Mediterranean region during the pre-evaporitic Messinian period: the Salento Peninsula (southeastern Italy), the Sorbas and Nijár Basins (southeastern Spain), the Heraklion Basin (Crete Island, Greece).

From field observations, it emerged that the *Halimeda*-rich deposits occurring in the Neogenic basins of southeastern Spain (Braga et al., 1996) and in the Heraklion Basin on Crete Island (Brachert et al., 2007) have developed in a similar mixed carbonate-siliciclastic depositional context. They are found in many locations both as large, isolated mound-shaped bodies and as extensive resedimented layers. The two *Halimeda* deposits of the Salento Peninsula (Bosellini et al., 2002), on the other hand, besides being smaller in size, have developed in a semi-enclosed environment with prevalent carbonate deposition and are located on the reef slope.

The integration of extensive field work, thin section analysis and taphonomic assessment on algal thalli allowed the identification of the main facies. The *Halimeda* deposits occurring in the three key areas exhibit more or less the same facies, predominantly represented by *Halimeda rudstones-floatstones*, along with abundant encrusting organisms like crustose red algae, vermetids/serpulids and acervulinids.

As the remarkable presence of *Halimeda* in the lower Messinian successions of the Mediterranean area is more significant than previously documented, the aim of this study is to shed light on the controlling factors responsible for the growth and development of this algae in the Mediterranean region during this specific stratigraphic interval, and to compare this fossil depositional systems with modern and extensive ones currently thriving in the tropical belt, specifically in the Great Barrier Reef, in order to obtain paleoenvironmental and paleoclimatic information.

Corresponding author email: pshenyuan@foxmail.com

Keywords: pseudo-desiccation cracks, network structure, Feixianguan Formation.

Thin-bedded marlstones in the second member of the Feixianguan Formation, Early Triassic, in the upper Yangtze region, northwestern South China, display pseudo-desiccation cracks of uncertain origin. Field survey show that pseudo-desiccation cracks developed both in the Yangtze carbonate platform margin and platform interior, frequently occurring in laminated or channel-shaped beds 2-10 cm in thickness. At the macroscopic observation, cracks can display quadrangular to pentagonal shape and give origin to reticulate pattern. In vertical cut sections, pseudo-desiccation cracks cut through the marlstone with high angle, and do not display "V" or "U" shape that is instead typical of structures like mud-cracks. Observation in thin section, scanning electron microscope and energy dispersive spectrum analysis show that sparry calcite veins with occasionally forked ends cut through mud clasts and bioclasts in the positions where pseudo-desiccation cracks developed. Carbon and oxygen stable isotopic analyses display δ13C and δ13O values of calcite veins from -14.40 ~ -15.98‰ and -9.99 ~ -10.54‰ respectively, which are lower than those of the marlstone matrix (δ13C and δ13O values of -0.02 ~ 0.61‰ and -9.28 ~ -5.89‰). This indicates that calcite veins should be formed during the diagenetic stage and suggest that pseudo-desiccation cracks are not syn-depositional structures. Therefore, a model is proposed that pseudo-desiccation cracks were formed under diagenetic compaction and the influence of difference hardness and thickness of rock-layers combination, then pressure solution lead calcium carbonate fluid into the cracks and formed calcite veins. In conclusion, the identification of pseudo-desiccation cracks as diagenetic product could be of reference significance for the interpretation of the origin of reticulated limestones.

The record of paleoenvironmental change in Mesozoic carbonate platforms of Western Tethys: some half-baked ideas

Keywords: carbonate platform, Mesozoic, reefs.

The circum-Mediterranean region features a complete, substantially continuous and areally widespread record of Mesozoic carbonate platforms, which recorded profound changes in carbonate production, skeletal and non-skeletal associations and depositional geometries. This region was located about the intertropical belt throughout the Mesozoic, hence, palaeolatitudinal changes were unlikely to cause such modifications, leaving climate, palaeoceanography and seawater chemistry as potential main drivers.

The Mesozoic began with the end-Permian mass extinction, that reset Paleozoic communities of carbonate producers. This episode of mass extinction was associated with a disruption of the carbon cycle that continued for most of the Early Triassic. This time of prolonged perturbation is represented in the Southern Alps by carbonate ramp and clastic coastal deposits with common ooids. Afterwards, Middle Triassic microbial carbonate platforms developed significant relief and became increasingly large.

At least three major perturbations of the carbon cycle impacted on carbonate platform systems after the P/T mass extinction; in the Carnian, between the Rhaetian and the Triassic-Jurassic boundary and at the Pliensbachian-Toarcian boundary. Each of these major events coincided with changes of the shallow water carbonate factories, interrupting the growth of high-relief carbonate platforms. Carbonate production, however, never really ceased and, at times, accumulations of oolites are observed at these events. The response of carbonate platforms to Cretaceous carbon cycle perturbations and related OAEs seem instead less dramatic.

Along with this stepwise evolution, some long-term trends seem to emerge in the carbonate record: a progressive change from mainly microbial carbonates during the Triassic and Early Jurassic, to mainly skeletal by the end of the Cretaceous, and from relatively abundant marine cements and oolitic limestones in the Triassic and Jurassic, to Late Cretaceous deposits virtually devoid of these components. Such patterns occurred along with the steady rise in the abundance of calcareous plankton in Mesozoic oceans, and secular changes in seawater chemistry that led to a switch from the Triassic aragonite-sea to the Cretaceous calcite-sea.

With a few notable exceptions, studies on Mesozoic carbonate platforms of the circum-Mediterranean region focused on specific intervals. We suggest that a more comprehensive view at the time scale of the whole Mesozoic Era may offer insights on processes that impacted greatly on carbonate depositional systems, and that could not be captured by detailed studies on shorter time scales.

Diagenetic and tectonic history of the Upper Triassic, Dachstein-type margin of the Panormide Carbonate Platform (Sicily, Southern Italy)

Randazzo V.*[1], Berra F. [1], Todaro S.[2] & Di Stefano P.[2]

[1] Dipartimento di Scienze della Terra "Ardito Desio", Università di Milano.
[2] Dipartimento di Scienze della Terra e del Mare, Università di Palermo.

Keywords: carbonates, diagenesis, Triassic.

Dachstein-type carbonate platforms bordered the Neotethys Ocean in the Late Triassic, typically developing high-energy reef complexes dominated by corals and calcisponges seaward and inner platform facies landward, where Dolomia Principale-Hauptdolomit inner platform facies were deposited. Boundstone and framestone are characterized by widespread reef cavities filled by multiple generations of calcite cements, as observed in the Upper Triassic margin of the Panormide Carbonate Platform, well exposed in the Palermo Mountains (Sicily, Southern Italy). This platform preserves a sponge-dominated reef complex grading to upper slope massive carbonate breccia, known as *Pietra di Billiemi*. This breccia exhibits not only a complex network of primary porosity but also different sets of fractures (secondary porosity) filled by multiple generations of calcite cements and polychrome carbonate silts (black, white, red, yellow, and less often blue). Transmitted light, cathodoluminescence (CL), fluorescence (FL), and stable isotope analyses (C and O) have been performed on these fills in order to reconstruct the diagenetic history of the *Pietra di Billiemi*. This integrated approach allowed to define and characterize a succession of diagenetic events. Different generations of cements, occurring both in reef cavities and fractures, were identified in FL, while most of them were non-luminescent in CL. First generation of calcite cement (P1) consists of isopachous cloudy radiaxial calcite, dark green in FL, showing the same features both in reef voids and early fractures, thus suggesting an early (syndepositional) origin of primary fracture set (F1). The following P2, bright green in FL, shows clean/cloudy scalenohedral morphology and is related to a second set of subtle fractures (F2) that crosscut P1 and precipitate in persisting voids both within F1 and growth framework (GF), when not completely occluded by P1. P3 shows clean scalenohedral morphology and dark green fluorescence. It is related to a third set of fractures (F3) crosscutting P1 and P2 and filling remaining voids of GF and F1 fractures. P4, clean scalenoedral, is observed only in youngest fractures (F4) showing minor displacement and is bright green in FL. After P4 precipitation, reef voids and fractures can be completely occluded or, when still open, filled by clean blocky calcite, bright green in FL (P5). Polychrome silts (P6; bright to dull luminescent in CL and showing variable tones of green in FL) may follow; clean blocky calcite (P7, black green in FL) eventually fills remaining voids. Data from all calcite cement generations are consistent with Late Triassic marine values both for δ18O and δ13C (-0.5‰ - 1.5‰ and 2.0‰ - 3.5‰). Minor cement dissolution is associated with yellow silt and observed δ18O and δ13C values (P6; 4.7‰ - -4.6‰ and -4.0‰ - -1.2‰) may suggest influx of meteoric water.

Exploring shallow-water carbonate precipitation rates through geological time

Keywords: carbonate precipitation rates, carbonate platform, ocean saturation state.

Carbonate precipitation is a key part of the global carbon cycle and the rate at which this process takes place plays a pivotal role at many levels, from the production of shells and mineralized parts in calcifying organisms to determining the formation and evolution of carbonate platforms. To which extent and how biology and seawater chemistry steer carbonate precipitation, however, is still a matter of debate. We tried to explore the link between carbonate production rates on shallow water platforms in the geological past and some of the main parameters of the carbonate system in seawater, focusing in particular on carbonate saturation state (Ω). We examined 12 stratigraphic intervals of different tropical carbonate platforms, ranging from Devonian to Miocene in age, and estimated for each the carbonate production rate (G) as a mass of carbonate precipitated on a unit area in the unit time. As such, our Gs differ from the usually calculated accumulation rates which are instead computed as thicknesses on unit time and that, being influenced by accommodation, can be considered as crude estimates of actual carbonate production rate. Computing G in the fossil record poses challenges that range from the degree of preservation of the examined carbonate platform to the selection of the stratigraphic interval. Having such estimates and referring to modeled Ω in the geological past (Ridgwell, 2005) allows comparison to laboratory (Burton & Walter, 1987; Zhong & Mucci, 1989) and fields studies (e.g. Langdon et al., 2000) that investigate the influence of Ω on carbonate precipitation rates in abiotic and modern natural systems. In such comparison we also considered the influence of temperature – a parameter that strongly influences carbonate precipitation rates – and the issue represented by the fact that the impact of hiatuses in the completeness of the sedimentary record increases with the length of the time interval that is considered. A Generalized Linear Modeling approach (GLM) was applied on a dataset comprising fossil, modern and laboratory data (250 observations) in order to assess the importance and the mutual interaction of the proposed predictors on the carbonate precipitation rates. Results suggest that Ω is the most influential factor in determining the carbonate precipitation rates and a Ω/G relationship of fossil examples – which are characterized by the dominance of different carbonate precipitation modes – can be modeled by a relationship which is close to that that can model Ω/G of shallow water tropical carbonate systems and that both these latter share commonalities and differences with the empirical kinetic law that links carbonate precipitation rate and saturation state in abiotic systems. These results may help shedding light on the role of biotic influence and Ω in driving carbonate precipitation in the oceans through geological time and may offer insights for predicting future responses of marine carbonate ecosystems under changing environmental conditions.

Cretaceous cyclic peritidal carbonates of the Apulia Carbonate Platform (Apulia, southern Italy) in a hierarchical sequence-stratigraphic perspective: a case study from the Murge area (the Giovinazzo sea-cliff section)

Spalluto L.*, Petruzzelli M., Sabato L. & Tropeano M.

Dipartimento di Scienze della Terra e Geoambientali, Università di Bari "Aldo Moro".

Corresponding author email: luigi.spalluto@uniba.it

Keywords: peritidal facies, relative sea-level change, unconformity zone.

Cretaceous cyclic peritidal carbonates form the bulk of the Apulia Region in southern Italy and represent the vestiges of the Apulia Carbonate Platform (Ricchetti et al., 1988). In order to show, from a sequence stratigraphic perspective, the stratigraphic architecture of peritidal carbonates, the 17 m thick Albian Giovinazzo sea-cliff section was studied at a cm detail, aiming to: i) describe cyclic facies organization in beds and bedsets; ii) reconstruct the relative sea-level curve and its evolution over time; iii) interpret the long-term evolution of the accommodation space in terms of sequence stratigraphy. The hierarchical stacking pattern of facies in beds and bedsets reveals Milankovitch cyclicity (Spalluto, 2012). As a working hypothesis, elementary sequences are assumed to represent the precession cycle (~20 kyr), and small- and medium-scale sequences the short (~100 kyr) and long (~400 kyr) eccentricity cycles, respectively. Four different types of elementary sequences (condensed, catch-down, catch-up and give-up) are recognized and interpreted in terms of relative sea-level changes to reconstruct the relative sea-level curve of the entire succession. The envelope of the reconstructed relative sea-level curve is used to represent the long-term accommodation change on the platform, that covers a time span of approximately 1.8 Myr. Most of this time was spent in subaerial exposure, as approximately 1.2 Myr was predicted to be condensed in a stratigraphic interval encompassing both the sequence-boundary zone/falling stage deposits and the lowstand deposits. Moreover, it was interpreted that about 2/3 of the total thickness of the studied succession was formed in only 280 kyr and consist of both transgressive and maximum-flooding deposits. The main implication of this study is that peritidal succession unconformities do not necessarily correspond to single surfaces but, rather, to very amalgamated intervals or unconformity zones. Moreover, based on biostratigraphic constraints, there is a correlation between the unconformity zone of the studied succession and the third-order KAl4 sequence boundary of the Cretaceous eustatic cycle chart (Haq, 2014).

Keywords: shallow water limestone, carbonate productivity, Lower Jurassic.

The End Triassic Mass extinction (ETE) event was one of the big five mass extinctions that caused the disappearance of more than 70% of marine and terrestrial species. Due to the strict connection with biological activity, the shallow water carbonate environments were mainly involved, suffering the marine acidification and the warming trend recorded at the end of Triassic. After the extinction event, the carbonate sedimentation continued in the shallow water realm, however, the biostratigraphy of Lower Jurassic strata is poorly represented. The microfacies analyses of a Lower Jurassic succession outcropping in southwestern Sicily allow to describe the progressive recovery of the benthic foraminifera community in a sector of the Western Tethys.

The succession consists of peritidal cycles characterized by an alternation of three main lithofacies. The low frequency of the intertidal stromatolitic and supratidal marly horizons allows to belong these lithofacies to an open lagoon bordered by oolitic/bioclastic sandy margins. The microfacies analyses allow to describe a benthic foraminiferal association covering Hettangian-early Pliensbachian interval. In detail, the benthic foraminifera association allows to divide the Lower Jurassic strata into two subunits. The lowermost unit is characterized by the exclusive occurrence of *Thaumatoporella parvovesiculifera* and *Aeolisaccus* sp. The second unit is characterized by an association of *Thaumatoporella parvovesiculifera*, *Aeolisaccus* sp., calcareous algae (*Paleodasycladus mediterraneus*), *Siphovalvulina* sp. and larger benthic foraminifera as *Mayncina termieri* suggesting an increase of taxonomic diversification. The fossil association belonging to the survival unit is characterized by r-strategist taxa capable of living in eutrophic conditions representing the survival phase after the ETE. The occurrence of the larger benthic foraminifera indicates more stable oligotrophic conditions suggesting the recovery phase of the carbonate productivity.

Response of a carbonate platform to the Cenomanian-Turonian Boundary Event: the Akrabou Formation of Southern Morocco

Keywords: Cenomanian-Turonian Boundary (CTB), OAE2, Moroccan North Saharian Platform.

The Late Cretaceous was one of the warmest periods in Earth history, with the acme reached near the Cenomanian/Turonian Boundary (CTB), corresponding with the highest sea-level stand of the Phanerozoic and one of the most important Oceanic Anoxic Events in the geological record (OAE2). This major eustatic sea-level rise led to the flooding of huge portions of continental margins, recorded all along North Africa, from Egypt to Morocco, by the emplacement of a neritic epicontinental carbonate platform known as North Saharian Platform.

Within this context, our research has been focused on Southern Morocco between the Central High Atlas and the Anti-Atlas mountain ranges, where continental sedimentation is interrupted near the CTB by a marine ingression, as witnessed by the development of an open-marine carbonate platform represented by the Akrabou Formation (Ettachfini & Andreu, 2004).

This succession, up to 100 m thick in the more subsiding areas, is characterized by an alternation of bioclastic floatstone and rudstone and laminated mudstones and marls. In the lower portion of the unit, oyster-rich beds are frequent, constituting part of the first bioclastic interval. Upward, the presence of laminated beds, chert lens and carbonate nodules with ammonites underlines a deepening of the system. Above it, a new shallowing upward trend is observed, with the return to more bioclastic levels interbedded with abundant chert plagues and ferruginous surfaces. On top, the re-establishment of continental conditions is recorded by post-Turonian sandstones and siltstones.

Stable isotope geochemistry (d13C and d18O) was performed on bulk carbonates and oyster shells of the Akrabou Fm. Cements were analyzed as well, to rule out the diagenetic signal. A net d13C positive shift of about +3 ‰ VPDB was identified in the sections analyzed, aligned with the values reported in literature for OAE2 (Jarvis et al., 2006). The d13C positive shift take place in the lower portion of the unit, just after the marine ingression, in correspondence with the first bioclastic interval and below the laminated interval. Further up in the succession, the d13C isotopic values decrease to around -2 ‰ VPDB, concurrently with the beginning of the laminated facies, interpreted as the maximum flooding interval. The isotopic signal allowed the correlation between sections at different subsidence rates.

The OAE2 represented a significant stress factor for the epicontinental platform, as evidenced by the temporary shift to deeper environments. However, the crisis of the platform was just transient, and did not determine the shutdown of the benthic carbonate community, as shallow-water bioclastic facies quickly restored after the shorth deepening episode.

Keywords: External Ligurian Domain, sedimentary mélange, Tolfa Unit.

The Tolfa Unit belongs to the eastern succession of the External Ligurian Domain. In northern Latium, the allochthonous succession of the Tolfa Unit tectonically overlays the Meso-Cenozoic Tuscan and Umbria successions. Recent fieldwork conducted as a part of the geological survey for the CARG Project 364-Bracciano provided important insights into the stratigraphic setting of the Tolfa Unit. A comprehensive approach, based on the use of high-resolution imagery, FieldMove software and biostratigraphic analyses, significantly changed the previously known geological and stratigraphic framework of the sedimentary successions outcropping in the western part of the 364-Bracciano sheet. In the study area, stratigraphical and geometrical evidence reveal the presence of an extensive mega sedimentary mélange (OMF) ("il Casone-Monte delle Fate" Olistostrome; Cipollari et al. 2024), lying on top of the Mignone clays (AGM). These latter, in turn, stratigraphically overlies the Flysch della Tolfa (FYT). The calcareous nannofossils biostratigraphic analyses constrain the sedimentary mélange of "il Casone-Monte delle Fate" to the upper part of the middle Bartonian (middle Eocene) and the Mignone clays to the lower part of the middle Bartonian.

Based on these results, we propose a new stratigraphic framework for the Tolfa Unit. Specifically, we suggest the Mignone clays to be formally assigned to the rank of formation. These clays overlie the top of the Flysch della Tolfa (FYT), which has been distinguished in two members: the lower Eocene marly-limestones and yellowish marls of Fosso Anitrella member (FYT2), and the Paleocene - Upper Cretaceous p.p. calcareous argillaceous succession of Poggio Vivo member (FYT1). Finally, the Pietraforte Fm. (Upper Cretaceous p.p.), stratigraphically located beneath FYT1, represents the lowermost stratigraphic unit of the allochthonous succession of the Tolfa Unit.

Keywords: geochemical domains, stream sediments, machine learning.

To deepen our understanding of the phenomena that drive the chemistry of environmental compartments (such as soil, water, and stream sediments), it is crucial to identify the unique geochemical fingerprints of both natural and anthropogenic sources of potentially toxic elements. Historically, geological maps have been used to understand the geochemistry of these environments better, even though geological units are not classified chemically. This study employs a combination of Compositional Data Analysis (CoDA) and machine learning techniques, along with geolithological information, to minimize uncertainty in defining geochemical domains and their reference values for 16 chemical elements. We use, as a case study, geochemical data from 887 stream sediment samples collected across the Volturno River catchment basin in Southern Italy, an area of significant lithological heterogeneity. Thus, we have identified five geochemical domains, or predominant components influencing stream sediments geochemistry: a) carbonatic, b) siliciclastic, c) pyroclastic, d) volcanic, and e) mixed. The predominantly carbonate domain is characterized by sediments rich in Ca, Mg, and Sr and poor in Th, La, Ba, Ga, K, Na, and Al. The predominantly siliciclastic domain shows a relative enrichment in Co, Ni, Fe, and Mn. Both the siliciclastic domain and the volcanic domain include sediments generally rich in Th, La, Ba, Ga, K, Na, and Al. Pyroclastic deposits are enriched in high-mobility elements (K, Na, Mg, Ca), while older volcanic rocks are enriched in low-mobility elements (Th, La, Ti, Ga, Mn). Mixed sediments, derived from a combination of volcanic and sedimentary material, do not show any particular enrichments. The area of each geochemical domain was defined by joining together the basin areas in which the samples belonging to that specific domain fall. Reference values for the geochemical background are calculated and assigned to samples based on their geochemical domains. The results of this study highlight the need to supplement the geological map with a map of geochemical domains, especially in areas with pyroclastic cover and sedimentary successions that show significant lithological variations.

The paleontological heritage and innovative communication modalities for the territorial development

Amore F.O.*[1], Argenio C.[1], Di Vito M.A.[2], Fistola R.[3], La Rocca R.A.[3], Messina M. Y.[4], Panarello A.[5], Rastelli A.[6] & Zingariello I.[7]

Keywords: paleontological heritage, territorial development, mixed reality.

We present the preliminary results from the research project (INSITE) - PRIN 2022 founded by MUR – Ministero dell'Università e della Ricerca. This study focuses on the consideration that geoheritage can act as a driver factor for territorial sustainable development also for cultural and slow tourism, particularly in inner areas. Two sites in Campania region have been considered as case studies because of their paleontology, paleoanthropology, geology, and geophysics significance The site of Pietraroja (PTJ), located in Benevento's province, is the place where a baby dinosaur, *Scypionix samniticus*, was found, drowned in a tropical lagoon about 110 Ma ago, known in the world for its perfect fossilization (Dal Sasso & Maganuco, 2011). The site known as "Le Ciampate del Diavolo" (LCD)" is in Caserta's province and preserves animal and human footprints, very likely referable to *Homo heidelbergensis* or archaic *Homo neanderthalensis*, which are among the oldest and rarest in the world (Mietto et al., 2022). Considering these two paleontological sites as part of the whole system of the cultural heritage supply in Campania, the project INSITE considers two primary levels for their promotion. On one hand, it tries to define a global design to help residents and social parts of the territorial context in which the sites are located realize the uniqueness in which they live.

On the other hand, based on the potentialities of the innovative technologies, the project proposes to develop new models of knowledge by using immersive technologies for virtual, augmented, and mixed reality models and communication modalities supported by widely used devices. Referring to the knowledge model, the use of GIS-based informative technologies allows for the systematization of information in the shared database and the construction of a knowledge model applied to cultural contexts and paleontological sites as a cultural part of the heritage. Referring to the elaboration of digital models, the two pilot sites could be elaborated in mixed reality environments (AR/VR) and, thus, propose additional methods of use than the on-site fruition.

Keywords: multi-proxy analyses, enviromental recostruction, San Giuliano Lake (Matera).

A geological field mapping in the area near Lago San Giuliano (Matera-Italy), and sedimentological, micropaleontological, paleoecological and palynological analyses of a composite section (Meo et al., 2024). These analyses were performed to reconstruct the depositional environment of a fossil cetacean was discovered. The sedimentological analyses, carried out on samples taken from a borehole (Giuli 1) and from a stratigraphic section (Assiolo) identified in the Giuli 1, silt and silty clay that in the upper part of the succession, show the presence of silty-sandy sediments with bioclastic fragments. The Assiolo section, showed silt and clayey silt sediments. The depositional units have been identified and interpreted by means of the sequence stratigraphy (Catuneanu et al., 2011) that provides the context within which to interpret the evolution of depositional systems through space and time. In this framework the SGL stratigraphic succession has been inserted in a in stratal stacking patterns to the responses to varying accommodation and sediment supply through its time span of deposition. The succession is Early Pleistocene in age for the presence, from the bottom, of the nannoplankton species *Reticulofenestra asanoi* CN 13b Biozone. The LO of *Helicosphaera selli*, dated 1.2/1.1 Ma (Raffi & Rio, 1979; Di Stefano et al., 2023) occur in the middle part of the succession at 101, 8 msl and the LCO of *R. asanoi*, at ≈ 0.91 Ma, in the upper part were also detected. The integrated study conducted on the benthonic foraminifera and ostracods assemblages of San Giuliano Lake composite section documented the occurrence, along all the section, of the opportunistic species group, together with episodes of the hypoxic group prevalence, indicating phases of oxygen depletion at the bottom, which are interrupted by sporadic events of bottom re-oxygenation, as evidenced by the increase in abundance of superficial microhabitat oxic taxa, typical of relatively high oxygen and oligotrophic bottom conditions. These patterns allow to define the depositional environment characterized by repeated events relatively high organic matter and low oxygen contents of the bottom water masses and which varies in depth from 600 m to 1000 m from the base of the section up to 1020 ky (≈ 3.5 meters in the Giuli1); from 1020 upwards the depths show a shallowing trend from epibathyal to circalittoral environments. The regionally extinct tree taxa *Tsuga, Cedrus, Pterocarya,* and *Zelkova,* with sporadic appearances of *Cathaya*, *Picea, Carya*, *Liquidambar*, and *Taxodium* type, suggest a late Calabrian age, consistent with nannoplankton data.

Keywords: oblique convergence, orogen translation, Southern Apennines, Calabrian Arc.

The Bradano Basin is a foreland basin lying along the Africa-Apulia/Eurasia plate boundary. It serves as a natural recorder of Plio-Pleistocene tectonic processes because of its physiography and location between the Southern Apennines (SA) and the Calabrian Arc (CA).

Integrated analysis of seismic reflection profiles, exploration well logs, and seafloor bathymetry allowed us to unravel the basin architecture and the interplay between tectonics and sedimentation, providing stratigraphic and structural evidence on deep and shallow morpho-structural processes (Basso et al., 2021). Since Pliocene, two major tectonic events affected the area and controlled the development of three interregional unconformities (MPCU – Middle Pliocene Unconformity; EPSU – Early Pleistocene Unconformity; MPSU – Middle Pleistocene Unconformity) which bound four sedimentary sequences (P1, P2, P3, P4 of Zecchin et al., 2015).

During Pliocene times, an obliquely convergent margin led to collision between SA and CA along a regional deformation zone which is estimated to be ~10 km wide and ~100 km long and is associated with shelf-to-deep marine turbiditic deposits. Around the Pliocene-Pleistocene boundary (~2.58 Ma or EPSU), a sudden and widespread rearrangement took place. The SA front, along with portions of the earlier obliquely collisional margin, started to move toward the NE along progressively deeper detachments involving the lower Apulia plate. During this second phase, the orogenic wedge initially translated for a distance of ~50 km and, since ~0.78 Ma (or MPSU), started to uplift, shorten and fold the seafloor. This second phase is marked by deep marine deposits in the central part of the basin, clinoforms in the shallower western and northern sectors, and mass transport complexes which still shape the seafloor. On a larger regional scale, our data suggest that the deformation zone developed during the oblique convergence affects the upper plate and is the remnant of a Pliocene transfer zone that accommodates differential retreat of the lower subducting Apulia plate. This remnant and reshaped transfer zone, which is now part of the SA-CA accretionary wedge, had to prosecute in the Tyrrhenian Sea (Jolivet et al., 2021; Vitale & Ciarcia, 2013) where it should be reshaped by back-arc extension.

Keywords: Northern Apennines, External Ligurian Units, ocean-continent transition zone.

In the sector of the Alps – Apennines junction (i.e., the Monferrato and Torino Hill) in NW Italy, the Ligurian Units are unconformably overlain by a middle-upper Eocene – upper Miocene episutural succession, represented by the Tertiary Piedmont Basin. In contrast to the Northern Apennines, these units have always been described as an upper Cretaceous–Paleogene(?) undifferentiated chaotic complex or mélange, complicating the reconstruction of the Late Cretaceous - Early Eocene tectono-stratigraphic architecture of this sector.

We document that the undifferentiated chaotic Ligurian Units of the Monferrato and Torino Hill consist of three different units that are well-comparable with the Cassio, Caio and Sporno Units of the External Ligurian Units of Northern Apennines. Their internal stratigraphy reflects the character of units deposited in an ocean-continent transition zone between the northwestern termination of the Ligurian-Piedmont oceanic basin and the thinned passive margin of Adria microcontinent. The inherited wedge-shaped architecture of this ocean continent transition zone, which gradually closed toward north in the present-day Canavese Zone, controlled the Late Cretaceous – early Eocene flysch deposition at the trench of the External Ligurian accretionary wedge during the oblique subduction. This favoured the formation of an accretionary wedge increasing in thickness and elevation toward the southeast, from the Monferrato and Torino Hill to the Emilia Northern Apennines. Our results, therefore, provide significant information on both the paleogeographic reconstruction of the northwestern termination of the Ligurian-Piedmont oceanic basin and the role played by inherited along-strike variations (stratigraphy, structural architecture and morphology) of the ocean continent transition zones in controlling subduction-accretionary processes.

Linking the exposed belt to the buried one: preliminary data and results in the framework of the project CARG 160 Pavia

Keywords: Northern Apennines, Po Plain, transition zone.

The study of complex transition zone between the outcropping front and the buried one of collisional belts usually faces some challenges due to the difficulty in homogenization and correlation of field and subsurface data. An attempt to unravel this complicated relationship, aiming to understand the spatial and evolutionary connection of outcropping units and buried structures, is being pursued in a sector of the Northern Apennines (namely in the central part of the Emilian arc), within the activities for the implementation of the "Foglio 160 – Pavia", as part of the CARG Project. The study area is specifically located at the southeastern portion of the Pavia Sheet, between Casteggio and Stradella (Oltrepo Pavese), where the units exposed in the Northern Apennines outcropping chain slopes rapidly below to the Po alluvial plain. The hill sector includes a Paleocene to Pleistocene sedimentary succession, involved in the SW-NE oriented thrusts and folds of the Apennines front, which can be traced along the western flank of the Emilian arc, currently buried below the Quaternary deposits of the Po Plain where it controlled the syntectonic sedimentation of the Plio-Quaternary sequence (Amadori & al., 2019; Maesano et al., 2024).

In the hill sector, the 1:10.000-scale geological survey activity for the CARG project allowed the collection of a dataset regarding the outcropping units, implemented by the integration with shallow well data provided by local public administrations (Provincia di Pavia, Regione Lombardia), due to the scattered distribution of outcrops and the extensive development of alteration profiles and soils. By contrast, the spatial arrangement of folds and thrusts forming the buried front of this sector of the Northern Apennines below the Po Plain deposits was obtained by a comprehensive 3D reconstruction of the regional scale structures and Plio-Pleistocene unconformities, derived from the integration of well logs and available seismic data (ongoing PHD project by Daniel Barrera Acosta, University of Pavia). Based on this integrated data set, it is possible to carry out several geological cross sections, showing the geometry and mutual relationship of structures and geological units moving from the exposed belt to the buried one.

This work presents a preliminary attempt to correlate and homogenize field and subsurface data, in order to set up a conceptual model of the transition zone between topographic front of the Apennines with its tectonic front and, in perspective, to evaluate the flexural response of the foredeep to the emplacement of the Northern Apennines buried fronts. The obtained conceptual geological model is expected to provide a more complete knowledge of the structural and stratigraphical evolution of the Apennine border, as well as the understanding of the dynamics of frontal chain uplift and foreland basin subsidence and their time/space correlations.

Keywords: Sicilian foreland basin system, syntectonic sedimentation, CARG Project.

The Menfi basin represents one of south-western Sicily's largest wedge-top basins (WTBs), identified by a broad depression mainly oriented NW-SE belonging to a larger Plio-Pleistocene foreland basin system. This basin lies in the outer sector of the Sicilian Fold and Thrust Belt, which consists of Meso-Cenozoic S-verging tectonic units (Saccense Domain) unconformably overlain by Late Miocene-Early Pliocene and Late Pliocene-Pleistocene WTB deposits (Vitale & Sulli, 1997; Catalano et al., 1998; Gasparo Morticelli et al., 2015; Pucci et al., 2023). The field data and samples used for this work were collected during the geological surveys carried out within the Italian National Cartography Project at 1:50.000 scale-CARG Project (sheets n.628 - "Sciacca" and n.618 - "Castelvetrano"), also supported by the analysis and interpretation of different previous data. Sedimentological and stratigraphic analyses were carried out on different outcrops, integrated by detailed calcareous plankton biostratigraphy (planktonic foraminifera and nannofossils), which allowed the reconstruction of a complete chronostratigraphic framework of the Plio-Pleistocene succession. In detail, the stratigraphic succession of the Menfi WTB is constituted at the bottom by hemipelagic marly clays and sandy-silts, laterally and vertically passing to shallow water biocalcarenites (Marnoso-Arenacea del Belice Fm.), Piacenzian-Gelasian in age. This unit is overlain by hemipelagic clayey marls, alternated with inner shelf bio-calcarenites and sands, of the Agrigento Fm. (Calabrian). Conformably overlying the Agrigento Fm., hemipelagic clays and marls with local intercalation of sands and calcarenites, late Calabrian-Chibanian in age, are present. Lastly, marine terrace deposits and continental deposits (late Chibanian to recent in age) unconformably overlie different terms of the Menfi WTB succession. The stratigraphic succession shows an average S-SW dip direction thickening towards the coast and reaching values greater than 1 km. The depositional geometries highlight the interplay between tectonic and sea-level changes characterised by syntectonic sedimentation during the Late Pliocene-Early Pleistocene. In this period main unconformities were generated followed by the deposition of a continuous Calabrian-Chibanian succession, containing only minor hiatuses.

In conclusion, progressive variations of the accommodation space during the growth phases of the Menfi WTB were observed. Notably, in the central-western part, hemipelagic and neritic conditions persisted until the Chibanian, while towards south-east they ended in the late Calabrian.

Keywords: paleoceanography, facies analysis, carbonate ramp.

This study provides a detailed stratigraphic reconstruction of the Oligo-Upper Miocene ramp carbonate sequence exposed in Majella, which is the northern extension of the large Apulian Platform within the Mediterranean region. The performed stratigraphic analysis included a detailed facies analysis integrated by biostratigraphic analysis based on calcareous nannofossils. Six new stratigraphic sections were measured and sampled in the southern and eastern regions of Majella, and correlated with nine previously published sections. This analysis not only facilitates the reconstruction of the stratigraphic architecture but also enables insights into the evolution of oceanographic conditions.

Between the Rupelian and Chattian interval, a carbonate ramp was established, characterized by extensive dune fields in the middle ramp environment, indicating vigorous currents transporting sediment from southeast to northwest. Subsequently, during the Chattian to Aquitanian transition, a shift towards more siliceous facies occurred, marked by deposits rich in planktonic and spicule, suggesting a transition to deeper depositional environments and a reduction in carbonate production, followed by further deepening.

During the Burdigalian, a resurgence of north-directed currents led to the formation of a new dune field in the mid-ramp. Subsequently, from the end of the Burdigalian to the middle Serravallian, a renewed phase of deepening occurred, characterized by the deposition of outer ramp facies with a notable increase in the terrigenous component. Successively a significant drop in sea level resulted in an erosive surface demarcating the lower boundary of the subsequent lower Tortonian to upper Messinian carbonate deposits.

These deposited on an extensive ramp where carbonate production was dominated by red algae in the middle ramp and by the epiphytic component in the inner ramp. Upwards a new drowning is recorded and it is linked to the progressive deterioration of environmental conditions due to the closure of the Mediterranean.

Bioclastic intercalations in the Tortonian hemipelagic marls of the Latium-Abruzzi carbonate platform domain (Central Apennines): the link between oceanography and climate

Keywords: Tortonian, Internal wave, paleoclimate.

The sedimentary record of a foreland basin provides insights into the interplay between shallow-water carbonate production and subsiding basins. This work aims to identify the source and the triggering mechanism behind the deposition of Tortonian bioclastic intercalations found within hemipelagic deposits of the Latium Abruzzi Domain (Central Apennines). These deposits are represented by the *Orbulina* marls that lies on the Burdigalian to Serravallian Miocene carbonate ramp, the *Lithothamnion* and Bryozoan Limestones. The hemipelagic deposits are overlain by turbiditic, siliciclastic succession deposited in the foredeep system. The calcareous nannofossil assemblages at the base of the intercalation indicate a Tortonian age, attributable to Biozone MNN9.

Two distinct types of intercalations were distinguished. The first exhibits a diverse skeletal assemblage comprising oligophotic and aphotic organisms, while the second consists solely of planktonic biota. The presence of these intercalations indicates the existence of an active carbonate ramp during the Tortonian, while the sedimentary structures of carbonate intercalation indicate deposition through gravity flows (turbidity currents). The triggering mechanism for the sedimentation of these deposits has been attributed to the influence of internal waves. These waves emerged as a result of the development of a robust pycnocline, fueled by global and regional climate changes that led to pronounced stratification in the water column due to heightened thermal and density gradients.

Neogene evolution of the inner northern Apennines and the related geothermal systems: insights from the Elba Island

Brogi A.*, Liotta D. & Zucchi M.

Dipartimento di Scienze della Terra e Geoambientali, Università di Bari "Aldo Moro".

Corresponding author email: andrea.brogi@uniba.it

Keywords: Northern Apennines, extensional tectonics, exhumed geothermal systems.

The Neogene evolution of the Northern Apennines was the result of the Cretaceous-Early Miocene continental collision, the subsequent Miocene dismantling of the stacked units and the development of the Tyrrhenian basin. Due to its geographical position, the Elba Island is a crucial sector for the study of this evolution. Indeed the Elba island is part of the inner Northern Apennines and represents an exhumed crustal sector that has undergone: (i) HP metamorphism > 1. 6 Gpa at about 20 Ma; (ii) Miocene extensional tectonics; (iii) Miocene magmatism and associated HT metamorphism, resulting in the emplacement of two intrusive magmatic systems between 8.5 and 5.9 Ma. The Elba island thus represents a natural laboratory for studying the processes related to the the relationships among crustal structures, emplacement of anatectic magmas at shallow crustal levels and the circulation of geothermal fluids leading to the development of ore deposits. This presentation illustrates the up-date knowledge on the geological setting of Elba Island and the implications for the Neogene-Quaternary evolution of the inner Northern Apennines. At the same time, the key role of Elba island in representing an exhumed geothermal system is highlighted, providing key elements for a better comprehension of the Tuscan geothermal systems.

Chronostratigraphy of Palaeozoic formations by means of palynological studies: the case of the Filladi e Quarziti di Buti Formation (Northwestern Tuscany)

Capezzuoli E.*[1], Spina A.[2], Molli G.[3], Brogi A.[4-5], Liotta D.[4-5], Zucchi M.[4] & Degl'Innocenti N.[1]

Corresponding author email: enrico.capezzuoli@unifi.it

Keywords: Palaeozoic, Northern Apennine, chronostratigraphy.

The inner Northern Apennines represent a key area for analyses of Palaeozoic succession and the overlying units. Unfortunately, Palaeozoic outcrops are often patchily exposed in some areas (Tuscan and Latium) and most of them suffer of precise chronostratigraphic attribution, due to metamorphism and the general absence of fossils. One of these formations is the Filladi e Quarziti di Buti Fm (Rau & Tongiorigi, 1974), cropping out in the northwestern sector of Tuscany, in the area between Monte Pisano and Punta Bianca. It consists of intensively deformed and foliated grey-white quartzite and grey phyllite with relics of an older foliation of Variscan age, transposed from Alpine foliation. The base of the unit is never exposed, while at the top it shows erosional relationship (angular unconformity type) with the overlying deposits of the Middle Triassic cycle. Radiometric data on the whole rock give a lower Permian age of 285 ± 12 Ma (Rb/Sr; Borsi et al., 1967) that is interpreted as the closure age of Variscan metamorphism. As regards to the age of deposition, it was attributed to the Silurian (Bagnoli et al., 1979) for petrological analogy with the Ordovician Porphyroids, or to lower Palaeozoic (Cambrian? - upper Ordovician?) for correlation with different metamorphic units exposed in the Apuan Alps (alternatively Filladi inferiori Fm and Filladi superiori Fm by different authors). Generally, no fossils are reported from the formation, even if Bagnoli et alii (1978) reports conodonts (*Pseudooneotodus beckmanni* and *Panderodus* sp.) from a controversial limestone outcrop (and no longer identifiable) internal to the formation and referred to the Middle Ordovician-Lower Devonian. Similarly to other Palaeozoic successions from the Northern Apennines, palynological studies have been here applied to the Filladi e Quarziti di Buti Fm as a possible tool for age attribution and to obtain biostratigraphic data.First preliminary results performed on a number of 10 samples of dark grey phyllites collected in different areas of Punta Bianca and Monte Pisano evidence the presence of a quite diversified microfloristic assemblage of Cryptospores (*Tetrahedraletes medinensis, Dyadospora murusdensa, Dyadospora murusattenuata, Gneudnaspora divellomedia, Pseudodyadospora laevigata)* and Trilete spores (*Emphanisporites rotates, Chelinospora poecilomorpha, Retusotriletes maculatus, Retusotriletes triangulates, Retusotriletes abundo, Concentricosisporites Sagittarius, Ambitisporites avitus, Retusotriletes warringtonii)*. Such a microfloristic assemblage allows us to attribute Filladi e Quarziti di Buti Fm to the Ludlow (middle Silurian).

Tectono-stratigraphic evolution of the Apulia plate and the role of the advancing Southern Apennine/Calabrian Arc wedge on its present-day structural and stratigraphic architecture

Chizzini N.*[1], Artoni A.[1], Torelli L.[1], Quadir A.[1], Polonia A.[2] & Gasperini L.[2]

Keywords: Northern Ionian Sea, Apulia Plate, transpressive tectonics.

In the Northern Ionian Sea, the Apulia plate, a sliver of continental crust covered by about 8 km of Mesozoic carbonates (Maesano et al., 2020), serves as the foreland of two opposed and verging chains. One is the SE-verging Southern Apennine, to the SW, which merges with the Calabrian Arc wedge in the Taranto Gulf (Basso et al., 2021), and the other is the SW-verging External Hellenides, to the NE (Chizzini et al., 2022). With the primary goal of precisely identifying the major tectonic processes that have controlled the onset of the existing structural architecture of this region, we use deep seismic reflection profiles to define the tectonic structures and stratigraphic relationships between the frontal part of the Southern Apennine/Calabrian Arc wedge and the adjacent Apulia plate. Based on seismo-stratigraphic analysis, three main regional unconformities are identified: i) the Jurassic/Cretaceous unconformity is characterized by Cretaceous reflectors that clearly onlap the Jurassic carbonate platform; ii) the Messinian unconformity is connected to a regional erosive event linked to the Messinian dissecation of the Mediterranean basin; and iii) the middle Pliocene unconformity, an erosive and angular unconformity that truncates the Lower Pliocene reflectors. Although the Apulia plate is generally considered a stable region given its foreland setting, our analysis indicates that it underwent significant tectonic activities, with deformative style controlled by its interaction with the nearby Southern Apennine/Calabrian Arc wedge. In fact, an active NW-SE-striking extensional fault system generated due to the Apulia plate bending under the load of the two opposite orogens, is superposed and locally coeval to: 1) smooth and open folds close to the Calabrian Arc wedge-Apulia plate contact zone; 2) several active NE-SW-striking positive flower structures, likely enucleated from inherited Mesozoic normal faults which have been reactivated since the middle Pliocene; 3) mobilized and squeezed Upper Triassic evaporites which form teardrop diapirs (Chizzini et al., 2023). All the above deformations migrate in space since the late Miocene till present days and they are interpreted to be the result of compressive and transpressive regimes related to shortening processes and oblique plate convergence along the Eastern and Western boundaries of the Apulia plate. These observations make both the regional geological context and the pre-collisional grain of the Apulia plate pivotal features controlling the location and geometry of future tectonic structures in the Northern Ionian Sea posing the bases for a more accurate analysis of the natural hazards threatening the populated coastal area.

Keywords: southern Apennines, stratigraphy, tectonics.

We present a review of the orogenic evolution of northern Calabria and the southern Apennines (Vitale & Ciarcia, 2013, 2018, 2022) in terms of stratigraphy (poster 1) and tectonics (poster 2). Three main tectonic complexes characterize this orogenic chain: (1) remnants of the overriding plate, including Variscan Paleozoic basement (Calabria-Peloritani Terrane; CPT) that tectonically cover (2) an Alpine metamorphic belt, corresponding to an exhumed subduction channel, formed by slices of CPT, metaophiolites (metamorphic Ligurian units), and some successions of the continental Adria plate (downgoing plate); in turn superposed to (3) a fold-and-thrust belt made of remnants of an oceanic accretionary prism (non-metamorphic Ligurian units) on the top, and an imbricate orogenic pile consisting in shallow-water to pelagic continental Adria successions, also including the buried shallow-water carbonates of the Apulian Platform. The exposed Apulian Platform domain (Puglia region) and the Adriatic Sea represent the current foreland. The orogenic chain results from the subduction of the Ligurian Ocean lithosphere beneath the European Plate/CPT starting during the Paleocene-Eocene.

The synorogenic sedimentation was ruled by the migration of the forebulge-foreland basin system, with the flexure of the continental part of the Adria plate since the Oligocene with the erosion of a large part of the Apennine and Apulian carbonates that fed the foredeep basins with calciclastic supply. Siliciclastic input, which originated both by the overriding plate and orogenic wedge, joined with orogenic volcaniclastics, marked the sedimentation in the foreland basin system, including the mature stage of the foredeep troughs and the wedge-top basins located on the top of the chain, the latter also recording a calciclastic sedimentation originated by the erosion of the piled-up Adria carbonate successions.

Keywords: southern Apennines, stratigraphy, paleogeographic evolution.

We present a review of the Pliocene wedge-top depocenters belonging to the hundreds of kilometres long Foreland Basin System (FBS) in the southern Apennines (Ascione et al., 2012; Ciarcia & Vitale, 2013). As a whole, the stratigraphic successions are made of clastic deposits, including conglomerates, sandstones, siltites, and clays, organized into several members, reaching hundreds of meters and a maximum thickness of about two kilometres. The oldest Pliocene deposits are of late Zanclean in age and are mainly exposed in the northern portion of FBS. The occurrence of scattered specimens of *Globorotalia margaritae* constrains the lower terms to the upper MPl3 zone; in contrast, the remaining successions fall in the MPl4a zone based on the occurrence of *Globorotalia puncticulata*. A subsequent Pliocene clastic succession, constrained by *Globorotalia bononiensis* and the absence of *Bulimina marginata*, unconformably covers previous deposits.

The filling of the basins started in the northern part of the FBS (Ariano and Ofanto depocenters), characterized by relatively deeper water. In contrast, the southern basins (Calvello, Potenza and Vietri depocenters) were much shallower. The facies associations assemblage indicates alluvial, coastal-marine, and shelf environments. An alluvial progradational system and a gradual transition from neritic to low-gradient nearshore facies occur in the northern sector. Locally, the deposits in the pelitic facies yielded mixed assemblages, containing very shallow (upper infralittoral) and open shelf (circalittoral) benthic foraminiferal and ostracod species. A SE-ward migration of depocenters age, followed by basin filling and uplift, is observed along the southern Apennine FBS in late Zanclean to Early Pleistocene times, associated with the SE migration of the downgoing slab breakoff (Ascione et al., 2012).

The impact of an integrated stratigraphic and structural analysis on the updating of the regional tectonic scheme: an example from the Hyblean Plateau (SE Sicily)

Keywords: regional tectonics, Hyblean Plateau, sedimentation.

The local geometry of geological units is the signature of the interaction between the sedimentary regime and the tectonic dynamics of a region over time. The integration of stratigraphic and structural analyses is therefore crucial in geological investigation, since the reconstruction of a geological setting, regardless of the objectives pursued, needs validation for consistency with the tectono-stratigraphic history of the area. This goal is difficult to achieve if stratigraphic and structural investigations are conducted separately and at different periods.

We here would illustrate how an integrated stratigraphic-structural study, focused on mapping of the Geological 1:50.000 sheet “Ragusa” in the frame of the CARG Project, produced a significant updating of the tectonic history of the entire Hyblean Plateau, in SE Sicily. The area is an uplifted portion of the African continental shelf, forming the peripheral bulge in front of the Sicilian orogenic belt. The plateau consists of a culmination of an Oligo-Miocene carbonate succession, now dissected by distinct fault systems, controlling the main features of the landscape inside the plateau and plio-pleistocene depocenters along its borders.

The new integrated studies have resulted, differently from the past interpretation, in some new relevant insights, summarized as follows:

1. The Hyblean Oligo-Miocene succession consists of shallow-water sediments that are very sensitive to bathymetric variations due to syn-sedimentary deformation;
2. A main unconformity, marked by an obvious stratigraphic gap, separates the nearly homogeneous Late Oligocene-Aquitanian interval (Leonardo Fm.) from the early Burdigalian and Early Langhian horizons (Irminio Fm.), which are instead characterized by impressive lateral variability of lithofacies;
3. Heteropies within the Irminio Fm. occur mainly across major fault segments, as a direct response to differential syn-sedimentary movement between hangingwall and footwall structures;
4. An intraformational Burdigalian unconformity within the Irminio Fm. represents a new horizon-key useful for discriminating, among the set of faults active during Early Miocene sedimentation, the segments that reactivated during later deformation phases;
5. The new stratigraphic scheme implies a reassessment of stratigraphic separation across faults, which generally results in a drastic reduction of the cumulative offset;
6. Comparison of tectonic scarps with the geologically recorded offset is the tool for discriminating between fault-line scarps, along synsedimentary faults, and actual fault scarps along segments that reactivated after the area emerged.

We can conclude that most of the tectonic features of the Hyblean region actually formed during the Early Miocene tectonic deformation and conditioned the distribution of structures that reactivated during the successive stage of bulging and intraplate deformation, that dominate the tectonic picture of the region, since the Late Miocene.

New biostratigraphic data on the hemipelagic succession at the western escarpment of the Apennine Carbonate Platform: insights from the Volsci Range

Consorti L.*[1], Cardello G.L.[2], D'Onofrio R.[3] & Garzarella A.[4]

[1] Istituto di Scienze Marine, CNR, Trieste.

Keywords: biostratigraphy, foraminifera, calcareous nannofossils.

The Late Cretaceous-Eocene demise and drowning of the Apennine Carbonate Platform (ACP) stands out as a captivating phenomenon, with its structural inheritance profoundly influencing both the evolution of the platform to basin carbonate systems and the later development of the Late Miocene Apennine fold-and-thrust belt. This is locally recognized by the occurrence of heterogeneous base-of-slope and epiescarpment hemipelagic successions that cap the edges of carbonate platforms facing the adjacent basins. While these successions have been extensively studied elsewhere in the Apennines, the Volsci Range (VR) remained relatively unexplored, leaving its geological evolution only partially constrained. Building upon initial reports from the Velletri CARG sheet 388 (Servizio Geologico d'Italia, 2021), this study offers a comprehensive characterization at the western ACP margin. We examine stratigraphic contacts, facies composition, microfauna content, and discuss the regional significance of this hemipelagic succession. Exposed along the northernmost VR, the studied outcrops feature a few meters thin and discontinuous succession of Scaglia-type limestone, resting on a shallow-water carbonate succession of Cenomanian-Turonian age. Facies analysis reveals a spectrum of lithotypes including i) Bioclastic glauconitic wackestone-packstone containing coarse echinoderm, gastropod, and green algae fragments, along with planktonic and benthic (sometimes larger) foraminifera; ii) Reddish oxidized wackestone with coral fragments and planktonic and benthic foraminifera; iii) Packstone with a dense occurrence of planktonic foraminifera; iv) Dark hemipelagic wackestone.

The presence of planktonic foraminifera, such as *Acarinina bullbrooki*, *Acarinina topilensis*, *Subbotina senni*, *Globanomalina australiformis*, *Morozovelloides* cf. *crassatus,* which occurrence spans through the E7-E12 Zones (Wade et al., 2011), alongside calcareous nannoplankton species like *Sphenolitus spiniger*, *Furcatolithus obtusus*, *Coccolithus pelagicus* and *Reticulofenestra bisecta* of CNE 15 zone (Agnini et al., 2014) or NP17 Zone (Martini, 1971), indicates a depositional age ranging from late Lutetian to early Bartonian. Based on the patchy distribution of the succession, stratigraphic contacts and facies features, the environment can be interpreted as an escarpment characterized by an articulated topography, which received intermittent bioclastic inputs from an active, no longer exposed, Eocene photic carbonate factory. Notably, the occurrence of reworked Campanian-Maastrichtian calcareous nannofossils suggests winnowing of preexisting Upper Cretaceous deposits. Ongoing research on these hemipelagic successions, dubbed "Scaglia detritica" in the CARG database, holds promise for paleogeographic and regional tectonic reconstructions connected with the evolution of Cretaceous-Eocene platform margins.

Keywords: morphotectonics, intermontane basins, fault kinematics.

The Vallo di Diano basin is a flat-bottomed NW-SE-trending fault-bounded intermontane basin of the axial zone of the southern Italian Apennines. This elongated tectonic depression is bordered to the east by an impressive N140-150°-striking master fault whereas the western flank is articulated by an array of pre-existing N120°-trending left-lateral strike-slip faults. The infill is made of a thick succession (i.e. at least 200 m in the depocentral zone) of lower to middle Pleistocene fluvio-lacustrine deposits and coeval slope to alluvial fan deposits. Their deposition is associated to the higher slip rates of the master fault and such sediments pass upward to middle Pleistocene to Holocene palustrine and slope successions located along the valley flanks. We investigated the evolution of the basin by a multidisciplinary approach based on the integration of geomorphological observations, subsurface geological datasets, and geophysical surveys. Data were interpreted with the aim of building a detailed stratigraphic and tectonic model for the Pliocene-Quaternary deposits and the buried morphology of the Mesozoic-Cenozoic bedrock. Morphotectonic data consist of topographic analysis, drainage network morphometry, river profile analysis, and spatial distribution of alluvial fans and lacustrine depositional tops. The geometry and thickness of the basin infill were constrained by a campaign of seismic surveys integrated with stratigraphic data coming from deep and shallow boreholes. ESAC method and HVSR curves were tested as effective tools to reconstruct the architecture of the subsurface deposits and the Quaternary offsets of the basin-border faults. Finally, data interpretation allowed us to chronologically constrain the activity of several faults and to reconstruct the Quaternary evolution of this intermontane basin, where relevant anthropic activities persist.

Constraining the early stage of the post-orogenic extensional tectonics in central Italy: new evidence from a long sediment core from the tectonically active L'Aquila basin (Central Italy)

Keywords: central Apennines, intermontane basins, post-orogenic tectonics.

The central Apennines is among the most seismically active sector of the central Mediterranean region, as testified by the recent sequence of earthquakes with Mw >6 (L'Aquila Mw 6.3, 06/04/2009; Amatrice Mw 6.2, 24/08/2016), which recently struck it. Although many recent studies focus on the recent history of the active and seismogenic faults, due to the poor understanding on the age of the tectonically bounded intermontane basins and on the early stage of their continental deposition, less is known on their long-term behavior.To try to fill this gap of knowledge, in this work an integrated multiple-dating approach, including 40Ar/39Ar dating, magnetostratigraphy, multiproxy paleoclimatic data (palynological analyses, Pollen Temperature Index and clumped isotopes), and astrocyclostratigraphy, was applied on a long sediment core (230 m depth, Castelnuovo 1 borehole; CN-1) recovered from the infill of the Plio-Pleistocene tectonically active L'Aquila Basin (Paganica-S. Demetrio-Castelnuovo Sub-basin -PSC).

Combining the results from the CN-1 pollen record, the 40Ar/39Ar dating of a tephra (1.77 ±0.15 Ma), and the magnetostratigraphy of the CN-1 sediment core, we can refer the longest normal polarity interval (N3) to the Olduvai subchron, which we use for constraining the CN-1 age model. Moreover, spectral analysis of the CN-1 calcimetry data series shows the presence of 13 obliquity-modulated cycles, resulting in an age of ca. 1490 ka, for the top of the core, and an age of ca. 2027 ka, for its base. This time span encompasses the Marine Isotopic Stages (MIS) 75 to 50. The occurrence of lacustrine ostracod fauna since the lowermost portion of the CN-1 core points to the presence in the PSC Sub-basin, already at 2 Ma, of a well-developed intermontane lake. Both pollen record and clumped isotopes show warm-to-cold climate changes along the CN-1 sediment core, with temperatures of 15.4 ±1.6 °C (MIS 53) and 11.5 ±1.3 °C (MIS 52), whereas temperatures of 21 ±1.7 °C and 15.6 ±1.7 °C correspond to MIS 67 and MIS 64, respectively.

The PSC Sub-basin shows a complex subsurface architecture, with thresholds and depocenters showing maximum thickness of the lacustrine deposits up to 450 m. Since the CN-1 age model points to a sedimentation rate of 0.3 mm/yr for the deep lacustrine deposits, the onset of the continental sedimentation in the L'Aquila intermontane basin started at ca. 3 Ma. This age for the post-orogenic formation of the tectonically active L'Aquila Basin is well in agreement with the kinematic evolution of the central Apennines, where the last documented compressional tectonic phase occurred at ca. 3.5 Ma. This post-orogenic extensional domain, which is still active, represents an archive of ca. 3 Myr of continued crustal extension and one of the most seismically active sectors of the central Mediterranean region.

Microfloristic evidence in metamorphosed rocks of Elba Island: new constraints and correlation of the early Palaeozoic

Keywords: palynomorphs, Elba island, Central Mediterranean.

Elba Island, located in the Northern Tyrrhenian Sea, is part of the inner Northern Apennines, an alpine chain deriving from the convergence and collision (Cretaceous–Early Miocene) between the Adria microplate and the Sardinia-Corsica Massif. The age of the Palaeozoic protolith of the metamorphic rocks has always been uncertain due to the HT-metamorphism caused by the emplacement of a Messinian monzogranite.

The Palaeozoic rocks of Elba Island are part of three tectonic Units (Bianco et al., 2015). The succession occurring in the deepest tectonic Unit is attributed to ?Precambrian and Palaeozoic and is mostly composed of micaschist, quartzite and phyllite, covered by continental metaconglomerate and metapelite -to-littoral dolostone, metalimestone and phyllite. The second tectonic Unit consists of micaschist overlaid by felsic metavolcanics with local typical augen texture (porphyroids) to which porphyritic schists are interlayered, particularly in the upper part of the succession. Porphyroids and porphyritic schists were dated through geochronological methods and referred to Middle Ordovician (Sirevaag et al., 2016). These are covered by phyllites and quartzitic phyllites dated at the Middle Ordovician and Silurian and Carboniferous-Permian. The third tectonic Unit consists of low-grade metamorphic rocks formed by phyllite, metasandstone and metaconglomerate (Rio Marina Fm), attributed to the late Carboniferous-Permian. In the present study, we report palynological data from the succession exposed in the lower part of the first tectonic Unit cropping out in the Ortano and eastern side of the Monte Calamita areas. The succession consists of brown to grey-greenish cornubianitic quartz-muscovite-biotite micaschist with levels of quartzite, metasandstone and blackish phyllite. Microflora yielded mainly consists of permanent tetrad as *Tetrahedraletes medinensis*, dyad as *Dyadospora murusattenuata* and *D. murusdensa* and monad as *Gneudnaspora divellomedia* in assemblage with smooth and ornamented trilete spore as *Chelinospora poecilomorpha*, *Concentricosisporites sagittarius*, *Emphanisporites rotatus*, *Retusotriletes triangulatus* and others. Based on comparison with similar microflora recorded in Laurussia (UK, Ardenne-Rhenish region, Canada and Nova Scotia) and in the Western Gondwana (Tunisia, Algeria, Spain, Britanny, Libya, Turkey and Saudi Arabia), the present assemblage is here attributed to the Wenlock (Homerian)-Ludlow time interval. This is the first findings of a Silurian microflora in the Northern Apennines: the palynological study has proven to be an excellent tool helping to resolve stratigraphic and geodynamic problems even in rocks affected by pervasive dynamic HT-metamorphism.

pH soil measurements of the Sant'Antuono CO_2 gas vent in the Sannio area (southern Apennines, Italy): insights on the active Southern Matese Fault system

Fabozzi C.*

Dipartimento di Scienze e Tecnologie, Università del Sannio, Benevento.

Keywords: pH soil surveys, non-volcanic CO_2 vents, southern Apennines.

pH is one of the most frequently measured parameters in standard soil analyses and probably the most valuable single indicator, especially in cultivation, for soil functioning and processes (Borggaard, 2000). Measured soil pH values offer insight into the chemical-physical reactions occurring in the soil. This work presents a study of the area around Sant'Antuono spring, located in the Solopaca hills (SE sector of the Matese Massif). This area is characterized by small scattered vents including the Sant'Antuono spring that represents the main non-volcanic CO_2 gas vent. Furthermore, in the whole area, acid fouling and alteration spots occur. This results from the soil pH survey carried out in the area around the CO_2 gas emissions. The pH soil measurements range from 2 to 8, indicating the coexistence of soil portions characterized by pH from highly acidic to weakly basic. The spots characterised by pH=2 are well-defined, localized, and relatively small (a few metres), suggesting that the phenomenon contributing to soil acidity follows specific pathways. Consistent with soil exhibiting such acidity levels, a whitish patina forms on the ground surface, associated with an absence of vegetation, indicating unfavourable conditions for biological activity. This important data fits in well with the findings of the study published by Vitale et al. (2023) and other geophysical investigations conducted in this area, adding a further piece to the characteristics of the ongoing phenomenon.

Keywords: mud volcanoes, southern Apennines, multidisciplinary surveys.

In this study, we present the results of an integrated multi-methodological approach to illuminate the relationships between the mud emission, which characterizes the "*Bolle della Malvizza*" mud volcanoes, and fault. Our aim was to investigate the mud and gas leakage process and source. The mud volcanoes of *"Bolle della Malvizza"* are situated in the Irpinia sector of the southern Apennines (southern Italy), in the Upper Cretaceous-Upper Miocene Fortore succession (Lagonegro-Molise Basin). Specifically, they are hosted in Upper Cretaceous-Burdigalian varicoloured clays with intercalations of calcareous turbiditic beds covered by upper Tortonian-lower Messinian unconformably clastic deposits of Castelvetere Group. These volcanoes emit mud, salt water and gases (CH_4 and CO_2). They are concentrated in a narrow area of ca. 5000 m2 in nine main groups, which vary in size (from a few centimetres to 13 meters) and height (from ca. 3 to 15 cm). These sedimentary structures are aligned along the directions ENE-WSW and N-S in correspondence with two main normal faults. Our research was approached with a multidisciplinary study, including stratigraphic and structural surveys, topographic evaluations using drone photogrammetry and a Virtual Outcrop Model, geophysical investigations using Electrical Resistivity Tomography (ERT), Induced Polarization (IP) and Self Potential (SP), and geochemical exploration through CO_2 and radioactivity soil flux, and pH soil measurements.

3D Structural architecture of the front of the Sicilian Apennine (Southern Italy) as derived from well-calibrated seismic reflection profiles interpretation

Gambino S.*[1-2], Conigliello E.[1], Monaco C.[1-2-3] & Barreca G.[1-2-3]

[1] Dipartimento di Scienze Biologiche, Geologiche e Ambientali, Università di Catania.

Keywords: chain front, 3D model, seismic profile, well-log data.

The front of the Sicilian Apennine in southern Italy is a roughly E-W regional structural feature which extends for several km both on-land (Gela-Catania) and offshore (Sicily Channel), separating the Sicilian fold-and-thrust-belt to the North from the under-thrusted foreland domain to the south. While mapped in several regional maps and structural sketches, the tectonic architecture of the Front along with its space/time evolution are still poorly constrained. To reconstruct its 3D geometry and retrieve tighter constraints about its kinematics (e.g., cylindrical and/or oblique), propagation time, and deformation rates, commercial multichannel seismic reflection profiles and well-log data (available from the VI.DE.PI. national repository, www.videpi.com) were analysed within a 3D digital environment in the offshore sector between Gela and Sciacca. The seismic dataset includes about 100 km-spaced T.W.T seismic lines oriented parallel to the coast (WNW-ESE) and transversally (N-S). About 20 wells, drilled in the offshore during 60's-80's, have been also considered to i) gain additional information on the age of the offshore sedimentary units, ii) to calibrate the main reflectors along seismic lines, and iii) to build a velocity model for a reliable time-depth conversion of the seismic dataset. Seismic lines (released as PDF format) were initially checked and managed to reduce geometric distortion, which is common with most of the scanned copies of available geophysical profiles. Wells-log data were revised and the drilled units renamed to be in line with the modern stratigraphic nomenclature available from literature. All input data have been then converted as digital 3D features within the Move software package (Petex ltd), and seismic lines were interpreted on screen following age constraints coming from wells-logs data projected to seismic sections. Once all the horizons were picked, line-to-surface interpolation allowed modelling the 3D structural architecture of the Front whereas internal reflectors pattern of most of the illuminated seismic units provides insights on its latest tectonic advancement. Preliminary interpretation confirm that the front emplaced during the Plio-Pleistocene, propagating on an irregular paleo-surface corresponding with the top of the underthrusted Hyblean carbonates (mostly Hybla and Amerillo Formations). Basement buttressing and tectonic elision have locally controlled differential advancement of the front and hence its final shaping. Frontal thrusting is generally accompanied by the development of roughly coaxial splays that show evidence of over-step propagation. Further 3D elaborations will allow a better understanding about thrusts architecture and their deformation timing. In addition, numerical simulations such as back/forward modelling will be performed to retrieve information about the long-term tectonic shortening of the front.

Groundwater-rock interaction and mixing in fault-controlled karstic aquifers: a structural, hydrogeochemical and multi-isotopic review of the Pontina Plain (Central Italy)

Keywords: hydrogeology, normal fault, Apennines.

Regional karstic aquifers represent indispensable water resources, the effective management of which relies on well-defined tectonic and hydrogeochemical models. This study investigates the complex groundwater-rock interaction and mixing processes within a fault-controlled karstic aquifer adjacent to the Pontina Plain at the piedmont of the northern Volsci Range in the Central Apennines. We conducted field-based structural, hydrogeochemical, and multi-isotopic screening of ten selected springs with different mineralization degrees, ranging from Ca-HCO3 to Na-Cl hydrofacies. Our analysis incorporated novel assessment and modeling for δ 34S(SO4), δ 18O(SO 4), 87Sr/86Sr, and δ 11B. Additionally, a seismic stratigraphic section extending to a depth of about 5-7 km provides a detailed geological framework, identifying the geometry of normal faults serving as pathways for upwelling fluids. Our findings unveil complex hydrogeochemical compositions resulting from multiple interactions across shallow to deep systems, with mixing increasing towards the southeast. Employing geothermometers, alongside geochemical modeling and trace elements

analysis, enabled the estimation of water temperature equilibrium with Triassic evaporites at 95.5 ± 3.5 °C, likely corresponding to a depth of about 3 km. Further equilibrium temperatures, potentially associated with ultrapotassic volcanic rocks at 35.5 ± 6°C, possibly indicating interactions with a diatreme of the tectonically-controlled Volsci Volcanic Field at approximately 1 km depth. This multidisciplinary approach enhances the understanding of groundwater behavior in fault-controlled karstic aquifers, potentially involving deeper crystalline basement or magmatic-derived fluid components. From a regional perspective, this work lays the groundwork for further studies on the regional mixing processes affecting fault-controlled aquifers. Beyond regional interest, this research bears implications for water resource management and environmental protection strategies in similar geological settings worldwide.

Seismo-stratigraphy architecture of the transgressive and highstand systems tracts during the Last Glacial-Holocene and the NYT reflector in the Gulf of Gaeta (Eastern Tyrrhenian margin, Italy)

Keywords: seismic stratigraphy, transgressive system tracts, Neapolitan Yellow Tuff.

The Neapolitan Yellow Tuff (NYT) caldera-forming eruption (ca. 15 ky, Deino et al., 2004) is a large event that occurred at Phlegrean Fields during the Late Glacial – Holocene. The eruptive products represent a widespread isochronous marker that links the marine and terrestrial archives of the central Mediterranean area and Northern Europe. In this work, we describe the stratigraphic signature of the NYT deposits in the Late Glacial - Holocene shelf sequence of the Gulf of Gaeta (northern Campania region, southern Tyrrhenian Sea) throughout the seismo-stratigraphic interpretation of a grid of high-resolution Chirp seismic profiles. The Late Pleistocene - Holocene stratigraphic architecture of the continental shelf is characterized by an offlap prograding succession followed by a very thick transgressive onlapping unit and by the upper highstand unit, mainly characterized by undulations probably linked to gas-prone sediment. The NYT reflector observed is parallel and displays a high amplitude. It has been continuously detected from the shelf to the slope within the transgressive deposits. On the inner shelf, its continuity is interrupted by shallow gas pockets. The NYT depths ranges from 2 ms bsf on the slope to 38 ms bsf on the continental shelf, reaching maximum thickness at the Volturno River mouth. The NYT event appears to have played a key role in controlling the stratigraphic architecture of the studied area during the last transgression, acting as a trigger for the formation of the aggradational sedimentary successions fed by pyroclastic and volcaniclastic deposits.

Deino A.L. et al. (2004) - The age of the Neapolitan Yellow Tuff caldera-forming eruption (Campi Flegrei caldera, Italy) assessed by 40Ar/39Ar dating method. J. Volcanol. Geotherm. Res., 91(2–4), 285, https://doi.org/10.1016/S0377-0273(03)00396-2.

Alternative origin for the Middle Miocene mass transport deposits of the Marnoso Arenacea Formation

Mainini A.*, Conti S. & Serventi P.

Dipartimento di Scienze Chimiche e Geologiche, Università di Modena e Reggio Emilia.

Corresponding author email: alessio.mainini1999@gmail.com

Keywords: foredeep intrabasinal high, Miocene, seep-carbonates.

During the Miocene, the migration of the northern Apennine accretionary wedge produced a segmentation of the inner part of the foredeep. The segmentation was related to the growing of anticlines on top of blind thrust faults, creating various intrabasinal highs draped by fine-grained sediments (Conti, 2001). The progressive growth, deactivation, and migration of intrabasinal highs were coupled with an intense seepage activity, occurring at various levels of the pelitic intervals (Argentino et al., 2019; Conti et al., 2021). Various portions of pelitic sediments above the intrabasinal highs are involved in spectacular slumps. In some cases, pelitic intervals are associated with extraformational deposits sourced by Ligurian- Subligurian Units and were interpreted by some authors as mass transport complexes (MTC). Stratigraphic studies on Visignano pelitic interval (Upper Serravallian), located in the "Alto Mugello," along the border between the regions of Emilia Romagna and Tuscany (Northern Appennines), show elements in conflict with MTC interpretation, which should be limited to the extraformational portions of the intervals. The internal stratigraphic coherence, the concordance with enclosing deposits, the texture of fine-grained deposits, the presence of peculiar soft sediment structures, seep-carbonates, sinsedimentary faults, peculiar ichnofacies, transitional facies to basin plain turbidites, and glauconitic hardgrounds indicate that sediment instability was limited to the temporary slopes of the intrabasinal highs. The new data reveal a complex scenario useful to explain the evolution of pelitic intervals. The genetic model proposed, would be linked to structural highs characterized by depressions and axial culminations where migration and expulsion of fluids allowed authigenic carbonate precipitation, instauration of chemosynthetic fauna and limited sedimentary instability. Structural highs interact with mass transport deposits sourced by the slope of the accretionary prism. The highest culminations can also be the site of prolonged starving of sedimentations, with the consequent formation of glauconitic rich sediments.

Calitri Town is located in the irpinian sector of the Southern Apennines. The stratigraphy of the pre-Quaternary substratum (Ascione et al., 2012; Giannandrea et al., 2014; Servizio Geologico d'Italia, 2024) is dominated by the presence of a strong competence contrast among clayey units (Andretta Synthem, Lower Pliocene; SAD) and silty-sandy dominated units (Ruvo del Monte Synthem, Lower to Upper Pliocene; RVM). RVM highly competence portions are responsible for setting of the SW-NE strike of Calitri and Calvario hills and the conformal trending of minor left tributaries of the Ofanto River. In detail, the Cascina Creek, that bounds the eastern slope of the Calitri hill, can be related to the outcropping of the para-conformal, tectonized, contact between SAD and RVM. E-W, N-S and NNE-SSW morphological lineaments are in good accordance with the tectonic setting of the area. The Quaternary deposits are mainly represented by slope-related and fluvial deposits. The drainage system seems to be greatly controlled by tectonics, the Ofanto R., the main hydrological feature of the study area, appears in its mature stage, associated with almost five orders of morphological surfaces. Finally, the study area is widely affected by the presence of landslide related morphologies. We reconstructed the tectonostratigraphic setting of the study area using a classical field geological survey, aided by aerial photointerpretation and geognostic data from available boreholes. Detailed delineation of main geological contacts has been defined using surveys with low-frequency Ground Penetrating Radar: a powerful tool able to high penetration and accurate resolution, enough to retrieve main stratigraphical features of the pre-Quaternary substratum and refine geometry of recent gravity-driven mass movements.

Keywords: Umbria pre-Apennines, foreland basin systems, Marnoso-arenacea foredeep.

The Umbrian pre-Apennines are characterized by extensive outcrops of the Marnoso Arenacea Miocene turbidite foredeep succession whose tectono-stratigraphic history is still under debate. Until recent years, the physical stratigraphy of these successions was poorly known and the biostratigraphic data were also unevenly available. As a consequence, the correlations between the different successions were poorly constrained and some aspects of the tectonic evolution of the foredeep, including the timing of deformation, remained unresolved. In north-central Umbria, a unique opportunity to fill this gap of knowledge, is provided by the carrying out of new high-detailed geological mapping at 1:25.000 scale, in the framework of the national CARG Project. After three years fieldwork, supported by the application of the most suitable analytical methodologies, we are finally able to synthesize a large amount of data that highlight the main depositional and deformational events and the mutual relationships between tectonics and sedimentation in the Miocene foreland basin system. A detail geological-structural mapping was accompanied by elaboration of composite LOGs, obtained by correlating several stratigraphic sections measured in the field. The latter were constrained and correlated by quantitative nannofossil biostratigraphy and petrographic determinations, which led to determine and characterize the different sedimentary inputs that fed the foredeep. Finally, to implement the field data and reconstruct the three-dimensional geometry of the structures at depth, a study of the subsurface was carried out interpreting a set of commercial seismic sections down to the buried top of the Meso-Cenozoic carbonate multilayer (depth~ 1- 1.5 km). Such a multidisciplinary approach allowed us to: (i) elaborate original and detailed geologicalstructural maps showing the thrust-related internal subdivisions of the basin (tectonostratigraphic units); (ii) obtain an overall litho-biostratigraphic reconstruction of the successions cropping out in most of the Miocene foredeep basin; (iii) highlight the presence of peculiar sedimentary bodies, having limited extent but local stratigraphic importance, derived from transversal Apennine sources; (iv) highlight the subsurface geometry and continuity of the main contractional tectonic structures affecting the study area; (v) elaborate a synthetic evolutionary scheme of the Umbria foredeep related to the chronology of the compressive deformations.

3D Structural model of the Messinian Umbria-Marche Foredeep basin: insights from the Ascoli Piceno sector, southern Marche (Italy)

Keywords: balanced geological sections, fold and thrust belts, 3D model.

Understanding tectonic structures and the relationships between stratigraphic units in depth is a fundamental challenge for geologists. This goal has been pursued through the interpretation of geological and geophysical data in one or two dimensions and through structural analysis. Three-dimensional geological modeling synthesizes geological data and knowledge, aiding in the comprehension of subsurface structures through improved visualization (Basilici et al., 2023). This approach has been particularly valuable in the study focused on the sector analyzed in the northern Apennines foredeep basin, specifically the Laga turbidites (Milli et al., 2007).

The Laga basin, a key depositional player during the Miocene, bridges the internally uplifted Lower Miocene Umbria-Marche fold-and-thrust belt to the west and the newer segment of the chain buried beneath synorogenic Plio-Pleistocene clastic deposits to the east (Bigi et al., 2009). It is comprised mainly of turbiditic sedimentary sequences defining a deep-marine foredeep to wedge-top basin. This study concentrates on the southern part of the Marche region, a transition zone to the largest turbiditic depocenter of the Apennine foredeep in the southern Abruzzo region (Artoni, 2003).

Recent outcomes of the updated 1:50,000 national geological mapping project for the Sibillini area (Sheet Ascoli Piceno-326) provide an opportunity to review and propose the first detailed 3D model of the area. Specifically, it examines the Messinian Laga siliciclastic turbidites from the Sibillini Mountains to the Montagna dei Fiori anticline, showcasing a general fining and thinning-upward trend indicative of eastward basin migration and its relationship with the main eastward Pliocene unconformities outcropping in the area.

Our methodology involved the integration of a variety of techniques including surface geological mapping, seismic interpretation and well data correlation, cross-section balancing and restoration, and gravimetric modeling. To characterize the complexity of structural style and stratigraphic variations of the area, we constructed thirteen W-E balanced cross-sections using a 10 m-cell size Digital Elevation Model and the brand-new geological map in a 3D environment. To outline deep structural frameworks, vintage seismic line datasets, and borehole data were interpreted, and depth-converted to perform a 3D structural model illustrating thrust belt geometry.

The resulting 3D model provides a comprehensive overview of the foreland basin associated with the northern Apennine chain and the geometrical arrangement of the geology in the study area, including major faults and key horizons (main stratigraphic tops and unconformity-bounded units), ensuring accuracy and fidelity with surface and subsurface data. This work highlights first-order N-S tectonic trends and their influence affecting the Mio-Pliocene depositional setting of the basin along strike and dip, which are largely driven by tectonic forces.

Keywords: Marnoso-arenacea Formation, basin confinement, turbidite lobes.

This paper focuses on the Serravallian age turbidite deposits of the Marnoso-arenacea Formation (MAF, Northern Apennines, Italy) known in the literature as Firenzuola turbidite system and consisting of Unit V by Muzzi Magalhaes & Tinterri (2010). This Unit records the progressive infill of the MAF inner basin and the consequent depocenter shift towards the external basin due to the simultaneous uplift of two important structural alignments know in the literature as Mt. Castellaccio thrust and Verghereto high. Furthermore, the geometries and facies of the turbidite deposits of Unit V are also influenced by the emplacement of the Casaglia mass-transport deposit (MTD) about 500 meters thick in its source area (Tinterri & Tagliaferri, 2015). Unit V deposits were analyzed through fieldwork involving the measurement and detailed facies analysis of 28 stratigraphic logs located in Santerno and Senio Valleys and with a total thickness of about 3000 meters. Field activities were also supported by a laboratory work, involving grain size analysis of 260 samples using a laser diffraction particle size analyzer. The measured logs were correlated using a hierarchical approach, in order to reconstruct a general physical stratigraphy of the study area (see also Tagliaferri et al., 2018). This study includes the entire stratigraphic thickness of Unit V split into two sub-Units (Va and Vb) thanks to the presence of the Bedetta MTD, observed for the first time in the Santerno Valley during this study. The two sub-Units differ significantly in both stratigraphic and facies terms. The turbidites of Unit VA exhibit characteristics similar to basin plain deposits, whereas Unit Vb features a drastic increase in the net to gross ratio, mud draped scours, poorly sorted and crudely laminated medium to coarse-grained beds, often characterized by abundant mudstone clasts, flame structures and bypass surfaces. By combining facies with the stratigraphic cross sections, the observed beds could be classified into 7 categories, organized into two distinct facies tracts, one for each sub-Unit. The purpose of the facies tract is that to describe the downcurrent evolution of the flows that led to the formation of these deposits.Thanks to 5 detailed stratigraphic cross sections, Unit Vb could be subdivided into 17 turbidite lobes, separated by interlobe deposits. Consequently, where possible, the depositional lobes were further subdivided into their respective lobe elements. Finally, by analyzing the lateral and vertical facies distribution observed in the lobes, their evolutionary phases could be reconstructed.This work is part of a broader study that wants to show lateral and vertical facies distribution at different scales of a tectonically confined turbidite system characterized by lateral and frontal morphologies (see Tinterri et al., 2023).

Keywords: NW Offshore Sicily, inversion, extensional basins.

The North-Western offshore region of Sicily, located at the convergence zone of the Eurasian and African tectonic plates is characterized by intricate geological and tectonic setting. The opening of the Tyrrhenian back-arc basin led to the development of Plio-Quaternary extensional basins, which are characterized by inversion structures. These structures located in the extensional basins of the examined region, have been identified after the interpretation of several multi-channel seismic reflection profiles. The structural and stratigraphic analysis was performed in compliance with the grid of seismic reflection profiles and the boreholes available in the public ViDEPI database. The in-depth analysis of these inverted tectonic structures is attention-worthy. We identified three basins in the area that highlight the inversion of variable intensity. They were all formed during the Early Pliocene rifting phase, paired with extensive volcanic activity; the basins also suffered a contractional episode afterward that resulted in their tectonic inversion. An inversion is registered within these basins involving the Plio-Quaternary deposits. One among these basins shows a strong impact of inversion on the entire sedimentary fill and it affects the sea floor.

This contractional episode has been linked to the proximity of the Sicily Maghrebian thrust front (Argnani & Torelli, 2001) or a shift in the stress direction, signifying a compression in the N-S stress direction (Catalano & Milia., 1990; Sulli, 2000).

Our analysis of inversion features is in agreement with previous studies in the NW offshore of Sicily and provides insights into the deformation history of this region.

Keywords: accretionary prism, folds, Ligurian Units.

The External Ligurian Accretionary Wedge preserves tectono-sedimentary assemblages that were originally deposited at the transition between the Ligurian oceanic basin and the passive margin of the Adria plate (e.g. Marroni et al., 2010). It is characterized by the tectonic superposition of different terms of a Late Jurassic–Early Cretaceous to middle Eocene unmetamorphosed succession consisting of a basal clay-rich sequence, followed by a thick pile of calcareous and/or siliciclastic turbidites. The unconformable overlay of middle Eocene slope deposits (i.e., the Epiligurian Units, Ricci Lucci, 1987) constraints the timing of the accretionary stage, also documenting that deformation occurred at very shallow structural levels, up to the seafloor. The deformation style within the accretionary wedge, resulting from offscraping and frontal accretion is characterized by regional-scale folds with mainly overturned or recumbent geometries, and a plethora of associated brittle structures (Vannucchi & Bettelli, 2002; Nirta et al. 2024). These structures represent the product of rock buckling and shearing at the front of subduction zones.

Although such structures are ubiquitous products of deformation at shallow structural levels in both modern and ancient shallow accretionary prisms worldwide – e-g Barbados, the Miura-Boso accretionary complex, and the southern Shimanto belt in Japan or the Nankai or Hikurangi margins - they are not adequately considered in the dynamics of accretionary wedges at the timescale of the seismic cycle, favoring the role played by slip on major faults. Through a detailed structural analysis of the External Ligurian Units in the Northern Apennines, we review the deformation structures characterizing the frontal and shallowest part of the subduction complex. Our findings document that fold-related brittle structures might be associated with transient deformation events at elevated strain rates and in the presence of high fluid pressure, having the potential to cause distributed microearthquake swarms under low effective normal stress and affect the distribution of surficial displacement. The study of deformation in the exhumed ancient accretionary wedges, such as the External Ligurian Units in the Northern Apennines, is therefore highly significant to better understanding modern wedges and related seismic behavior.

Keywords: Messinian-Early Pliocene turbidite successions, geological mapping, sub-surface geology, 3D modelling.

East of the Gran Sasso chain, the sub-Apennine foothills, are characterized by extensive outcrops of turbidites belonging to the Laga and Cellino formations. Despite in the past decades they have undergone several investigations, the poorness of stratigraphic and petrographic data, and the complexity of the orogenic deformations left numerous unsolved questions. These latter concern the precise dating and the possible correlations between adjacent successions (which also imply problems of nomenclature), their basin of origin, and the amount of their tectonic translation.

Our work tries to fill this gap of data starting from an original, and updated, geological survey of a 20 km long – 4 km wide, W-E trending, area straddling the Colledara-Montefino transect.

This area, falls entirely within the 350 Penne geological Sheet, which will be surveyed in the coming years (CARG Project), therefore the mapping was mainly set on the stratigraphy of the 339-Teramo sheet, which contains the northern continuation of the studied structures.

The fieldwork was carried out using digital devices, which led to collect a large amount of stratigraphic and structural data. The initial stratigraphic scheme, already very detailed, has been further implemented with the distinction of newly found facies associations and key-horizons. The high-grade stratigraphic resolution has allowed us to precisely identify the main folds and thrust faults, synthesized in a balanced geological section.

The surface geology was subsequently used to constrain the interpretation of 11 seismic lines also calibrated at depth by the Logs of the public wells drilled for hydrocarbon exploitations (both sections and well-logs are available in the ViDEPI project).

Their correlation allowed us to: i) recognize the unconformity between the Lower Pliocene and the Upper Pliocene successions, ii) describe the deep geometry of the outcropping thrusts, and iii) highlight the complexity of the whole thrust systems, which also includes several blind splays.

Finally, a 3D subsurface geological model has been built, including the most important seismo-stratigraphic units from the top of the Triassic Dolostones to the top of Lower Pliocene turbidites and showing the geometry of the main tectonic structures.

The Palaeozoic succession of the Giglio Island (Tuscan Archipelago)

Keywords: Palaeozoic successions, Giglio Island, palinology.

The Giglio Island is part of the NNW-trending Giglio-Formiche di Grosseto Ridge, a partially submerged structural high in the northern Tyrrhenian Sea bounded by normal faults, where an exhumed crustal sector of the inner Northern Apennines is exposed. On the Island, a Messinian monzogranite emplaced at 5.7 ± 0.4 Ma (Ibe et al., 2023) is widely exposed together with part of its host rocks. The latter are only preserved in a few limited exposures in the northern part of the island, and consist of metapelitic rocks affected by contact metamorphism. Due to their lithological characteristics, mainly consisting of alternation of quartz metasandstone and metasiltstone, and their low pressure metamorphism, the age of the protolith and its relations with the stratigraphic units exposed in the inner Northern Apennines have not been well constrained. For this purpose, we present the results of a microfloristic and palynological analysis of many key samples from the organic metasiltstone the form the host rocks. The palynological assemblage is quite preserved and diversified. It mainly consists on taeniate bisaccate pollen as *Protohaploxypinus* spp. (*P. limpidus* and *P. microcorpus*), *Striatopodocarpites* spp.. (*S. cancellatus* and *S. fusus*) and *Striatoabieites* sp. with taeniates as *Alisporites* sp. and *Sulcatisporites* sp. and polyplicates as *Vittatina costabilis*. Trilete spore sas *Calamospora* sp., *Densoisporites* sp. and *Kraeuselisporites* sp. were also documented. Microflora recorded shows close similarities with the palynological assemblages documented from different middle to upper Permian formations cropping out in Southern Tuscany and Elba Island (*i.e.*, Arenarie del Monte Argentario, Poggio al Carpino, Farma and Rio Marina formations) and from Bellerophon Formation cropping out in the Southern Alps (Italy) which were independently-dated by conodonts. Based on this correlation, the microfloristic assemblage from the host rocks of the Giglio monzogranite can be assigned to late Guadaluapian (Capitanian)-Lopingian age.

Keywords: southern Apennines, stratigraphy, tectonics.

We present a review of the orogenic evolution of northern Calabria and the southern Apennines (Vitale & Ciarcia, 2013, 2018, 2022) in terms of stratigraphy (poster 1) and tectonics (poster 2). Three main tectonic complexes characterize this orogenic chain: (1) remnants of the overriding plate, including Variscan Paleozoic basement (Calabria-Peloritani Terrane; CPT) that tectonically cover (2) an Alpine metamorphic belt, corresponding to an exhumed subduction channel, formed by slices of CPT, metaophiolites (metamorphic Ligurian units), and some successions of the continental Adria plate (downgoing plate); in turn superposed to (3) a fold-and-thrust belt made of remnants of an oceanic accretionary prism (non-metamorphic Ligurian units) on the top, and an imbricate orogenic pile consisting in shallow-water to pelagic continental Adria successions, also including the buried shallow-water carbonates of the Apulian Platform. The exposed Apulian Platform domain (Puglia region) and the Adriatic Sea represent the current foreland. The orogenic chain results from the subduction of the Ligurian Ocean lithosphere beneath the European Plate/CPT starting during the Paleocene-Eocene.

After the complete closure of the Ligurian Ocean in the Early Miocene, the subduction continued with the involvement of the continental part of the Adria plate, triggering the crustal shortening up to the Middle Pleistocene. Complex geometries, reflecting the articulated paleogeographic domains formed by alternating shallow-water carbonate platforms and deep basins, controlled the shape of the thrust front-foredeep-forebulge system.

Thin- and thick-skinned thrusting episodes have alternated during the orogenic shortening; however, since the Early Pliocene, deep-seated ramp-dominated thrust faults, resulting in widespread envelopment thrusting and appearing as out-of-sequence structures in the allochthonous wedge, drove the crustal shortening. The alternating different tectonic styles also resulted from the involvement in the subduction system of the continental Adria lithosphere, thicker under the carbonate platforms and thinner under the interspersed pelagic basin and the western margin facing the Ligurian Ocean. This variable lithosphere thickness caused two main backstops that triggered the thick-skinned tectonics. The restored mean tectonic vergences indicate that the thrust front migrated to the south in the Eocene-Langhian period, turning to E during the Serravallian-Pleistocene interval.

Keywords: non-volcanic degassing, southern Apennines, geophysical and geochemical surveys.

This study aims to investigate the CO_2 leakage mechanisms in relation to tectonic structures in some degassing vents in the Oliveto Citra area. These CO_2 emissions are associated with normal fault arrays that crosscut a tectonic pile formed by carbonates (Apennine Platform) tectonically covered by an oceanic succession (Ligurian Accretionary Complex) made of clay and turbiditic limestones (Vitale & Ciarcia, 2018; Vitale et al., 2020). We performed geophysical surveys, including 2D Electrical Resistivity Tomography (ERT), Induced Polarization (IP) Tomography, 2D Seismic Refraction Tomography (SRT), Magnetometry (MAG) and Self Potential (SP) mapping and geochemical investigations, consisting of soil pH and CO_2 flux mapping. All these surveys were accompanied by structural analysis and mapping of major faults (e.g., Vitale et al., 2023). The results of this multidisciplinary study indicate that most of the gas emissions are along the intersection between the major faults, and once fluids approach the surface following the main fault zones, their migration and leakage become mostly controlled by the surficial segmentation of faults and local permeability paths.

The mesorif unconformity in the external rif (Morocco): new insights from stratigraphical and biostratigraphical constraints

Abbassi A.*[1-2], Cipollari P. [1], Zaghloul M.N. [2] & Cosentino D. [1]

Keywords: calcareous nannofossils biostratigraphy, wedge-top basin, Mesorif (Rif Chain).

The Rif Chain (Northern Morocco) is in the westernmost extend of the Apennine–Maghrebian Belt, resulting by the convergence of the African and Eurasian plates during the Tertiary evolution of the western Mediterranean subduction system. Throughout the compressional tectonic phases responsible for the Neogene deformation of the External Zone (Rif Chain), three stacked tectono–paleogeographic sub-domains developed, from north to south and top to bottom: Intrarif, Mesorif, and Prerif.

In this study, we present new stratigraphic findings regarding Middle Miocene sedimentary successions belonging to the Mesorif Sub-domain. In Tamda area, 50 km east of Taounate City, a thick deposit of conglomerates, marls, and marly-limestones, with intercalations of calcarenites (Tamda section) unconformably overlies (Mesorif unconformity Auct.) a Late Jurassic-?Aquitanian continuous stratigraphic succession made up of silty-clay marls, marly-limestones, and limestones deposits (pre-orogenic succession).

The sedimentary succession of the Tamda section, which shows slight evidence of compressional deformation, sedimented in a late-orogenic depositional stage. In contrast, the pre-orogenic succession underlying the unconformity is highly affected by compressional deformation.

The investigated stratigraphic section starts with a thick to very-thick-bedded polygenic conglomerate with thin intercalations of marls and marly-limestones. Moving upward, the succession predominantly consists of calcarenites, marls, and marly limestones, characterized by several slumping horizons.

The quantitative biostratigraphic analyses performed on the marly samples collected along the section, provided a new age for this succession, which was previously referred to the Oligocene (e.g., Gimeno-Vives et al., 2020). In this regard, the total assemblages of the calcareous nannofossils from the Tamda section point to a late Serravallian age and allow us to refer the Mesorif unconformity to the Middle Miocene.

This result offers significant insights into the kinematic evolution of the Mesorif Sub-domain, bringing to consider the Tamda succession as deposited in a wedge-top basin on top of the deforming Mesorif Sub-domain. Our biostratigraphic results indicates that the Mesorif was involved in the Rif fold-and-thrust belt during the late Serravallian (~12 Ma). During this time, the leading edge of the Rif Chain was marked by the basal thrust of the Mesorif, while the Prerif Sub-domain was still part of the foreland domain of the Middle Miocene orogenic system.

Keywords: Gelasian GSSP, Monte San Nicola type-section, high-resolution climatostratigraphy.

As part of the GELSTRAT project (Head & Caruso, 2022), we present high-resolution climatostratigraphic results at the Monte San Nicola type-section (MSNt-s) in Sicily, the Global Stratotype Section and Point (GSSP) of the Gelasian Stage (Rio et al., 1998). The GELSTRAT project focuses on the reinvestigation, at high stratigraphic detail, of the Gelasian GSSP, which defines the base of the Pleistocene Series and of the Quaternary System. The interval falls within a critical shift in Earth's climate, including the progressive intensification of the North Hemisphere Glaciation. The mechanisms accompanying this crucial climate phase and the regional responses to this transition in the Mediterranean area are still debated. By improving the dataset on such a relevant section, we intend to strengthen the correlation potential of the MSNt-s and of the GSSP itself outside the type-area and illuminate a crucial phase of Earth history. Next to the recent climatostratigraphic reconstruction (Addante et al., 2024) performed on the type-section, across Marine Isotope Stage (MIS) G4-103, we now extend our study to the interval encompassing Marine isotope Stage (MIS) 104 to MIS 100, not yet studied in the type-section with a high-resolution detail. Based on the high-resolution sampling of 5 cm, which allows a sub-millennial scale resolution (~800 years), we provide an updating on planktonic foraminiferal ð18O record and calcareous plankton assemblage and we present new alkenone data (total C37 alkenone concentration and alkenone-derived SST°C). The stratigraphic pattern of C37, in conjunction with field observation, enhance positions of sapropels and allow precise tuning of the stratigraphic record to insolation cycles, improving chronology of the section. In addition, the implemented dataset constraints precise position of calcareous nannofossil biostratigraphic events close to the GSSP and provide clear documentation of both orbitally forced glacial-interglacial phases and suborbital cyclicity. The overall results contribute to frame the Gelasian GSSP within a global climatostratigraphic evolution, enhancing its correlation on regional and global scale.

Keywords: shelf margin, seismostratigraphy, Adventure plateau.

Using seismic reflection profiles for the detailed seismo-stratigraphic analysis of prograding systems is a widely used technique also in the Adventure Plateau, characterized by a wide, shallow water, submerged plateau in the Sicily Channel offshore (central Mediterranean Sea) (Colantoni et al., 1985).

Here, we analyse a couple of shelf margin prograding systems, using Ultra High Resolution (UHR) seismic reflection profiles (acquired with a 48-channel sparker seismic source) which allowed a high-quality spatial resolution seismo-stratigraphic analysis.

One of these prograding systems is located along the western Sicily mainland continental shelf edge and consists of only one, wedge shaped, sedimentary unit made up by a succession of clinoform reflectors; the wedge, which is up to 25 m thick, pinches out at - 135 m water depth at its landward termination and at - 157 m water depth at its seaward termination. The basal surface is characterized by enhanced erosional truncation of underlaying reflectors and by downlapping terminations of the overlaying clinoforms which display an oblique-tangential geometry and erosional truncation of upper termination.

The other prograding system, in the northern margin of the Adventure Plateau, displays a more complex internal geometry: indeed, it consists of four laterally stacked wedges with clinoform reflectors displaying oblique-tangential configuration with downlap and erosional truncation as bottom and top termination respectively. To separate two adjacent prograding wedges, a thin lens of high frequency, continuous, prograding-to-aggrading reflectors lies in between of them. The four wedges show different width and vertical thickness, both controlled mainly by depth and dip of the bottom surface. The outermost wedge is up to 13 m thick and pinches out at - 140 m water depth at its landward termination and at - 163 m water depth at its seaward termination.

The analysed sedimentary systems show many similarities with other prograding depositional wedges observed along the Mediterranean continental shelf margins (Chiocci et al., 1997, 2004). Based on their stratigraphic relationship, seismic facies, and internal depositional geometry, we suggest the prograding wedges accumulated as shallow water deposits during sea level falling to lowstand stages related to high frequency (about 100 ky) and high amplitude (about 100 m) glacio-eustatic changes occurred during middle-late Quaternary.

The above illustrated differences in thickness, lateral extension, and seismic facies can be attributed to the different physiography of the margins on which the prograding systems developed, to their opposite exposure to fetch, and to the different sedimentary supply, also considering that during the highstands stages, the prograding depositional system of the Adventure Bank remained completely isolated from the emerged mainland (Civile et al., 2015).

The stratigraphic signature of the Carnian Pluvial Episode in the northern Greater Adria

Caggiati M.*, Gianolla P., Riva A., Alverà G. & Aldrighetti E.

Dipartimento di Fisica e Scienze della Terra, Università di Ferrara.

Corresponding author email: marcello.caggiati@unife.it

Keywords: paleoclimate, Triassic stratigraphy, Adria.

The Triassic record is marked by a significant worldwide climate and biological crisis known as Carnian Pluvial Episode (CPE, ~232-234 Ma), linked to C-cycle perturbations and global warming, triggering many important consequences on the sedimentary, environmental and global ecosystem evolution: changes in shelf carbonate factories and demise of high-relief carbonate platforms, biological turnover of different taxa occurred together with radiation and extinction of some groups. In the circum-Tethyan region, the shift from the arid to semi-arid conditions towards more humid conditions favored an increased runoff with the development of siliciclastic successions. This occurred in conjunction with a relative sea-level drop that locally amplified the sedimentary effects linked to the CPE. The resulting stratigraphic signature is particularly evident in the northern part of the Adria plate, from the Southern Alps to the Outer Dinarides, but also in other inland settings such as the Tuscan nappe. In basinal settings the onset of the CPE (late Early Carnian) corresponds to the loss of calciturbidites shed from nearby high-relief carbonate platforms. This is associated with the shift to humid conditions, documented by various proxies. The upward sharp transition to coarse siliciclastics, well-expressed in the Dolomites and Julian Alps, reflects both the increased runoff related to the enhanced hydrological cycle and the seaward shift of the siliciclastic shoreline associated with the relative sea-level drop. The platform top of the demised carbonate platforms underwent subaerial exposure, developing karst surfaces (Dolomites), emersion breccia and spodic paleosols (Carnia) and bauxites (Western Julian Alps, northern Outer Dinarides). A subsequent relative sea-level rise resulted in some cases in a shift to outer ramp settings (Dolomites), while elsewhere established new accommodation space in previously emerged areas, coupled with a new siliciclastic pulse related the CPE. Common abundant plant debris, ambers (Dolomites) and coal horizons (Dolomites, Carnia, Lesno Brdo, Outer Dinarides) represent signals of humid climate and environmental stress. The lowermost Upper Carnian is characterized by the return of prevailing carbonate sedimentation, with a shallow ramp setting developed on an almost flattened paleotopography in the Southern Alps up to the Outer Dinarides. Another sea-level fall then produced a significant unconformity on the whole region. Above, alluvial to marginal marine settings within a semi-arid climate were established basin-wide, closing the stratigraphic and sedimentary window opened by the CPE and enabling the development of the epeiric Dolomia Principale / Hauptdolomit carbonate platform. The CPE therefore records one of the most prominent rearrangements of the stratigraphic framework of the Western Tethys, as evident in Greater Adria.

Ratifying the upper Campanian to Paleogene shallow-water carbonate unit to fill a lithostratigraphic "gap" within the Apennine Carbonate Platform succession

Cipriani A.[1], Consorti L.*[2], Fabbi S.[3], Barattolo F.[4] & Pampaloni M.L.[1]

[1] Dipartimento per il Servizio Geologico d'Italia, ISPRA, Roma. [2] Istituto di Scienze Marine, CNR, Trieste.

[4] Dipartimento di Scienze della Terra, dell'Ambiente e delle Risorse, Università di Napoli "Federico II".

Corresponding author email: lorenzo.consorti@cnr.it

Keywords: carbonate platforms, lithostratigraphy.

The uppermost Campanian-lower Paleogene of the Apennine Carbonate Platform usually refers to a shallow-water carbonate unit called "calcari cristallini" or "calcari saccaroidi", despite these designations do not comply with the International Stratigraphic Guide (Salvador, 1994). In this contribution, we aim to outline key elements necessary for ratification as a formal lithostratigraphic unit for inclusion in the official geological mapping (CARG) project at 1:50,000 scale.

We performed a new survey in the Gorga-Morolo area (Lepini Mts, Central Italy), where these rocks extensively crop out, and re-examined thin sections from samples collected by Molinari Paganelli & Tilia Zuccari (1987).

At Mt Filaro, above the rudist-rich "calcari a radiolitidi" intertidal succession with *Cuvillierinella salentina*, characteristic dolomitized mudstones with discorbids and ostracods occur (lowermost part of the unit; lithofacies 1). These are overlain by well-bedded, coarse grained, bioclastic packstones (cf. "calcari saccaroidi" or "calcari cristallini" *auctt.*; lithofacies 2) made by rudist and echinoderm fragments with *Orbitoides media, Sivasella monolateralis, Siderolites* sp., among others. Locally, interfingered with the lithofacies 2 are mudstones to wackestones with discorbids, miliolids and *Rhapydionina liburnica* (lithofacies 3). The whole faunal assemblage points to a late Campanian-Maastrichtian age, whereas both lithofacies 2 and 3 are eventually capped by paleokarst features like *Microcodium*, red/green veneers filling mesoscale dykes or forming beds. The uppermost part of the succession is made by a few tens' meters of gray-hazelnut mudstones with Characeae, ostracods, miliolids and dasycladacean algae of Paleocene, or possibly early Eocene, age (lithofacies 4), characterized by traces of subaerial exposure. Future analyses will allow us to understand whether the lithofacies 4 can be compared with the "Trentinara formation". The upper boundary is unconformable with the Miocene "calcari a briozoi e litotamni".

Listed lithofacies may exhibit latero-vertical variations in organization due to migrations of the facies pattern typical of carbonate platforms. The total thickness, reaching up to 500 m at Mt. Filaro, considered its maximum vertical extent, can significantly decrease or even be absent in other areas of the Apennine Carbonate Platform (including Abruzzi, Latium, Molise, Campania, and possibly north Calabria regions).

This upper Campanian-Paleogene *p.p.* unit is partially coeval with the Orfento Formation, "Mt. Sant'Elia dolostones" or to the "Ciolo limestone" of the Apulian Carbonate Platform, and the "liburnian limestone" of the Adriatic Carbonate Platform of NE Italy.

Keywords: Burdigalian GSSP, Malta Island, integrated stratigraphy.

The Global Stratotype Section and Point (GSSP) of the Burdigalian (Lower Miocene) is still missing for the Miocene Epoch. In the recent literature, different criteria have been adopted to identify or approximate the base of the Burdigalian stage (Raffi et al., 2020). In terms of calcareous plankton, one of the criteria suggested by Haq et al. (1987) and also reported in the GTS 2020 is the FO calcareous nannofossil *Sphenolithus belemnos* with an age in open ocean of 19.01 Ma (Backman et al., 2012). A multidisciplinary study has been performed of S Thomas section combining calcareous plankton biostratigraphy, chemical analyses based on xrf data, magnetic susceptibility, colour signals and stable isotope records. Major aim of this study was to analyze St. Thomas record as potential candidate section for defining the criteria for the Burdigalian GSSP in the Mediterranean area.

The sedimentary record of St. Thomas section (91.15 m thick) is characterized by an alternation of calcareous marls and marly limestones with subordinated prominent bioturbated indurated limestones that are deposited in a deep marine environment (the Middle Globigerina Limestone member of Globigerina Limestone Formation). Foresi et al. (2014) presented a bio-magnetostratigraphic study of St. Thomas section and chronologically placed this central Mediterranean record in the lower part of the Burdigalian, between ~19.7 and ~17.2 Ma. We present oxygen (d18O) and carbon (d13C) stable isotope records (mean time resolution of 17 kyr) obtained from planktonic foraminifer *Globigerinoides quadrilobatus* (a warm to temperate and oligotrophic waters species). The d18 G. quadrilobatus signal shows light values, ranging between -2.5 to 0 ‰, well comparable with the other O isotope data available in the Lower Miocene deposits from Malta Island, and the obtained record as well as the d13C ones (ranging between 2.6 to 0.14 ‰) are almost in phase with the recent open ocean record of Westerhold et al. (2020). According to the chronology proposed by Foresi et al. (2014), the d18 G. quadrilobatus record shows, in the lower most part of the study section between 19.41 and 19.5 Ma, a cooling event that chronologically could correspond to the Miller's glaciation event Mi1aa. This cooing event seems almost in phase with a node of 1.2 My obliquity cycle as the other Miller's glaciation events (van Dam et al., 2006). In terms of calcareous plankton, this cooling event is also constrained by the FCO of planktonic foraminifera *Paragloborotalia acrostoma* (estimated age of 19.54 Ma) and, at the top, by the FO and FCO of calcareous nannofossil *Sphenolithus belemnos* (estimated age of 19.09 Ma and 19.04 Ma, respectively). As for the definition of the Burdigalian GSSP (Lower Miocene), the robust integrated bio-magnetic and isotope stratigraphies of S. Thomas section suggest that it is a GSSP potential candidate. In particular, the onset of Miller's glaciation event Mi1aa at ca. 19.5 Ma combined with the FO of *S. belemnos* at 19.09 Ma, could represent two valid criteria for the identification of this GSSP.

Deltaic processes and depositional canyon-heads in a narrow continental shelf: examples from the north-eastern Sicilian margin

Distefano S.*[1], Di Stefano A.[1] & Gamberi F.[2]

[1] Dipartimento di Scienze Biologiche, Geologiche ed Ambientali, Università di Catania.
[2] Istituto di Scienze Marine, CNR, Bologna.

Corresponding author email: salvatore.distefano@unict.it

Keywords: deltaic sedimentation, distributary channels, gully.

In this work, through the integrated analysis of Multibeam bathymetric and seismic/Chirp profiles, we analyse the proximal part of canyons in the area between Capo Milazzo and Capo Peloro (Messina). In particular, we discuss the interaction between river-borne sediment, seafloor instability and sediment-gravity flows in the evolution of canyon heads located.

The shelf has an average width of less than 5 km, and presents a varied bathymetric setting with numerous geomorphic elements (bedforms, distributary channels, gullies) which especially insist deltaic bodies, which form the current highstand wedge on the shelf. The analysis of the seismic profiles allows the contouring of the base of this wedge and the identification of the upper portion of the underlying deposits of the last lowstand stage.

In the distal offshore portion of the shelf, near the shelf break, several canyon-heads are concentrated and, sometimes, interconnected: Cocuzzaro, Rometta, Villafranca, Tarantona, Sindaro, Rosocolmo 1, Rosocolmo 2 and Rosocolmo 3 canyons. Here the interaction between the canyon-heads and the deltaic processes results in an articulated network of several distributary channels. The western canyons-heads (Cocuzzaro, Rometta and Villafranca) reach closer to the coastline (even <500 m) with a meandering pattern and a complex branching of gullies before merging into the main channel within the canyon containment. Conversely, the eastern canyons-heads (Tarantona, Sindaro, Rosocolmo 1, Rosocolmo 2 and Rosocolmo 3) develop further away from the coastline (about 3 km) with a markedly straight planform and poor branching of the distributary channels on the outer continental shelf. In the inter-channels areas, the seismic profiles show a depositional character with the presence of well-stratified reflectors: their setting highlights low-energy and fine grained flows, with a possible reworking by oceanographic currents along the shelf. Conversely, in the channels area the presence of laterally truncated reflectors is a proof of erosional flows associated with coarse-grained sedimentation and chaotic bodies, which are indicative of the action of higher-energy flows and seafloor instability. The distribution of the coarse-grained deposits within the canyon axis causes a high-amplitude floor, which does not allow the visualization of the deepest units.

In conclusion, our work shows the nature of the geomorphic elements and processes that contribute to the infill of the canyon-heads. It highlights that in margins with a narrow shelf, during the present-day highstand, deeply carved canyon heads form a peculiar deep-water and confined environment, where deltaic processes result in a unique geomorphologic and stratigraphic setting.

Sediment distribution in the Brazos Delta: Estimation and numerical modelling of sedimentation rates and the effect of bioturbation in event beds preservation

Ezeh S.C.*[1], Bhattacharya J.P.[1], Dellapenna T.M.[2] & Carlin J.A.[3]

[1] School of Earth, Environment and Society, McMaster University, Hamilton, Ontario, Canada.

Keywords: shelf, mud, sediment.

The sedimentology of twenty-five core samples from the Brazos Delta offers insights into its lithological composition. Analysis reveals five distinct facies characterized by varying colors and sediment grain sizes: red mud, brown mud, grey mud, brown silty sand and muddy, calcareous sand. These colors provide clues about the sediment sources, indicating a blend of materials from the Brazos River beds and the shelf-derived sediment of the Gulf of Mexico (GOM). Examination of the sediment grain size distribution indicates a composition of 40% clay, 50% silt, and 10% sand, emphasizing sedimentary processes, distribution patterns, and biogenic reworking. Swath bathymetry data unveils the asymmetrical nature of the delta, with notably deeper water depths observed across the shelf slope and the updrift area situated in the northeastern segment of the basin, in contrast to the shallower depths along the downdrift in the northwestern region.

The facies correlation highlights distinct sediment patterns along the river mouth to the downdrift and updrift areas of the Brazos Delta. The prevalence of red mud, brown mud, and muddy-calcareous sand facies characterizes the river mouth and downstream sections, while updrift parts are dominated by brown silty mud and grey mud. The grey and brown mud predominantly represent the basinal facies. XRF elemental analysis shows an increase in Mo/Al in the red and brown mud, indicating varying redox marine conditions, contrasting with the display observed in grey mud. Similarly, Ti/Al is significantly higher in red and brown mud, signifying the terrigenous inputs of the Brazos River. In contrast, the marine-sourced shelf grey mud, which consists of material from updrift rivers (Neches, Calcasieu, Mermentau, Atchafalaya and Mississippi), exhibits lower ratios.

Examination of sediment accumulation rates, determined through excess 210Pb geochronologies of six cores, discloses varying sedimentation rates characterized by deposition from fluvial flood events and remobilized sediment from the proximal shelf alongside relics from the older delta, contrary to steady-state accumulation patterns previously posited. Event beds were mainly preserved nearshore but displayed moderate to complete bioturbation deeper into the basin. The numerical model shows that preservation potential and biogenic activities are inversely related and dependent on physicochemical conditions at deposition.

The alternating layers from fluvial flood events and marine processes indicate the delta susceptibility to local climate dynamics. These findings underscore the profound impact of sediment processes (sedimentation rate) and biogenic events (such as bioturbation) on strata preservation within modern deltas. Moreover, they offer valuable insights that could inform predictions regarding sediment accumulation in ancient deltaic environments.

The Orfento formation of the Maiella Mountain (Central Apennines, Italy): depositional facies model of an Upper Cretaceous bioclastic wedge

Gaspari R.*[1], Rusciadelli G.[1-2], Ricci C.[2] & Cestari R.[2]

[1] Dipartimento di Ingegneria e Geologia, Università "G. d'Annunzio" Chieti-Pescara.

Corresponding author email: riccardo.gaspari.ss@gmail.com

Keywords: bioclastic limestone, Upper Cretaceous, Apulia.

The Orfento formation is an Upper Cretaceous bioclastic wedge developed along the northern margin of the Apulia platform, magnificently exposed in the Maiella Mt., and characterised by a dynamic depositional history. Despite extensive research on this unit since the 1960s, the depositional facies model and the main factors controlling the sedimentation are still debated (Mutti et al., 1996; Vecsei, 1998; Eberli et al., 2019). New data acquired through geological field survey and drone-based remote sensing, across the Orfento fm outcrops in the Maiella Mt, provide new elements that contribute to clarifying the dynamics and sedimentary processes of the Orfento fm, and offer new insights on Upper Cretaceous bioclastic wedges and the evolution of the northern margin of the Apulia platform. The Orfento fm has been subdivided into two superposed intervals, characterized by different facies associations, thickness and geometries. These differences reflect two distinct depositional phases and facies models. The lower interval (a) (late Campanian - early Maastrichtian), is characterised by about 50 metres thick alternations of pelagic Scaglia-like limestones and tabular resedimented bioclastic deposits. This interval has been interpreted as the result of two delta fan systems, whose geometry was strongly influenced by earlier palaeomorphology, being developed at the mouth of two major indentations, incising the pre-Orfento platform margin. The delta fan systems were supplied by sediments produced within a narrow belt located in correspondence with the pre-Orfento platform margin. Sediment transport occurred under high hydrodynamic conditions, likely induced by accelerating currents generated by the morphological differences along the margin. The upper interval (b) of the Orfento fm (Maastrichtian p.p.) is characterized by a up to 250 thick succession represented by massive, tabular, and wedge-shaped biocalcarenites, with rare pelagic intercalations. This interval has been interpreted as the result of shallow water deposition with progradational sandwaves, incised by tidal channels. The production area expanded considerably with respect to the former interval, extending from the inner sector of the pre-Orfento platform to the pre-Orfento proximal basin. The produced bioclastic sediment was reworked by wave motion, tidal currents, and storms. NW-SE oriented synsedimentary faults locally interact with sedimentary processes, by creating asymmetric, relatively small depocenters, trapping the bioclastic reworked sediments. These faults belong to the same fault system that controls the sediment distribution of the Orfento fm-equivalent deposits along the Casal Bordino corridor, in the Rospo Plateau (Santantonio et al., 2013). The detailed analysis of the Orfento fm highlights the interplay between tectonics, local morphology, and sedimentation processes in shaping bioclastic deposits, providing a valuable framework for understanding similar systems in the region.

Keywords: shelf-deltas, aggradation, progradation, retrogradation.

This poster presentation summarizes the very preliminary results of a BSc-thesis project based at the University of Basilicata and focused on an outcrop section exposed in the north-eastern sector of the Sant'Arcangelo Basin (SA). The SA Basin developed first as a wedge-top depression and, later as a pull-apart basin during the Plio-Quaternary, at the forefront of the Apennine Orogen, southern Italy. Fan-deltaic sedimentation dominates over other deposits being replicated several times across four major depositional sequences, which represent the stratigraphic basin infill. Among the variety of spectacularly-exposed outcrop sections nowadays visible within the SA Basin, the Alianello Section is one of the best exposed and easily accessible. It is a 35-40 m high and ca. 420 m long cliff bordering the left margin of the modern Agri River Valley. The outcrop, which is E-W-oriented reflecting a landward-basinward cross-section, has for long been interpreted as the result of vertically-stacked, ancient shelf-deltas, entering a shallow-water embayment and resulting from flood-dominated high-sediment discharge episodes, whose rates outpaced the rate of tectonic subsidence. Strata are organized into a number of simple sequences or parasequences, consisting of well stratified delta-plain conglomerates (facies 1), passing laterally into coarse-medium-grained delta-front sandstones (facies 2), in turn merging basinward into indistinctly-stratified prodelta mudstones (facies 3). The section has been documented based on high-resolution drone ortho-photos integrated by a Li.D.A.R. DTM, with the aim of detecting possible shoreline trajectories during deltaic stacking, with the final goal of defining patterns of progradation, aggradation and retrogradation of the deltaic sequences. Our preliminary achievements indicate a complex interplay between river-dominated processes, entering a shallow-marine environment and producing rapid lateral wedging of the various deltaic tongues into prodeltaic fines.

Deflected deltas: what are they?

Longhitano S.G.*

Dipartimento di Scienze, Università della Basilicata, Potenza.

Corresponding author email: sergio.longhitano@unibas.it

Keywords: deltas, deflection, current-dominated.

Deltas form conventional fan-shaped morphologies along regular shorelines with no lateral constraints, delivering sediments radially distributed from the entry point basinwards, in both subaerial and subaqueous environments. River floods, waves and tides impact on sediments distribution and environment partitioning leading to a variety of deltaic shapes.

When dominant over other processes, along-shore currents modify the delta shape, generating asymmetrical coastal plains, deflected delta fronts and elongate sandbanks. This setting leads to sedimentary facies distribution and sandbody physical attributes that may depart from predictable models on deltas.

In this presentation, a series of modern delta examples are considered, particularly impinging confined coastal settings such as seaways or straits, where alongshore water circulation is amplified due to the lateral constriction. Then, a few case studies documenting ancient deflected deltas are presented. Common elements in these deltas are: (i) the progressive-upwards change in the dominant process of sediment dispersion recorded in the delta facies; (ii) the predominance of river- and wave-influenced lithofacies on early stages of progradation; (iii) current reworking on the delta front deposits during late stages of deltaic advancements, with consequent in-plan morphologies deflected/elongated in the direction of the dominant flow.

Deflected delta models suggest analogies with the spatial distribution of many hydrocarbon reservoirs investigated along the margins of confined, narrow, linear basins, the interpretation of which is challenging in subsurface exploration.

Coralgal buildup in a mixed carbonate-siliciclastic succession of the Upper Eocene San Martí Xic Formation (Orís, Vic, SE Ebro basin, Spain)

Mancini A.*[1], Brandano M.[1] & Ferràndez-Cañadell C.[2]

[1] Dipartimento di Scienze della Terra, Sapienza Università di Roma.

Keywords: cluster reef, turbidity, mixed sedimentation.

The mixed carbonate siliciclastic deposits of the Upper Eocene San Martí Xic Formation (Orís, Vic, SE Ebro basin, Spain) shows the presence of two sedimentary cycles, characterized by coralgal bioconstructions, developed in a fine sedimentary matrix, mainly composed by marls. Such layers, characterized by cluster reef with lens-shaped geometries, developed on top of well sorted bioclastic wackestone to packstone rich in *Discocyclina* at the base of the succession and *Nummulites* at the top of the succession. Facies analysis allows to better constrain the paleoenvironment where coralgal buildup developed, mainly characterized by high sedimentation rate, mesotrophic conditions and turbid waters. The Upper Eocene mixed carbonate-siliciclastic succession of San Martí Xic Formation was strictly influenced by local factor associated with the evolution of the Ebro Basin. In particular, from the early Eocene to the Oligocene, the south-eastern margin of the Ebro Basin evolved as a consequence of the uplift of the Catalan Range thrust. The central part of this zone shows the most pronounced deformation, which took place from the middle to late Eocene accompanied by sin-sedimentary evolution of fan and fan-delta depositional systems. These deposits gradually evolved into basin sedimentation with shallow water limestones and clastic sediments corresponding to the last marine event in the Ebro Basin. In this view, such stressed environment shows the resilience of coralgal buildups. In particular, the first sedimentary cycle characterized by the presence of wackstone to packstone with *Discocyclina*, developed in a deeper and oligophotic environment associated with more humid conditions, while the subsequent sedimentary cycle shows more arid conditions testified by the presence of *Nummulites*. Coralgal buildups interdigitated with progradational and aggradational deltaic sediments of San Martí Xic Formation were strictly influenced by the evolution of delta fan system associated with the uplift of the Catalan Range thrust and was also controlled by climatic changes occurred during the late Eocene.

Vertebrate pits recorded in carbonate sedimentary succession: the case study of the Pliocene Macco formation (Tarquinia - Central Italy)

Mancini A.[1], Brandano M.[1], Cardello G.L.[2] & Ronca S.*[1]

[1] Dipartimento di Scienze della Terra, Sapienza Università di Roma.
[2] Dipartimento di Scienze Chimiche, Fisiche, Matematiche e Naturali, Università di Sassari.

Corresponding author email: sara.ronca@uniroma1.it

Keywords: facies analysis, marine vertebrates, Pliocene.

The Macco formation (Middle to Upper Pliocene) predominantly consists of bioclastic limestones. Detailed facies analysis reveals a prevalence of packstone to rudstone rich in red algae and benthic foraminifera. These facies, in conjunction with paleontological evidence, suggest a depositional environment characterized by a bathymetric depth of approximately 30 to 40 meters. Notably, an outcrop of the Macco formation exposed in the town of Tarquinia exhibits peculiar lenticular concave shapes, ranging in depth from 1.36 to 0.96 meters and with a length from 1.04 to 3 meters. Intriguingly, microfacies analyses conducted within and outside these concave structures reveal similar textures and compositions. The absence of flame structures typically associated with fluid circulation within sediment, and the same sediment textures, suggests that the formation mechanism is unlikely to be linked to seismic events or debris flow mass transport. On contemporary sea floors, seabed pockmarks are among the most conspicuous and common morphological features. Such morphologies are generally attributed to the venting of hydrocarbon fluids from sedimentary deposits. However, several investigations in seafloor worldwide, at both shallow and deep depth, have highlighted similar pits, the origin of which seems to be tied to benthic foraging behaviours of marine vertebrates, particularly cetaceans. This perspective underscores the significant role of marine megafauna in processes such as bioturbation, sediment transport, and their impact on marine ecosystems worldwide. While the debate surrounding benthic feeding activity persists within the scientific community, the presence of such traces in the fossil record remains largely unexplored. Therefore, the concave structures observed within the Macco formation may represent a novel instance (the first one?) of benthic feeding registered in the geological record.

Environmental and human control factors on the Holocene evolution of Venice lagoon: sedimentological and geochemical approach

Keywords: Venice lagoon, sedimentology, geochemistry.

The lagoons are among the most fragile environments on the Earth's surface, since they are naturally subject to submersion or filling after few millennia from their formation, without any human activity aimed at balancing the variables of the system. They are important sites for socio-economic reasons, because of the typically richness of nutrients and biodiversity. Lagoons play an important role in biogeochemical cycles due to their capability to bury C and N and to re-emit N into the atmosphere. The factors affecting their evolution worldwide are mainly related to climate change and human activities. Changes in sea-level, precipitations, temperature, meteo-marine conditions and of the relative contribution between marine and continental supply of water, sediment and OM are linked to climate change. Current and past human activities, in all its forms, largely affecting these areas with a range of environmental impacts. The high variability of physico-chemical and biological conditions of these environments is recorded in the sediments, due to their high degree of preservation. Sedimentology, chronostratigraphy and archaeological data from an archaeological site in Lio Piccolo (Venice lagoon), combined with geochemical proxies, can led to a better understanding paleo-depositional events related to paleoenvironmental and paleoclimatic variations of the Holocene. Proxies such as $\delta^{13}C$ combined with the C/N ratio, can distinguish between marine phytoplankton / algae (autochtonous) and terrestrial plants (allochtonous) (Lamb et al. 2004, Tue et al. 2011); $\delta^{13}C$ can discriminate the abundance between C3, C4 and CAM plants, which can be related to the climatic conditions, due to the adaptability of each species to certain temperature, precipitation and humidity (Liu et al., 2005); δ15N can distinguish terrestrial plants and algae, the latter more controlled by the isotopic composition of DIN, which is strongly influenced by human activities. Nitrates from agricultural runoff and animal sewage have high δ15N and can produce δ15N-enriched phytoplankton, which can enrich the sediments (Mayer & Wassenaar, 2012). The archaeological site represents a Roman inland production area with a wall structure over large wooden foundations, probably linked to salt production and storage. The site is close to a sunken Roman villa dating from the 1st century AD, suggesting the occupation of the area before the foundation of Venice. Preliminary research results will be presented, with the aim of outlining the Holocene stratigraphic-depositional facies, determining the changes in sedimentation rate and burial rates of C and N between the completely natural phase and the human occupation and identifying the origin of the OM in the Lio Piccolo cores, which can provide information on primary productivity and sedimentation patterns of the last millennia.

Corresponding author email: claudio.pellegrini@cnr.it

Keywords: along-strike facies variations, Late-Holocene, palaeo-flood occurrence.

Depositional processes recorded by subaqueous deltas may vary widely along-strike, depending largely on the mode of delivery and deposition of sediments to the basin. In fine-grained systems in particular, depositional processes are difficult to reconstruct with standard facies analysis of sediment cores due to the ostensibly featureless and homogenous appearance of muds. In this study, sedimentological, palaeontological, geochemical and oceanographic data were combined in a detailed characterization of depositional conditions via sedimentary structures, type of organic matter, trace-metal geochemistry and benthic fauna assemblages (foraminifera and ostracods) along the 600-km-long shelf subaqueous delta of the West Adriatic shelf (Italy). Processes inferred from sedimentary facies and micro-structures were then considered in the context of the modern Adriatic oceanographic regime. Specific attention was given to the Little Ice Age stratigraphic unit (1500–1850 CE), which contains a continuum of genetically related fine-grained strata. The Little Ice Age deposit offers the opportunity to examine a source-to-sink system with the high resolution typical of modern analogs, at a time interval when Apennine rivers were not yet hydraulically engineered with man-made sediment traps along their trunks. Individual beds within the Little Ice Age muddy prodelta form hectometre to kilometre-wide bedsets that reflect the interplay between energetic meteo-ocean conditions (storm-dominated beds), flood supply (river-dominated beds or hyperpycnites), and along-shelf bottom-current dispersion (drift-dominated beds). The multidisciplinary approach applied at different scales of observations helped in understanding sediment provenance and the relative timing of sediment transport before final burial that strongly promoted organic matter oxygen exposure and the loss of carbon by microbial degradation. Overall, the distinctive depositional processes that acted in concert along the prodelta slope produced a subtle lateral heterogeneity of preserved sedimentary structures, faunal associations, and organic matter composition in a laterally-continuous lithostratigraphic unit deposited at centennial scale. These findings have implications on the forcing conditions that ultimately control the location and nature of fine-grained beds in both modern and ancient, mud-dominated subaquous delta systems.

Keywords: seismic microzonation, Bradanic Trough, H/V patterns, earthquakes emergency planning

Site response analysis at the scale of municipality requires specific procedures aiming at evaluating lateral variability of seismic effect based on unevenly distributed and heterogeneous data. Retrieving subsoil seismic configuration at the scale of interest requires the joint interpretation of surface and borehole geophysical data, geological and geotechnical information collected during preliminary level microzonation studies. The problem is also made more complex when available information reveal the presence of significant heterogeneities at shallow depths and reference soil conditions are located at depths of the order hundreds of meters. This is the case of the city of Foggia which is in the middle of the Bradanic Trough and is characterized by high seismic hazard. The geological configuration of the study area indicates the presence of a buried carbonatic platform at depths of the order of sever hundreds of meters. Above this layer, pliocenic sediments including clay and sands develop up to few tens of meters from the surface, where conglomeratic lenses of different sizes and thicknesses exist. Inversely dispersive profiles are widespread in the area. A preliminary zoning was defined based on the cluster analysis of H/V spectral ratio curves widely available in the study area. This allowed the definition of a set of H/V patterns each representative of a possible subsoil configuration. Each H/V pattern has been inverted to retrieve a corresponding Vs profile down to the respective geological and engineering bedrocks compatible with information provided by available geological and geophysical data relative to areas where the considered pattern lies. This allows to differentiate a geological bedrock located at a depth of the order 600 m and a shallower engineering bedrock at depth of the about 150 m. Moreover, the lateral extension of conglomerate lenses and respective thicknesses have been tentatively estimated. Based on this information, a set of 1D simulations have been carried out to estimate amplification effects expected at each site where H/V measurements were performed. Based on these outcomes, a new detailed microzonation map of Foggia has been determined, which can be used to support land management activities and emergency planning to improving resilience of the local community against future earthquakes.

Depositional architecture and provenance analysis of the non-marine deposits of the Oldman Formation (Campanian, Belly River Group) at the U.S.-Canada border

Salvador C.*[1-2], Fanti F.[1-3] & Catuneanu O.[4]

[1] Dipartimento di Scienze Biologiche, Geologiche e Ambientali, Università di Bologna. [2] Associazione Paleontologica Paleoartistica Italiana - Parma. [3] Collezione di Geologia "Museo Giovanni Capellini", Università di Bologna. [4] Department of Earth and Atmospheric Sciences, University of Alberta, Canada.

Corresponding author email: claudia.salvador@studio.unibo.it

Keywords: non-marine deposits, depositional architecture, provenance anlysis.

The Oldman Formation (Campanian - Upper Cretaceous) is the middle unit of the Belly River Group, widely exposed in the southern plains of Alberta (Canada) and northern Montana (USA). This non-marine unit is known for its rich and diverse fossil fauna and has been the subject of multiple studies focusing on source-to-sink relationships during large-scale regressive events. Recent field surveys in the Milk River Valley drainage system along the Canada-U.S. border have led to the identification of a previously unmapped stratigraphic interval characterized by highly cemented, white quartz arenites, nicknamed 'Big White'. In 2022 and 2023, eight new stratigraphic sections representative of the lower 70 meters of the Oldman Formation were acquired along the Canadian bank of the Milk River and one in the U.S. side (Kennedy Coulee area): measured sections extend from the Taber Coal Zone (TCz) which marks the base of the Oldman Fm., to the Comrey Member sandstone, a sand-dominated interval associated in the literature to the maximum basinward progradation of the Belly River Group. In this process, 18 sandstone samples were collected for petrographic analyses.

Big White, occurring at about 30 metres above the TCz, comprises two distinct intervals: the lower part (c. 3 meters in thickness) is characterized by high-angle, epsilon stratification, typical of fluvial environments. The upper portion (2 meters thick) shows low-angle, fining-upward beddings overlain by a thin interval of massive deposits interpreted as beach environment. Overall, Big White is composed of unsorted clasts, with over ~90% quartz and ~10% feldspar in a phyllosilicate matrix. The lower part is clast-supported with sub-rounded and well sorted clasts, whereas the upper portion is matrix-supported with smaller, poorly to well sorted clasts. Big White sediments where then compared with sandstones representative of the TCz-Comrey interval: results indicate an overall trend toward quartz-enriched sandstones, with no major shifts in the matrix composition or clasts morphology. This trend changes in the deposits overlying Big White, as in the Comrey quartz clasts abruptly decrease to ~ 40%, and ~15% of clasts are represented by olivine, not present in the lower Oldman beds. Therefore, petrographic data suggest three sediment source areas during the lower Oldman Formation, a thickness interval of c. 70 meters representative of ~1Mya and a complex source-to-sink relationship for the basal beds of this unit. Similarly, in terms of depositional environments and sequence-stratigraphic interpretations, the identification of smaller-scale and higher frequency depositional cycles delimited by subaerial surfaces change current understanding of the processes leading to the deposition of the Oldman Formation.

Multi-proxy investigation of Pliocene transgressive-regressive high-frequency cycles in Geological Sheet 274 Empoli (Tuscany, Italy): insights from the CARG Project

Keywords: Pliocene, multidisciplinary data set, paleo-depositional evolution.

We present a new multidisciplinary dataset (sedimentology, facies analysis, paleontology, biostratigraphy, geochemistry, geochronology) related to the sedimentary sequences of Zanclean to Piacenzian age outcropping in the geological sheet 274 Empoli (1/50000 scale) as part of the ongoing CARG project. The study area is part of the extensional basin systems formed in response to the opening of the Tyrrhenian Sea (starting from the Late Tortonian) and the contemporary counterclockwise migration of the foreland chain system (Malinverno & Ryan 1986; Patacca et al. 1990). In spite of this, over the latter years, several scientists have proposed that compressional tectonics have significantly influenced the development and progression of these basins (Buttinelli et al., 2024, and references therein). Depositional facies are mainly characterized by shallow-marine deposits that are replaced laterally by deltaic, lagoonal, and fluvial deposits. Within this depositional context, we observe multiple vertical stacks of high-frequency transgressive-regressive (T-R) cycles (*sensu* Embry & Johannessen 1993), offering a robust record of even minor relative sea-level fluctuations. In some cases, these cycles exhibit unconformities of different scale orders, while the transgressive surfaces are characterized by shell lag horizons (wave ravinement surfaces) and/or flooding surfaces. We document phases of both positive and negative relative sea-level changes within these sequences. Positive changes with the creation of new space of accommodation may or may not be compensated by the volume of sedimentary supply; depending on the ratio between these two components, they may result in progradational, aggradational or retrogradational sequences. Negative changes with subtraction of the accommodation space led to a forced regression, expressed as erosional unconformities or facies jumps. Building upon extensive, 1/10000 scale surveys, detailed stratigraphic section measurements and sampling for multiple proxy analyses, our study, allows for a preliminary reconstruction of the paleo-depositional evolution of the study area during the Pliocene. We also discuss the possible implications in terms of controlling factors, both local and general, that may have influenced the identified depositional sequences.

How did the plant ecosystem adapt to climatic variations (shifts) during the middle to the late Permian? A case study from Northern Gondwana

Spina A.*[1], Rettori G.[2], Cirilli S.[1], Mansour G.[3] & Rettori R.[1]

[1] Dipartimento di Fisica e Geologia, Università di Perugia. [2] Dipartimento di Filosofia, Scienze Sociali, Umane e della Formazione, Università di Perugia. [3] Department of Geology, Shahid Beheshti University, Tehran, Iran.

Corresponding author email: amalia.spina@unipg.it

Keywords: Guadalupian, land plants, Northern Gondwana.

The Palaeozoic Era ended in two mass extinction events: the end-Guadalupian and the end-Permian. These were triggered by a combination of factors, including ocean anoxia and acidification linked to the onset of the Emeishan Large Igneous Province and the Siberian Traps, respectively. The volcanic activity released substantial volumes of greenhouse gases such as CO_2, SO_2, and CH_4 into the atmosphere, resulting in exceptionally warm global temperatures that had profound ecological impacts on both terrestrial and marine environments, leading to a drastic reduction in biodiversity. The case study examined the changes in microflora throughout middle to late Permian in various sedimentary successions, both as outcrops and subsurface in several regions of SW (Zagros Basin) and NW Iran (SW Azerbaijan and Julfa area). The data obtained from microfloral analysis enabled the identification of four palynozones attributed to the Roadian-Wordian, Wordian-Capitanian, Wuchiapingian and Changhsingian, correlated with the microfloristic assemblages recorded in other Northern Gondwana regions (Oman, Saudi Arabia, Southern Turkey, Iraq, Pakistan, etc.). This chronostratigraphic framework allowed to attribute the microfloral variations, and consequently those of parent plants, to specific temporal phases. Pollen-producing land plants such as conifers and pteridosperms appeared abundant throughout the Guadalupian and Lopingian, surviving across the end-Guadalupian extinction event. Conversely, Lycopodiceae producing spores decreased in abundance across the Guadalupian-Lopingian boundary and increased in the Changhsingian.The analysis of middle to late Permian microflora highlighted the resilence of plants to stresses caused by hyperthermal events and abnormal atmospheric CO_2 concentrations, as no major clade of terrestrial plants disappeared during this period. Instead, a gradual change in flora was observed, unlike marine organisms, which seem to have experienced a much more intense crisis. Furthermore, the microfloral variations of plant groups with xerophytic and hygrophytic affinity across the middle to late Permian interval revealed a clear overall trend. The xerophytic group showed a gradual decrease from the Roadian-Wordian to the Changhsingian, albeit maintaining appreciable percentages. In contrast, the hygrophytic microfloral group increased from the Roadian-Wordian to the Changhsingian. Correlating the temporal values of these two groups with global-scale geological and geodynamic events revealed a correspondence between warm and humid climate microflora and the eruptive episodes of the Emeishan and the Siberian Traps.

The end-Guadalupian anoxic event in Northern Anatolia: new constrains and correlation through palynological data

Spina A.*[1], Yilmaz I.O.[2], Capezzuoli E.[3], Cirilli S.[1] & Bengul N.[1]

Keywords: End-Guadalupian, anoxic event, palynology.

The final extinction event of the Palaeozoic Era stands as the most significant occurrence in the history of life during the Phanerozoic Eon. However, its two-phased nature has only recently gained widespread recognition. The decline in biodiversity during the Permian period unfolded in two distinct stages: first, at the boundary between the Guadalupian and Lopingian epochs, and second, at the boundary between the Permian and Triassic periods. The timing of the end-Guadalupian extinction seemingly aligns with the emergence of superanoxia in Panthalassa, marking another globally impactful geological phenomenon spanning the Permian-Triassic boundary (Isozaki et al., 2007). In addition to the anticipated negative shifts observed at both the Permian-Triassic and Guadalupian-Lopingian boundaries, a notable period of heightened productivity was recently uncovered during the Capitanian epoch (late Guadalupian). This discovery was based on a significant shift of elevated positive 13Ccarb values, ranging between +5 and +6‰ (Isozaki et al., 2007). Given that such positive values exceeding +5.0‰ are exceptionally uncommon in the Phanerozoic record, with only a few notable exceptions in the Palaeozoic era (e.g., Saltzman, 2005), this specific occurrence during the Capitanian epoch has been termed the "Kamura event." In this study, we examined the palynological content of a fluvio-lacustrine succession within the Çakraz Formation in the Zonguldak Terrane, spanning from Akçakoca to Eregli regions. Our aim was to characterize the Alaplı Member, which comprises black, dark-grey to greenish-grey shales, siltstones and limestones. Earlier palynological studies assigned this unit to the late Permian (Okuyucu et al., 2017). However, this study has instead yielded an older microflora attributed to the middle Permian. The palynological assemblage mainly consists of bisaccate pollen grains such as *Alisporites* spp., *Protohaploxypinus* spp., *Striatopodocarpites* spp., monosaccates as *Plicatipollenites* spp., *Potonieisporites* spp., and polyplicates as *Vittatina* spp.. Therefore, the occurrence of a black shale interval including a microflora association within middle Permian age informs us that possible equivalent of the "end-Guadalupian anoxic Event" is recorded within this fluvio-lacustrine environment in Pontides, NW Turkey for the first time. Geochemical analysis of the study interval will be carried out as a future study in order to clarify the level of "end-Guadalupian anoxic Event".

Keywords: palynology, stratigraphy, Southern Alps.

Analysis of palynological assemblages from the Val Daone Conglomerate Formation (VDC) provides new significant information on the age of this lithostratigraphic unit and, as a consequence, of the inception of the Permian tectono-stratigraphic cycle 2 (TSU2) in the Southern Alps (Gretter et al., 2013). The VDC Formation represents a nearly 100-metres thick, medium-grained fluviatile body which can be followed in western Trentino, from the NE part of the Permian Collio Basin to the west, up to the Tione Basin in Val Rendena to the east (Cassinis et al., 1983, 2008).

The microflora from the VDC Formation is from well- to poorly-preserved, in the Val di Scale (Val Rendena) and Ronchi (Val Daone) sections, respectively. Comparisons between the results of the present study with data from the Tregiovo, Val Gardena Sandstone and Bellerophon formations of the Italian Southern Alps reveal a sequence of distinct associations that are stratigraphically and perhaps palaeoenvironmentally controlled.

The stratigraphy of the microfloristic assemblages of the VDC makes it diagnosing for the late Capitanian-Wuchiapingian. Two different palynozones (Val Daone Conglomerate PalynoZone - VDCPZ) are established from the VDC Formation, the lowermost (VDCPZ1) from the Ronchi section, attributed to late Capitanian-early Wuchiapingian, and the uppermost (VDCPZ2) from the Val Rendena section, of Wuchiapingian age (Cortesogno et al., 1998). These VDCPZ biozones show close similarities with coeval associations recorded from other European and extra-European areas: this is consistent with the stratigraphic position of the VDC Formation and allow us: 1) to pre-date to at least to the late Capitanian-early Wuchiapingian the beginning of the Permian 2nd tectono-sedimentary cycle in this sector of the Southern Alps; 2) to estimate at about 16-18 Ma the duration of the depositional hiatus between the two cycles, that was caused by the intra-Permian tectonics, and straddled most of the Guadalupian. Moreover, the VDCPZ1 biozone is one of the few low-latitude associations time-equivalent or slightly younger than the end-Guadalupian mass extinction, a major climatic-driven event that significantly changed terrestrial floras and faunas.

Keywords: Gelasian GSSP, sub-orbital climate variability, central Mediterranean.

The central Mediterranean region is traditionally acknowledged as a key reference area for investigating the Northern Hemisphere climate variability over the last few million years.

In particular, the extraordinary well exposed, well preserved and highly fossiliferous open-marine successions, currently exposed along the shoreline of Southern Italy and Sicily, offer plenty of paleoclimatic and paleoenvironmental archives spanning the Neogene to Quaternary interval, which can be tightly constrained in time and deeply investigated providing pristine sedimentary records (e.g., Cita et al., 2008; Capraro et al., 2017, 2022).

In this context, the Monte San Nicola (MSN) section, located in Southern Sicily, provides an exceptional stratigraphic record for studying the climate evolution throughout the Piacenzian to Gelasian interval. The MSN succession hosts the GSSP for the Gelasian Stage (ca. 2.58 Ma; Rio et al., 1998), which presently marks the base of both the Pleistocene Serie and the Quaternary System (Head et al., 2008). The section is currently under revision, especially in the interval straddling the Gelasian GSSP, which includes the definitive establishment of the Northern Hemisphere Glaciation (NHG), at around 2.6 Ma. This cooling event is marked by a triplet of glacial stages (i.e., MIS 100, 98 and 96) that are found just above the Piacenzian-Gelasian boundary.

In the wake of the emerging interest towards the MSN section, we are currently committed to reconstructing a high-resolution multi-proxy record (benthic and planktic foraminiferal δ18O, Alkenones-derived SSTs) in the lower part of the "Mandorlo" section at MSN (Capraro et al., 2022; Zanola et al., 2024). Results achieved so far provide new insights on the paleoceanographic and paleoclimatic evolution of the central Mediterranean at the beginning of the NHG, specifically on a sub-orbital time scale.

The disappearance of sand: just a false alarm or a global emergency?

Alvisi F.*

Istituto di Scienze Marine, CNR, Bologna.

Corresponding author email: francesca.alvisi@cnr.it

Keywords: georesources, aggregate extraction, environmental impact.

If we type "Sand War" into Internet search engines, we are directed to the border conflict between Algeria and Morocco, which was fought in September-October 1963. The conflict stemmed largely from the Moroccan government's claim to some portions of the Algerian provinces. One of the main reasons for this war was the discovery of important mineral resources in the disputed area.

But if we add a single 's' to the end of 'war' (i.e. Sand Wars) we land on another kind of war, this time a global one. The documentary film by director Denis Delestrac (2013) forces us to open our eyes, perhaps for the first time, to a new 'gold rush' for a material that has become a key raw material. The film premiered at Cinéma Publicis in 2013, where it became the highest rated documentary of 2013. Among many other victories, the film inspired the United Nations Environment Programme (UNEP) to publish a global environmental alert in March 2014 entitled Sand, rarer than you think (UNEP, 2014).

But why should scientists address this issue? Sand has become a vital commodity for our modern economies. Sand and gravel are mined worldwide and represent the largest volume of solid material mined globally (Steinberger et al., 2010). The volume extracted, at a rate far greater than their renewal (Krausmann et al., 2009), is having a major impact on rivers, deltas, and coastal and marine ecosystems around the world, resulting in land loss through river and coastal erosion, lowering of the water table, and decreasing sediment in natural systems. Despite the huge quantities of sand and gravel used, our increasing dependence on them and the significant impact their extraction has on the environment, this problem has been largely ignored by policy makers and remains largely unknown to the public. Furthermore, although more sand and gravel are extracted than any other material, reliable data on their extraction in some developed countries are only available for the last few years (Krausmann et al., 2009). The absence of global data on aggregate extraction makes environmental assessment very difficult and has contributed to the lack of awareness on this issue, which in turn results in a lack of action. There is in fact a large discrepancy between the extent of the problem and public awareness. As this is a highly topical issue, in-depth research and assessments of the impact of the uncontrolled exploitation of this natural resource are needed at local and global scale.

Keywords: pyroclastic deposits, thickness, Campania, Italy.

Determining spatial thickness of fallout pyroclastic deposits provides key information on hydrological, geomorphological (both erosion and deposition) and volcanological processes. However, this is a challenging line of research because: (1) field-based measurements are expensive and time-consuming; (2) the ash might have been dispersed in the atmosphere by several volcanic eruptions; and (3) the expected spatial distribution of the fallout pyroclastic deposits was altered by wind during an eruptive event and have been changed by soil-forming/denudation processes after ash deposition. In this research, we tried to bridge this knowledge gap by compiling a dataset of 19 variables including thickness of fallout pyroclastic deposits measured in some sectors of Campania region and 18 predictor variables mainly derived from digital elevation models and satellite imageries. Then, three methods already available in the literature (i.e. GPT: Geomorphological Pyroclastic Thickness; SAPT: Slope Angle Pyroclastic Thickness; and SEPT: Slope Exponential Pyroclastic Thickness), stepwise regression model and random forest (RF) machine learning technique were used for thickness estimation. Finally, Simple Average, Minimum Variance, Ordinary Least Squares and Least Absolute Deviation (LAD) methods were implemented for developing a less biased model through statistical combination of different predictions. The results showed that RF returns the most accurate predictions (RMSE < 82.46 and MAE < 48.36), while statistical combination of the predictions obtained from the above-mentioned five models through LAD improves prediction accuracy (MAE < 45.12) in the study area. The maps for the values estimated by RF and LAD illustrate that the spatial patterns did not alter significantly, but the estimations by LAD are smaller. This combined approach can help to estimate thickness of fallout pyroclastic deposits in other volcanic regions and to manage geohazards in the areas covered with unconsolidated pyroclastic materials.

From the micro to the macro-scale: the contribution of the "Provenance Centre" (Unimib) in the study of sedimentary archives

Andò S.*[1], Barbarano M.[1], Caruso P.[1], Gambarotta O.[1], Garzanti E.[1], Limonta M.[2], Malusà M.[1], Paglia S.[1], Pastore G.[1], Resentini A.[1] & Vezzoli G.[1]

Keywords: heavy-minerals, bulk petrography, Raman spectroscopy.

The Departmental Study Centre called "Provenance", as part of the DISAT (Dipartimento di Scienze dell'Ambiente e della Terra) - TECLA (TErra CLima Ambiente) Project, wants to maintain and promote basic geological culture in the educational field and broaden its skills in petrology and geophysical modelling, through an integrated management of instrumentation and resources. The ability to trace sediments from their sources to sedimentary basins is a prerequisite for quantitative analysis of Earth-surface dynamics (Caracciolo et al., 2016). The Provenance Centre has been carrying out investigations and training in the field of Sedimentary Petrography for many years, aimed at reconstructing the evolution of the Earth's surface over geological time, using the study of the petrographic and mineralogical composition of sediments, and preparing new generations of geologists for provenance studies (Garzanti & Andò, 2019). Modern laboratories are used, applying the most advanced quantitative provenance techniques (analysis of heavy minerals and bulk petrography; Raman spectroscopy; fission-track thermochronology on zircon and apatite). The aim of this multidisciplinary approach takes advantage from the study of natural continental and marine sedimentary records to understand and where possible quantify all the factors that determine and influence the generation and composition of sediments. Much attention is paid to the factors that act together in the large natural systems studied, considering the mineralogy and age of the outcropping rocks, the physiography and climatic conditions existing in the source areas, the compositional modifications connected to the processes of erosion, transport, deposition, and the chemical weathering, carried out during one or more sedimentary cycles. These studies find notable applications both for the analysis of current and past climate changes (e.g.: Ross Sea Project in Antarctica; Amazon Basin) and for recognizing the effects of anthropogenic activities on the Earth system. The Centre has recently expanded its sphere of interest towards research topics that require a multidisciplinary approach, such as provenance studies applied in the archaeological field (e.g., Stonehenge project in the UK; Bevins et al., 2023) and the quantitative study of plastic pollution in the marine environment (Ferrero et al., 2022).

Corresponding author email: massimo.civitelli@unical.it

Keywords: sandstone diagenesis, Central California, Butano Sandstone.

The Butano Sandstone represents an Eocene deep-marine fan, deposited in central California within the La Honda Basin. The Butano fan includes three main sedimentary facies associations: inner-fan, middle-fan, and outer-fan facies, placed in the southern, central, and northern part of the basin, respectively. Despite the homogeneous quartzofeldspathic framework composition, the three outcrop belts exhibit several mineralogical differences, likely due to the post-depositional events ruled by the intricate tectonic history of the La Honda basin, resulting in deep-burial diagenetic processes and possible hydrothermal alterations. Both compaction and cementation reduced the intergranular volume (lower than 19 %), and the Compaction Index (average 0.9), indicates the major role of compaction in reducing original porosity. The outcrops of the southern proximal fan and northern distal fan show varying proportions of detrital quartz (43.5% in Qm) compared to the central outcrop of the middle fan (50.7% in Qm) (Critelli & Nilsen, 1996). During burial, plagioclase primarily and K-feldspar to a lesser extent experienced significant leaching and dissolution, especially in the central basin region, leading to the relative higher quartz volume. Additionally, this condition is quite consistent with the distribution of alteration degree of feldspar grains among the three outcrop belts, which occur more dissolved in the middle-fan sandstones (Civitelli et al., 2024). Extensive post-depositional alterations occur notably within the Butano Sandstone located in the central portion of the La Honda Basin, with a probable primary attribution to hydrothermal effects during burial.

Detrital modes of the Pennsylvanian-Permian sandstones in Central-Eastern Sardinia (Italy)

Criniti S.*[1] & Costamagna L.G.[2]

[1] Dipartimento di Ingegneria dell'Ambiente, Università della Calabria, Rende (CS).
[2] Dipartimento di Scienze Chimiche e Geologiche, Università di Cagliari.

Keywords: Pennsylvanian-Permian sandstones, central-eastern Sardinia, Variscan and neovolcanic provenance.

Late Pennsylvanian-Permian sedimentary successions are exposed in Central-Eastern Sardinia (Italy). Here, the sandstone detrital modes of several scattered basins (Mulargia-Escalaplano, Ingurtipani, Perdasdefogu, and Montarbu basins) have been investigated to highlight how the tectono-magmatic processes influenced the sedimentation. Sandstones were collected along well-characterized stratigraphic sections that usually start with a Upper Pennsylvanian - Early Permian dark limnic succession (Rio Su Luda Fm, Ronchi & Falorni, 2004; Costamagna & Criniti, 2024) lying unconformably on the Variscan basement, and continue upward with red bed successions (Mulargia and Pegulari Fms: Costamagna, 2022; Costamagna & Criniti, 2024) until the Lower-Middle(?) Permian. The sandstone composition testifies a changing nature of the source areas feeding since it is quartzolithic metamorphiclastic in the Upper Pennsylvanian sedimentary strata of the Mulargia basin, abruptly passing to volcaniclastic sandstones upward in the Early-Middle(?) Permian of all studied basins. In particular, the Upper Pennsylvanian strata always display low-grade metamorphic detritus, including metaradiolarite (lydite) and phyllite fragments deriving from the Variscan chain. An increasing metamorphic grade of the feeding is supported in the upward successions. The disappearance or dilution upward of this metamorphic detritus suggests the emplacement of the volcanic activity during a progressive tectonic fragmentation of the basins and more in general of large portions of the supercontinent Pangaea. In fact, the Lower -Middle Permian successions of all studied basins display an increasing content and variety of neovolcanic detritus (Critelli et al., 2023) revealing frequently andesitic, and rhyodacitic-rhyolitic coeval sources, while spots of basaltic and basaltic andesite lavas and pyroclastic rocks; whereas, andesitic-dacitic neovolcanic sources, are rarely encountered in the Perdasdefogu and Mulargia basins.

Keywords: Carboniferous detrital suites, Culm Cycle, Variscan Paleotethysian Orogeny.

Detrital modes of Carboniferous sandstones reveal the sedimentary budget of convergent plate boundaries during the Variscan s.s. to Paleotethysian orogenic time span (≈420–300Ma) within the Paleo-Mesomediterranean Domain. These sedimentary strata are usually referred to the regional Culm lithostratigraphic depositional unit, and cover an important gap of information to the area located between the Iberian-French massifs and the African Paleo-Atlas, in the western Paleotethys. The studied sandstones belong to the Middle Carboniferous deep-water turbidites of the Almogia and Marbella Conglomerate formations in the Malaguide (Betic Cordillera) and Ghomaride (Rif Chain) Complexes. Here, the sandstone composition is quartzolithic and records an important high-to-medium-low grade metamorphic content in both area (Criniti et al., 2023, 2024), with an increasing trend towards Morocco. The source area was a lithic-transitional recycled orogen with a signature of volcanic and ophiolitic detritus (≈330Ma and/or older). These supplies seem to be derived mainly from a mid-crustal deformed and thrusted terrane prior to the Early Carboniferous, that was involved into the plate convergence south eastwards of the Variscan s.s. orogenic system, rapidly exhumed and uplifted during the mid-Late Carboniferous time. Consequently, a metamorphic basement should be already structured during Middle Carboniferous when thrusting took place, allowing the Culm deposition in the Malaguide and Ghomaride Complexes, suggesting pre-Middle Carboniferous metamorphic highlands. The presence of ophiolitiferous detritus (≈330Ma and/or older) could indicate an obducted oceanic branch, while the synsedimentary volcanic activity (mainly andesitic) should be related to a lost magmatic arc, in good agreement with a nearby subduction area. As a consequence, the thick terrigenous Culm strata could be deposited in a complex foreland basin system connected northward with carbonate platforms and with a crystalline highland uplifted domain from the southern Europe Iberian-French massifs and southward with the African Paleo- Atlas Domain. The studied sandstone petrofacies deeply contributes to paleogeographic reconstructions since block fragmentation and spreading, during the Paleotethysian and Alpine orogenies, rearranged the Paleozoic paleogeography now part of the Cenozoic Perimediterranean Chains, removing the whole principal source rocks.

Keywords: erosion rates, isotope tracers, coastal erosion hazards.

During recent decades there has been an increasing interest in quantification of Earth surface processes (e.g., weathering, pedogenesis, erosion and sedimentation) at different temporal and spatial scales, also investigating mutual relations between those acting on slopes and others occurring within the hydrographic network. In this frame, a major focus of the current work is devoted to estimate long-term erosion rates and sediment residence times (average exposure ages) in a pilot stream catchment of Calabria (southern Italy) using cosmogenic beryllium (^{10}Be), along with medium-term soil erosion rates through fallout radionuclides ($^{239+240}$Pu). The combination of such methods, although recording soil and sediment dynamics at different timescales (Balco et al., 2008; Loba et al., 2022), can be of great help in understanding possible interconnectivity between the drainage system and potential source areas. This approach can also shed lights on the amount of deposits able to feed the coastal sector and provide useful tools for the assessment, monitoring and management of coastal erosion hazards and risks. The research activities are part of an ongoing project "TECH4YOU – Technologies for climate change adaptation and quality of life improvement", supported by the European Union (Next Generation EU – PNRR M4.C2.1.5). The existing literature mainly applied the aforementioned isotope tracers separately (Cyr et al., 2014; Meusburger et al. 2016) or each single nuclide at transect or site scales. Conversely, the distinctive and innovative character of this research consists in their catchment-wide application, combined with detailed geological, geomorphological and pedological surveys, a multi-temporal comparison of historical aerial photos and Google Earth images to identify land-use, land-cover and landscape changes, the use of GIS technologies for thematic mapping, in situ monitoring of water flow dynamics and properties (e.g., turbidity, water level, temperature, electrical conductivity), the application of Passive Integrated Transponder (PIT) tags for the evaluation of short-term transport of fluvial sediments after specific flooding events, and the development of an integrated model for the estimation of sediment production and erosion rates. Such an advanced and interdisciplinary methodological approach is essential to unveil the complex dynamics underlying erosive processes from source to sink areas, and can be established as a standard replicable protocol to be adopted for studying other hydrographic basins in any geographic and geo-environmental contexts.

Keywords: marine bioconstructions, coastal environment, worm reef.

Sabellarian bioconstructions, formed due to the activities of polychaetes of the genus *Sabellaria*, stand as remarkable structures within shallow marine ecosystems. Their dual role as natural breakwaters and biodiversity hotspots underscores their ecological significance. Along the Apulian coast of the Mediterranean Sea, *Sabellaria spinulosa* contributes to the formation of these bioconstructions, yet their sedimentological and morphological intricacies remain poorly known. This study delves into the sedimentological and morphological characteristics of Sabellarian bioconstructions along the Apulian coast, aiming to unravel their dynamic interplay with the surrounding environment. Through a comparative analysis of the sands trapped within the structures and those comprising the adjacent beaches, we elucidate the complex nexus between physical and biological processes shaping these bioconstructions. Utilizing a multi-scale approach encompassing textural and petrographic analyses, we decipher the temporal evolution of these structures with unprecedented resolution. Our findings unveil the profound impact of Sabellarian reefs on the sediment dynamics and ecological niches of sandy beach environments. By meticulously examining the morphology across macro-, meso-, and microscales, we offer nuanced insights into the intricate evolutionary pathways of these bioconstructions. In addition to advancing our understanding of Sabellarian bioconstructions, this research underscores the profound interconnectedness between ecosystems and coastal environments.

Integrated paleoenvironmental multi-proxy analysis of Late Quaternary fluvial sediments in the Côa Valley (northeast Portugal)

Keywords: multidisciplinary approach, fluvial sediments, paleoclimate.

Late Quaternary fluvial sediments in northeast Portugal's Côa Valley represent a significant repository of paleoenvironmental information at local and regional scales. Understanding their depositional history and dynamics is essential for unravelling paleoclimate and geomorphological evolution. This work provides a comprehensive overview of the nature, timing, and frequency of the environmental changes that have characterised the study area during the last ~150 ka, encompassing late Marine Isotope Stage (MIS) 6 to MIS 1. The investigation is based on a multi-proxy analysis of the sedimentary record preserved at the Cardina/Salto do Boi archaeological site. A combination of intersecting sedimentological, geochemical, geomorphological, and geochronological analyses of a ~5-m-thick siliciclastic sedimentary succession was implemented. To ensure the highest level of accuracy and reliability in our findings, we used high-resolution application techniques such as grain-size, whole-rock and clay mineralogy, major/trace-element geochemistry, magnetic susceptibility, sedimentary petrography, and abundance of organic particles, coupled with absolute dating on feldspars by optically stimulated luminescence (using a multi-grain pIRIR protocol). In addition, advanced techniques like back-scattered electron imaging and elemental mappings obtained by SEM-EDS spectroscopy were spent to enhance our field characterisations and allow us to interpret the sediments' hydraulic history and origin. The main results show that the studied stratigraphic succession begins with fine sediments accumulated under low-energy diffuse water-flow conditions, where the dominant process was the suspension settling over bedload deposition. This accumulation occurred relatively close to the paleo-channel margin, resulting in overbank sedimentation under low-intense precipitation with periods of enhanced effective moisture (rainfall seasonality) during late MIS 6 and MIS 5e (~150-116 ka). The MIS 5d-5a interval (~116-71 ka) is dominated by a rapid decrease in water-flow energy linked to progressively colder and still humid conditions. Successively, sedimentary accretion became farther away from the fluvial paleo-channel margin, with a new phase of overbank sedimentation punctuated by incipient pedogenetic activity under the pronounced climate instability that characterised most of the Last Glacial Period (~71-23 ka). The uppermost sedimentary units reflect the subsequent period of progressive increase in humid conditions and chemical weathering (the last ~23 ka), attested by the more superficial disturbed slope sequence (colluvium) moved by gravity-driven processes and shallow surface water flow, with evidence of pedogenesis, anthropogenic inputs/disturbances and redeposition. This research significantly advances our understanding of Late Quaternary fluvial dynamics and paleoenvironmental changes, providing crucial insights into the landscape evolution of the western Iberian Peninsula.

Crystallization of Mn-hydroxides for interaction between limestones and clay minerals in the Apulian karst (southern Italy)

Fornelli A.*[1], Micheletti F.[1], Acquafredda P.[1] & Mangone A.[2]

Keywords: red carbonate crusts, Apulia karst, Mn-hydroxide.

The mineralization of Mn-phases was found within the carbonate crusts that cover the Mesozoic carbonate basement. These crusts form on ancient erosional surfaces, which serve as the substrate for paleodolines within the Apulia karst region. The petrographic and mineralogical characteristics of nodules and red crusts suggest a supergene origin (Micheletti et al., 2023). The primary ore minerals identified through optical microscopy, SEM-EDS, and Raman spectroscopy, are Mn-hydroxides and romanechite. These minerals may contain impurities such as Ca, Al, Si, Fe, Mg, Na, K, and Co. Mn-hydroxides are primarily found as extensive granular aggregates exhibiting high luminescence. Late diagenetic characteristics of Mn-phases are evidenced by bright romanechite veins, indicating the deposition of thin films along the walls of pore spaces and outlining previous iron oxides. Mn-phase occurrences are observed even on clay minerals; pseudomorphosis of Al-Si-Mn phases is characterized by grey portions enriched in Al and Si (clay minerals) and luminescent regions richer in Mn. The composition of romanechite varies depending on its Ba content: i) romanechite with approximately 11-12 wt% Ba exhibits low levels of Al and Si, while ii) romanechite containing 6-7 wt% Ba contains approximately 1.0 wt% Al, 1.2-1.3 wt% Si, and K about 0.5-0.7 wt%. The presence of low Ba-romanechite may be associated with the occurrence of clay minerals mixed with Mn-phase. A strong correlation is evident between the combined concentrations of Al, Si, and Fe with Mn, whereas no correlation is observed between Mn and Ba or Mn and Ca. This observation suggests that the structure of romanechite can accommodate varying proportions of Al, Si, and Fe when these elements are available, with Si and Al reaching concentrations of about 14 wt% and 11 wt%, respectively. On the contrary, there are Al-Si-Fe rich phases containing significant quantities of Mn, reminiscent of clay minerals hosting Mn-hydroxide. The relationship between the growth of clay minerals and Mn phases may be influenced by environmental conditions such as Eh and pH. A more thorough examination of growth structures reveals slight misalignments among nanoparticles forming local aggregates. These aggregates have the potential to evolve into bulk phases as misalignments among component nanoparticles gradually correct, forming irregular grain morphologies. This process appears to be associated with Crystallization of Particle Attachment (CPA in Zhu et al., 2021; Yin et al., 2022). The emergence of Mn-phases on a calcareous substrate is likely linked to the chemical interplay between predominantly clay material carrying Mn, Ba, Si, Al, and Fe, and the dissolution products of limestone. These findings underscore the necessity for a more thorough examination of the red crusts found on karst carbonate basements in the Mediterranean region, as they may contain mineralization conducive to the extraction of raw materials such as Mn, Fe, and Al.

Late Paleogene syn-sedimentary volcaniclastic deep-sea succession of the Candela Gorges (Southern Italy). New constrains for the evolution of the Southern Apennines

Gallicchio S.*, Fornelli A., Maiorano P., Fanelli G. & Micheletti F.

Dipartimento di Scienze della Terra e GeoAmbientali, Università di Bari "Aldo Moro".

Corresponding author email: salvatore.gallicchio@uniba.it

Keywords: volcaniclastic turbidites, U-Pb zircon ages, late Paleogene.

A re-examination of the most representative succession of the Tufiti di Tusa along the Calabria-Basilicata boundary added new lithostratigraphic and depositional details to one of the internal turbidite successions of the Southern Apennines (Gallicchio et al., 2023). It also prompted new biostratigraphic, petrographic, geochemical, and chronostratigraphic studies to obtain more detailed information on the depositional age, the evolution of composition and sediment pathway; these collected data constrain the paleogeography of the depositional basin. The study section is exposed along the Candela Gorges (south of Rotondella Village, Italy) and comprises three main informal lithostratigraphic units from bottom to top: i) Unit I is mainly characterized by calciclastic turbidites, with poorly represented siliciclastic ones; ii) Unit II is mainly composed of siliciclastic turbidites with occasional intercalations of calciclastic ones and, iii) Unit III is dominated by volcaniclastic deep-sea gravity flow deposits.

Petrographic analysis and geochemical data of siliciclastic strata, allows us to detect the variability of siliciclastic supply over time. The selected samples derive from the three different units and represent siliciclastic strata with different grain size.

The samples of Unit I are represented by fine and coarse-grained sandstones in which calcitic fossils and carbonate cement occur. The silicatic detritus consists of micas, quartz and feldspars with many metamorphic, plutonic and volcanic lithic fragments. Some ophiolitic lithics with garnet and epidote locally occur.

The sandstone samples from Unit II have middle and coarse grain size. The framework is siliciclastic with minor bioclastic components. Single crystals and lithic fragments are similar to the samples of Unit 1 but a major amount of micaschists and ophiolites can be present, in addition some volcanic and acidic lithics are scattered.

In the sandstone samples from Unit III, volcanic detritus represented by porphyritic andesite lithics forms about 70% of the framework, while metamorphic lithics with garnet, glaucophane and muscovite prevail together with ophiolitic clasts. The geochemical data are in line with the petrographic evidences, the MgO (from 2.98%wt to 5.05% wt) and FeO (from 4.94% wt to 6.60% wt) contents increase upwards from Unit 1 to Unit 3 and the CaO contents depend on calcitic cement.

U-Pb spot ages detected on detrital and euhedral zircons from syn-sedimentary volcaniclastic sandstones of Unit III are about 33±1 Ma (Fornelli et al., 2020). This age is further supported by new calcareous nannofossil biostratigraphic data, which can be related with the late Eocene–early Oligocene. These results suggest a relationship with other volcaniclastic turbidite units of the Northern Apennines (Val d'Aveto, Petrignaccola, and Ranzano formations) and do not allow correlation with the Tufiti di Tusa Formation in Sicily, which is late Oligocene – early Miocene.

Keywords: paleoclimate, Jurassic, External Rif, Morocco.

This work focuses on Jurassic deposits belonging to the External Rif chain (Morocco). We performed elemental geochemistry analyses on selected samples of fine-grained Jurassic clay from nine stratigraphic sections belonging to the External Rif units. The main objective was to constrain the climate changes that affected northwestern Gondwana and its hyperextended conjugate Atlantic and Tethys margins during the Early-Late Jurassic. This work deals with the reconstruction of the paleo-floral landscape, paleo-humidity, and paleo-precipitation. We also aimed to unravel Early-Late Jurassic weathering, the source-to-sink transfer, and its impact on the paleoproductivity, paleo-redox, paleo-oxygenation, and paleosalinity of the flanking oceanic sinks. The obtained results indicate an early Jurassic dry-cool climate period with low rainfall and productivity, that evolved progressively to a warm climate under semi-moist and moist conditions, with high rainfall and evapotranspiration amounts in the middle Jurassic, leading to the increase of paleoproductivity. This period was marked by intense weathering with a huge terrigenous supply stored in a low-saline and well-oxygenated bordering sink(s) under oxic conditions. Later, the Upper Jurassic continuous as a warm climate under semi-moist to moist wet conditions with increasing rainfall and evapotranspiration and subsequent intense weathering triggered the transfer of huge terrigenous fluxes to the sink, before a shift to an arid cold climate in the late Oxfordian (Kairouani et al., 2024). This Jurassic climate change scenario in the northwest Gondwana hinterland may fit well with that proposed by Morgan et al. (1999) who suggested seasonal paleoclimatic changes in the Late Jurassic. The first order geodynamic control as plate tectonics reorganization, oceanic seafloor spreading triggering climate shift from dry "cool" to wet warm "greenhouse that seems to be controlled by successive mega-monsoons that occurred through the Inter-Tropical Convergence Zone (ICZ) over mid-latitudes margin and oceanic realms bordering the northwest Gondwana" during the Jurassic (Kent et al., 2015).

Keywords: phosphatic sandstones, microbial biomineralization, Toarcian Ocean Anoxic Event.

Phosphatic-carbonate sandstones have been reported for the first time (Kairouani et al., 2023) within early Jurassic Prerif succession belonging to the External Rif Chain (Morocco). Considering the scientific relevance of this finding, this research proposes an integrated investigation by merging petrographic, mineralogical, and micro-textural data, with inferences about genetic conditions. Multi-method analysis was performed by Optical Microscope, X-ray diffraction, and Scanning Electron Microscopy with the aim to constrain biogeochemical and mineralogical processes controlling phosphatic grain genesis. The phosphatic sandstones are represented by moderately to well sorted fine-grained hybrid arenites with sub-angular to well-rounded clasts cemented by sparry calcite. The phosphatic grains represent ca. 25-30%, while the remaining other grains are dominantly made up of carbonate (mostly micritic grains and foraminifera tests) and secondarily by siliciclastic grains (quartz and feldspars). The phosphatic grains can be grouped into two main classes: i) phosphatic peloids and ii) phosphatic bioclasts (as fish bone, representing less than 5%). XRD data reveal that the main phosphate phase occurs as CFA (carbonate fluorapatite) also if in many cases it can be found as amorphous/cryptocrystalline collophane. SEM investigations evidence a not homogenous chemical composition of the phosphatic grains which are characterized by different types of microtextures. BSE images reveal brighter acicular and fibrous growths with lower C and higher F contents boarding the external textures of voids and internal gray portions with lower F and higher C contents. Centripetal microboring from outside to inside was observed in the phosphate-coated foraminifera and skeletal fragments. Probably the endolithic bacteria feed on organic matter in the phosphate skeletons of organisms by precipitating a bright phosphate with low C contents, the portions not digested by the bacteria are instead represented by phosphates with more C. In some case, the advanced stage of endolithic bacteria swarming is evident with gradual rounding of the phosphatic fragment edges until the complete conversion of the phosphate test into an a peloidal structure. The genesis of sedimentary phosphorites can be controlled by heterotrophic microbial communities with high biogeochemical activity or can be related to precipitation of phosphates by fluids during diagenesis (El Bamiki et al., 2023). Microbial pathways and palaeoenvironmental conditions involved in the formation of phosphorite grains. Both these processes take place under low oxygen conditions in marine environments (Salama et al., 2015). The palaeclimatic studies on Pleinsbachian-Toarcian samples (Kairouani et al., 2024) belonging to the same succession indicate low oxygen conditions. Consequently, anoxic conditions during Toarcian Oceanic Anoxic Event (T-OAE at ~181 Ma) are related to the genesis of these Mesozoic phosphatic sandstones.

Keywords: (paleo)weathering, feldspathic sand(stones), dissolution.

Both (paleo)weathering and diagenesis are responsible for much labile Framework Grains Dissolution. Framework Grain Dissolution (FGD) involving feldspars was found to be significant to reservoir properties in grus and soil horizons developed on felsic plutonites of the Sila Massif (Calabria, southern Italy) bedrock under a Mediterranean climate. FGD porosity demonstrated an increase in well-connected porosity from negligible in the fresh rock to around 30-40% in the grus. In this surface weathering environment, the FGD, during the conversion from the original bedrock to the grus and soil, show a 14% loss of plagioclase and the total loss of K-feldspar. This dissolution led to an increase of porosity from 0,4% in the coherent rock facies to 28,0% of the soil. These results places constraints on the FGD and composition of ancient feldspathic arenites and the conditions designed to distinguish between paleoweathering from diagenesis. Previous studies of the stratigraphic record, in which the paleoclimate was more humid than the modern climate, suggests that FGD of unstable grain abundance, by ancient weathering efficiency, cannot be distinguished from unstable FGD occurred during burial diagenesis. Modern sands of humid climates have lower contents of unstable grains with a percentage decrease between 12% and 20% for unstable lithic grains and of 10% for feldspathic ones if compared to a provenance from the same source rocks under humid climate. Literature data from ancient feldspathic arenites and modern sands, derived from similar source rocks, demonstrate that pre-diagenetic near surface dissolution of unstable grains can be discerned from diagenesis only for those modern/ancient pairs where the modern climate is more humid than the inferred paleoclimate. In this case feldspar grains show a dissolution even higher reaching a 34% of loss of feldspars and a percentage decrease of unstable lithic grains ranging from 10% to 12%. Both intrastratal dissolution and replacement by authigenic clays may remove feldspars from the arenites framework thus affecting both the classification and the inferred tectonic setting of the arenites leading to an incorrect paleogeographic interpretation.

Tectonic forcing encoding in the geomorphic and stratigraphic records of a tight source-to-sink system (Northeastern Sicily, Italy)

Keywords: NE-Sicily, source-to-sink system, tectonic forcing.

Recognizing tectonically- vs. climatically-induced base level change signals encoded within the stratigraphic and geomorphic records of coupled source-to-sink systems is still a challenge (Sharman et al., 2019). In this study, we integrate sedimentological, geochronological, and geomorphic approaches to investigate the relationship between geomorphic transience and sediment deposition in a tight tectonically-uplifted source-to-sink system. At the sink we built a luminescence-based age model for the late Pleistocene Pagliara fan-delta complex, located on the eastern side of the Peloritani Mts. (NE-Sicily, Italy), and explored the signal periodicities encoded by environmental proxies. At the source we modelled the base level fall history and the paleo-erosion in the catchment. The ~150-200m-thick Pagliara fan-delta complex deposits are exposed up to an elevation of ~300 m a.s.l. and onlap steep east-dipping bedrock at the coast. Infrared-stimulated luminescence (IRSL) ages of the delta deposits range from ~327 ka to ~208 ka, and provide a vertical long-term sediment accumulation rate as rapid as ~2.2 cm/yr during MIS 7. Cosmogenic 10Be concentrations measured in two samples collected along the delta indicate MIS 8-7 paleo-erosion rates consistent with the modern rate of ~1 mm/yr (Cyr et al., 2010). In addition, the Magnetic Susceptibility time series analysis evidences the occurrence of some millennial to sub-millennial periodicities pointing out to cyclical past environmental changes, and inspirationally allowing to speculate on the origin of sediment in the source. The Pagliara fluvial topography recorded an unsteady base level fall history, in phase with eustasy and superimposed on a longer, tectonically-driven signal, the rate of which increased from ~0.95 mm/yr to ~1.8 mm/yr in the past 150 ky (Pavano et al., 2024). Finally, we reconstruct the accommodation space history of the hanging wall basin that hosted the Pagliara fan-delta complex deposits. We reconstructed an integrated geomorphic and depositional dynamics of the Pagliara source-to-sink system, evolving in response to regional-to-local tectonic deformation, and climate forcings.

Corresponding author email: elena.pugliese@unical.it

Keywords: provenance, heavy minerals, Crati River.

The knowledge of the heavy mineral composition of sediments in a river basin and the controlling factors (e.g., provenance, transport processes, and chemical weathering) is crucial in the study of both source-to-sink processes and in the evolution of river drainage area. Heavy mineral concentrations in modern sand sample of the main and tributary streams of Crati River drainage area were analyzed using optical microscopy and RaMan spectroscopy, in order to determine the types and abundance of heavy minerals, assess their weathering textures and infer their provenance. Heavy minerals concentration ranges from 5,6% to 42,7% in the Crati River main channel with irregular patterns in the abundance of heavy minerals observed across the trunk river from the upper to the lower reaches. Most of the heavy minerals display sub-angular to angular shape, grains with sharp edges on the surface, conchoidal fractures, deep troughs, and breakage blocks inferring that the provenance is close to the depositional area. Subrounded to rounded grains with smoother surface, arcuate steps, also occur. These minerals mainly include garnet, epidote and sillimanite, followed by pyroxenes, amphibole, titanite, rutile, pumpellyite, andalusite, tourmaline staurolite and a minor amount of cassierite, brookite and apatite are also present in trace amounts. The zircon-tourmaline-rutile index (ZTR), ranging between 3 to 13%, indicates a mineralogically immature sediment and a short transport history and provenance. Some species like amphibole, pyroxene and epidote show corroded morphologies while garnet and sillimanite grains are characterized by mainly physical breakage. The heavy minerals suite of garnet, epidote, sillimanite, green hornblende and staurolite suggest a provenance from moderate to high-grade metamorphic source terrain,such gneiss, amphibolite, granulite and schist . A provenance from an igneous source complex,granite, granodiorite and gabbro, is marked by detrital species such as rutile, green-brown hornblende, titanite, tourmaline, zircon, pyroxene and opaque minerals. Moreover, the occurrence of rounded to sub-rounded zircon and rutile grains indicate polycyclic supply from sedimentary and meta-sedimentary source rocks. Therefore, results show that the Crati River sand is derived mainly from the metamorphic and plutonic rocks of the western side of the Sila Massif and the eastern side of the Catena Costiera, and to a lesser extent from the sedimentary rocks outcropping in the Pollino Massif. These features suggest that the locally source signal (detected also in the tributaries) are preserved in the Crati River main trunk, indicating that the control on heavy minerals composition is chiefly provenance influenced and not related to fluvial processes.

Weathering and erosion rates at different timescales in a granitic area of the Mediterranean (Sila Massif, Calabria, southern Italy): an overview on recent advances

Scarciglia F.*

Dipartimento di Biologia, Ecologia e Scienze della Terra, Università della Calabria, Rende (CS).

Corresponding author email: fabio.scarciglia@unical.it

Keywords: weathering processes, landscape evolution, erosion rates.

Weathering processes and geomorphic dynamics including erosion, transport and sedimentation strongly contribute to shape past and modern landscapes worldwide. The Sila Massif (Calabria, southern Italy) represents a pilot area as a natural open laboratory in the central Mediterranean, where a variety of such physical, chemical and biological processes and corresponding landforms has been studied over more than three decades. Literature data span across different spatial scales, ranging from field (regional, catchment, slope, outcrop) surveys to microscopic and submicroscopic observations using optical and/or scanning electron microscopy. Among major research findings is the role of rock discontinuities, related to the specific geological history of the parent material, as weakness surfaces and predisposing factors of mechanical breakage patterns and preferential sites for chemical reactions. Similarly, microdiscontinuities at inter- and intra-mineral levels (fabric, contact surfaces, cleavage or twinning planes, compositional changes), coupled with a progressive development of neogenic products (clay minerals and iron (hydro)oxides), often act as upscaling factors, propagating their effects at the macroscale. This behavior leads to rock degradation and decomposition, with consequent sediment production and mobilization by water flows and mass movements. What has been less explored so far are the rates of weathering processes and erosion at different temporal scales. Some recent advances of the investigations in the Sila uplands focused on this topic. Different papers studied the formation of tors and spheroidal boulders as a result of past deep weathering, followed by their exhumation by erosion during the Pleistocene, in turn enhanced by tectonic uplift and climate changes. Their long-term rates of denudation were estimated using cosmogenic beryllium (10Be) and varied between 0.04 and 0.40 mm yr−1 during about the last 100 ka (Raab et al., 2018, 2019). Within the same range although more restricted are average erosion rates (ca. 0.10 mm yr−1) estimated using 10Be in river sediments for the low-relief upland landscape of the Sila Massif (Olivetti et al., 2012) and its surroundings. Medium-term erosion rates calculated by Raab et al. (2018) through fallout plutonium isotopes (239+240Pu) for soils in the same tor-and-boulder area of the Sila Massif are much higher and close to 1.23 mm yr− 1 for the last half a century. Short-term erosion rates of 13 to 0.30 mm yr−1 (mean value of 3.40 mm yr−1) were obtained through a multitemporal acquisition of 3D rock scarp retreat using terrestrial laser scanning (TLS) techniques (Scarciglia et al., 2022). Although obtained on varying morphologies and different methods, these rates can be of help for a deeper comprehension of how fast erosion can remove mobile weathering products through time also according to different modes and transport agents.

Keywords: soil genesis, weathering,heavy minerals.

Sediment and soil formation have been widely studied to assess and quantify the extent and rates of geomorphic processes such as chemical weathering and denudation dynamics. The present study aims to demonstrate the advantages of an integrated method including pedological, petrographic and geochemical investigations with the goals of: 1) studying the effects of chemical weathering and pedogenesis on rocks from two mountain environments in Calabria (southern Italy), such as a gneissic bedrock in the Sila Massif, and both a migmatitic gneiss and a gabbroic bedrock in the Catena Costiera; 2) identifying the concentration and stability of primary heavy minerals, the major weathering products and compositional changes along the weathering profiles (transect bedrock/grus/soil), in order to constrain their genesis. Specifically, a detailed description and classification of the surface microtextures displayed by the different heavy minerals identified along the weathering profiles (bedrock-grus-soil) is provided . Differences in the amounts of heavy minerals in each soil profile seem to be be controlled by the nature of the local bedrocks. The addition of allochthonous parent material and a varying extent of chemical weathering, likely is influenced by topography and duration of pedogenesis. The heavy mineral shapes and surface microtextures, together with the distribution of major and trace elements, the values of the chemical index of alteration and the relative abundance of the clay mineral types along the profiles indicate the different weathering degrees. These features are consistent with iron/manganese oxy-hydroxides and clay neogenesis observed on femic heavy minerals. Moreover, they suggest a lithological discontinuity between the bedrock and the upper soil horizons, which led to rejuvenation by erosive and colluvial processes along the slopes and/or aeolian deposition of allochthonous material, presumably including a Late Pleistocene to Holocene pyroclastic input. Chemical weathering affecting the majority of heavy minerals is consistent with high rainfall rates, soil moisture availability and acidic pH conditions likely favored by organic acids, prone to chemical reactions and leaching processes. The clay coatings and iron/manganese segregations in the Bt horizons of all the profiles studied suggest their development in a warmer humid climate during the interglacial stages of the Pleistocene.

Keywords: Pietraforte formation, detrital zircon U-Pb geochronology, sedimentary source.

The Upper Cretaceous Pietraforte Formation is an allochthonous turbidite unit belonging to the External Ligurian domain of the northern Apennines. It croups out as discontinuous successions of channelized bodies and thick-bedded coarse-grained sandstones occasionally intercalated with shales intervals, extending from the Tuscany region to the Tolfa Mountains (northern Latium).

In this work, we report exclusive results regarding the detrital zircon U-Pb geochronology, and calcareous nannofossils analysis of the Pietraforte Fm cropping out in the Tolfa Mountains. In the study area, the Pietraforte Fm is characterized by a lower lithofacies "Argilliti Varicolori manganesifere" (Varicoloured clays), dominantly made of variegated clays with intercalations of very think-bedded of limestones and sometimes siltstones, and an upper lithofacies, which mainly consists of thin to thick-bedded of fine to very coarse-grained hybrid sandstones, sometimes intercalated with fine-grained deposits.

Biostratigraphic analyses on calcareous nannofossils assemblages from fine-grained deposits of the "Argilliti Varicolori manganesifere" yielded a maximum age of middle Coniacian for this lithofacies, previously considered to be Turonian-Santonian (Servizio Geologico d'Italia, 2020).

Zircons have been separated from two sandstone samples (PF1 and PF2) for U-Pb detrital geochronology through the LA-ICP-MS technique. Most zircons display oscillatory to sector growth zoning in cathodoluminescence (CL) images and Th/U > 0.3, which are characteristic of igneous origins. Sample PF1 exhibits prominent age groups younger than the Precambrian, with peaks at ca. 280, 320, 370, 450, and 520 Ma. Precambrian age populations show peaks at ca. 550 and 700 Ma, with other minor clusters at approximately 800, 1000, 1500, 1700, and 2200 Ma. Sample PF2 shows similar age populations but lacks Mesozoic ages, with a major age peaks in Ordovician-Cambrian.

The detrital zircon ages of the two samples suggest a significant contribution from Hercynian, Caledonian, and Pan-African sources, with minor contribution from older Grenvillian and Eburnian sources.

In conclusion, these results, together with the Tuscan affinities of the sedimentary lithics, indicate that the detrital grains of the Pietraforte sandstones were sourced by sedimentary and metasedimentary rocks of the Tuscan Domain at the western margin of the Adria Plate.

Linking sedimentary loading-unloading cycles and faulting in intermontane basins of the broken foreland of NW Argentine Andes: new prospective from numerical modeling and field observations

Ballato P.*[1], Brune S.[2-3] & Strecker M.R.[3]

[1] Dipartimento di Scienze, Università di Roma Tre. [2] Helmholtz-Centre Potsdam, GFZ German Research Centre for Geosciences, Potsdam, Germany. [3] Institute of Geosciences, University of Potsdam, Germany.

Keywords: sedimentary loading and unloading cycles, intermontane basins, intrabasinal faulting.

The dynamics of sediment removal, redistribution, and storage in tectonically active mountain belts are believed to play a crucial role in controlling shallow crustal stresses, influencing fault activity, and ultimately impacting the spatiotemporal evolution of regional deformation processes. While it is widely hypothesized that sediment loading and unloading cycles within intermontane sedimentary basins may either inhibit or promote intrabasinal faulting, clear evidence validating this hypothesis has remained elusive (Ballato et al., 2019).

In our study, we integrate 2D numerical simulations that replicate contractional deformation within a broken-foreland context (where shortening is absorbed by reverse faults uplifting basement blocks at different times and locations) with field observations from intermontane basins in the northwest Argentine Andes. Our modeling outcomes indicate that thicker sedimentary accumulations (> 0.7-1.0 km) are likely to suppress faulting within basins, whereas thinner deposits (< 0.7 km) tend to delay fault activation. Conversely, the removal of sediment loads through fluvial incision and basin excavation promotes renewed intrabasinal faulting.

These findings contribute to a deeper understanding of the tectono-sedimentary evolution of intermontane basins situated along the eastern border of the Andean Plateau in northwestern Argentina. For instance, the Santa María and Humahuaca basins exhibit evidence of intrabasinal deformation occurring concurrently with, or subsequent to sediment unloading, while the Quebrada del Toro Basin shows a reduction in intrabasinal faulting activity attributed to the presence of thick, coarse conglomerate loads. Consequently, we conclude that sedimentary loading and unloading cycles exert a fundamental influence on the spatiotemporal patterns of deformation within intermontane basins located in tectonically active broken forelands.

Keywords: integrated stratigraphy, Hyblean mountains, western successions.

In south-east Sicily, the succession outcropping in the western sector of the Hyblean Plateau is mainly composed of carbonate sediments interbedded with volcanic rocks, ranging in age from Early Oligocene to Quaternary. This succession has recorded the important climatic variations taking place during their formation.

The results of a refined integrated stratigraphic study, consisting of an accurate field mapping, integrated biostratigraphy (foraminifers and calcareous nannofossils), magnetostratigraphy and isotope stratigraphy, has provided the opportunity to carry out a thorough review of the successions cropping out in the area, whose last update dates back to the late ‘90s.

In the present study we present the results concerning the Lower Oligocene-Lower Miocene Leonardo Fm (ex Leonardo Mb. of the Ragusa Fm. *Auct.*) and its relation with the overlying Irminio Fm. (ex Irminio Mb. of the Ragusa Fm. *Auct.*).

An integrated study was conducted within the Leonardo Fm. sediments (Misericordia and Mangiagesso Caves) consisting of high-resolution calcareous plankton biostratigraphy and stable C and O isotopes content.

According to the biostratigraphic data, the succession is Early-Late Oligocene in age and is characterized by a hiatus corresponding to the MNP24 nannofossil biozone (27.14-26.81 Ma).

Preliminary analyses on carbon and oxygen isotope ratios, measured on bulk-rock samples belonging to the abovementioned sections, reveal a rather stable climatic phase, testified by the δ18O isotope record, during Chattian, characterized by several positive δ13C shifts. The latter are interpreted as moments of increased nutrient content into surface waters which, into deeper waters, correlate with the occurrence of cherty layer (e.g. Misericordia Cave).

Through Sr isotope analyses, coupled with detailed nannofossil assemblages’ analyses, we identified an interval of phosphogenesis and sedimentary condensation, marked by a well evident hardground, at the Leonardo/Irminio boundary.

This hiatus occurs at the base of the Aquitanian (23-22 Ma) thus coinciding with a global cooling event and glacial maximum (Mi-1 Event) and is interpreted as the result of the upwelling of nutrient-rich deep waters, increased weathering and phosphorous availability triggered by global cooling and enhanced circulation in the Mediterranean basin.

Coeval phosphatic hardgrounds also occur in the Oligo-Miocene succession of the Malta Island, lining up from South to North. This correlation supports the interpretation of increased bottom-water currents, which, originating in the deep Eastern Mediterranean basin, rose up to the eastern sides of the Central Mediterranean carbonate platforms during abrupt climate shifts.

Diagenesis and paleo-fluid characterization of the Bathonian-Callovian platform carbonates from the southern Paris Basin sub-surface

Bellinvia L.[1], Gasparrini M.[1], Montano D.*[1], Mangenot X.[2], Berra F.[1], Decarlis A.[3] & Ceriani A.[3]

Keywords: burial diagenesis, cement stratigraphy, fluid inclusions.

Past circulations of hydrothermal fluids in sedimentary basins are challenging to establish. They may severely affect the maturation of organic matter and mineral diagenesis reactions and, consequently, the accurate assessment of thermal history of the basin successions. This has a crucial impact on establishing thermal models for exploring sub-surface fluid resources. Past hydrothermal events are commonly of short duration (from a few to tens of Myr). However, they may perturbate the thermal regime for a longer time, causing thermal anomalies that persist up to the present. Therefore, the timing, sources, and pathways of past hydrothermal fluids are of interest for the exploration present-day geothermal fluids in sedimentary basins.

In this study, we investigate two well-cores drilled in potential geothermal reservoirs of Bathonian-Callovian platform carbonates from the intracontinental Paris Basin, where literature did not initially consider hydrothermal circulations. Only recently, progress in carbonate isotope geochemistry allowing Δ47/U-Pb thermochronometry, combined with fluid inclusion microthermometry of calcite, dolomite, and fluorite cements, suggested hydrothermal fluids may have locally ascended through deep-seated faults during late Mesozoic and Cenozoic times (Mangenot et al. 2018a, 2018b; Brigaud et al. 2020; Lenoir et al., 2024).

This study focuses on samples located between well-cores from the basin depocenter (Mangenot et al., 2018a, 2018b) and outcrops from the Burgundy/Morvan regions (Lenoir et al., 2024); samples contain calcite and dolomite cements precipitated during burial diagenesis.

An accurate petrographic analysis in transmitted-light, UV-light, and cathodoluminescence microscopy allowed the reconstruction of the cement stratigraphy. Further insights on the thermal conditions and composition of the fluids precipitating the cements were obtained via O-C stable isotope analyses and fluid inclusion microthermometry, allowing us to discriminate the type of paleo-fluid circulations in the area.

Control of the synsedimentary tectonics on turbidite channels dynamics: an integrated study between field and subsurface data

Catto B.*[1], Muzzi Magalhães P.[2] & Tinterri R.[1]

[1] Dipartimento di Scienze Chimiche, della Vita e della Sostenibilità Ambientale, Università di Parma.
[2] Petrobras – Petróleo brasileiro S.A., Brazil.

Corresponding author email: bruno.catto@unipr.it

Keywords: synsedimentary tectonics, turbidite channels, facies analysis.

A turbidite system can be considered as a fluvial system, characterized by a source-erosional zone, a transfer zone and a depositional zone (Mutti et al., 2003). Turbidity currents are among the most effective processes on Earth for redistributing sediment in deep-sea systems, and turbidite channels play a key role in this process. That is why the oil industry is particularly interested in turbidite channels in slope environments since they can control large accumulations of sediment and thus hydrocarbons worldwide. As is well known, channels can be "erosional" dominated by bypass facies, "depositional" characterized by depositional lobes and "mixed" characterized by fining-upward facies sequences, where coarse-grained bypass facies pass upward into depositional facies (Mutti & Normark, 1987). Although channel dynamics can depend on various types of allogenic controls, increasing evidence from subsurface and outcrop data suggests that tectonics can have a key role in creating morphological barriers that can control channel dynamics, i.e., whether a channel works as a sediment transfer or trapping/depositional zone. Thus, the objective of this work is to study the relationship between tectonics and sedimentation in controlling the turbidite transfer zone dynamics through a comparison between subsurface and field data coming from the Campos basin (Brazilian offshore) and Mediterranean-type foreland basins respectively. As to field cases, the Fontanelice turbidite system of the Marnoso-arenacea Formation (MAF) in the northern Apennines (Italy) and some channelized systems of the Broto and Cotefablo turbidite systems in the Ainsa basin (south-central Pyrenees) were taken into account.

These studies have been carried out through physical stratigraphy, well logs and 3D seismic interpretation and facies analysis in outcrops and subsurface cores. This analysis was carried out following the classic scheme by Mutti et al. (2003) and the more recent one by Tinterri et al. (2023), which proposes a facies scheme for turbidite systems characterized by tectonic confinement able to decrease flow efficiency, especially through the formation of transversal morphologies (i.e., perpendicular to the paleocurrents) as slope breaks and counterslopes.

Preliminary results support the hypothesis that transfer zones tend to be depositional in the presence of frontal morphological barriers, as in the cases of the Fontanelice system (Miocene, MAF) controlled by the transversal Forlì line, and of the Upper Cretaceous channel in Campos Basin, controlled by a topography known in the literature as "central high". Conversely, transfer zones tend to be erosional, i.e., dominated by bypass, especially in periods of tectonic quiescence and, therefore, with no transversal obstacle, as in the cases of Gerbè-Cotefablo channel (Eocene, Pyrenees) and of the Oligocene channel in Campos Basin. Consequently, a comparison between foreland and passive margin deposits supports similar conclusions.

Detailed field mapping and revised litho-biostratigraphy of the Castelvetere Formation cropping out at the NW Campania-Basilicata border (Southern Apennines, Southern Italy)

Cerone D.*[1], Notaro A.[2] & Prosser G.[1]

[1] Dipartimento di Scienze, Università della Basilicata, Potenza.
[2] Dipartimento di Ingegneria e Geologia, Università "G. d'Annunzio" Chieti-Pescara.

Corresponding author email: davide.cerone@unibas.it

Keywords: Southern Apennines, Castelvetere Formation, litho-biostratigraphy.

The Castelvetere Formation is one of the most important foredeep/thrust-top deep-marine sedimentary units of the Southern Apennines, nowadays considered upper Tortonian-lower Messinian in age (Servizio Geologico d'Italia, 2002 and references therein). In the literature (e.g. SGI, 2002), it is described as an up to about 1000 m-thick succession, made up of an alternation of typically-coarse-grained sandstones, conglomerates, mudstones, olistostromes of "argille varicolori" *sensu lato* and olistholiths deriving from the Apenninic Carbonate Platform. Ongoing geological field mapping at a 1:10.000 scale and litho-biostratigraphic study (within the CARG Project, sheet n.469 Muro Lucano) in the outcrop type area of the formation, among the Muro Lucano, Castelgrande and Laviano villages (NW Campania-Basilicata border, Southern Italy) have resulted in the following main points.

The study interval of the Castelvetere Formation is highly deformed: it forms wide and at-times-overturned, partly fault-related folds with around E-W orientation of the hinge lines; moreover, it is affected by both around E-W-oriented contractional-to-extensional faults and N-to-NE-oriented high-angle faults.

It was deposited during the Langhian-Serravallian times, as testified by nannoplankton analyses of some tens marls-to-marly-clay samples collected from different sections spanning throughout its thickness.

It has a thickness of several hundreds of metres, lies on Apenninic-Carbonate-Platform deposits along an unconformity, marked by basal conglomerate, and passes upward unconformably to Pliocene conglomeratic and sandy deposits of the Tolve Synthem (SGI, 2013).

The Castelvetere Formation is mainly represented by tens of metres thick (in outcrop) packages of amalgamated medium-to-coarse grained sandstones including up to very-thick conglomerates with erosional base; the sandstones are ungraded to graded and they rarely show plane-parallel to cross lamination, convolute lamination, load casts and flame structures. The lower interval of the study succession is characterised by a Langhian huge olistostrome made up of Argille-Variegate-Group terrains containing m- to 10 m-sized olistoliths of the Apenninic Carbonate Platform. The upper interval is characterised by up to several tens of metres thick (in outcrop) packages of marlstones to marly claystones with intercalations of thin-to-very-thin siltstones to fine-grained sandstones, at-most-metres-thick medium-to-coarse-grained sandstones and large slabs of Sicilide-affinity terrains, as well as up-to-thousands-of-cubic-metres olistoliths coming from the Apenninic Carbonate Platform within mass transport deposits. Accordingly, the Castelvetere-Formation basin, floored by the Apenninic Carbonate Platform, was formed no later than the Langhian time and its deformation could start from the late Serravallian-Tortonian, unlike stated in current regional models (e.g. Vitale et al., 2020), which postpone both these events.

Keywords: foredeep, trench-slope basin, confined turbidite systems.

One of the key controls on turbidite systems is the presence of confining morpho-structural elements with different topography and evolution over time, resulting in characteristic facies and architecture. In this study, two turbidite systems are compared: the Miocene Serra Palazzo Fm. (SPF) and the informal late Paleogene tufiti delle Gole Candela succession (tgc, classically referred to the Tufiti di Tusa Fm.), both cropping out along the outer border of the Southern Apennines, in Basilicata Region. The study area for the SPF is near the Campomaggiore village (Middle Valley of Basento River, in province of Potenza), where a c. 300 m-thick coarse-grained sandstone-rich succession crops out. This is compared to tgc, an about 230 m-thick muddy-sandy succession cropping out near the Rotondella village (Lower Valley of Sinni River, in province of Matera). Detailed facies analysis based on high-resolution physical stratigraphy was used to infer basin morphology and evolution for both systems (Cerone et al., 2021; Gallicchio et al., 2023). The SPF outcrop is characterised by palaeocurrents directed towards SE, with flows moving parallel to the thrust front of the chain. This configuration suggests that the flows, after reaching the slope base of the foredeep basin, were deflected by the inbound slope made up by the proximal flank of the forebulge, and that they then travelled along the basin long axis. The sandstone to mudstone ratio (S/M) is relatively high (over 2) and it does not show any upward increase, suggesting that the succession was not fully confined and that did not experience any change over time in confinement. Sedimentary features, such as load casts, convolute lamination and mud-draped scours, observed at several different stratigraphic intervals, indicate that flows decelerated due to a reduction in gradient and the possible presence of morphological obstacles. The studied tgc succession lies unconformably on highly-deformed terrains of the Argille Variegate. Unlike the SPF, it shows a very high-dispersion of the palaeocurrent directions and an upward increase in the S/M ratio from 0.6 to 2.5, reflecting an evolution from a flow ponding phase to a flow stripping phase. Biconvex ripples with sigmoidal-cross laminae, hummocky-type structures and thick mudstone caps are widespread throughout the stratigraphy. This evidence suggests that the tgc was deposited in a fully-confined setting represented by a trench-slope basin. In conclusion, the studied outcrops represent two examples of turbidite systems controlled by different morpho-structural configurations and evolution of basin topography and the presented facies and architectures can help interpret turbidite systems in less well-exposed areas or in the subsurface.

Assembling and dismantling the supercontinent Pangaea recorded from provenance relations of Phanerozoic sandstones of the circum-Mediterranean Region

Critelli S.*

Dipartimento di Ingegneria dell'Ambiente, Università della Calabria, Arcavacata di Rende (CS).

Corresponding author email: salvatore.critelli@unical.it

Keywords: detrital signatures, sandstone suites, provenance relations, circum-Mediterranean orogens.

The composition and stratigraphic relations of clastic strata in diverse sedimentary basins of the circum-Mediterranean region reflect a complete record of provenance relations since break-up of Pangaea, neo-Tethyan rifting, and subsequent plate convergence between the two major plates of Europe and Africa, and other related microplates of Iberia, Adria and Mesomediterranean microplate (Critelli, 2018; Criniti et al., 2023).

Since the plate reorganization to the breakup of Pangea (Criniti, 2023), at the end of Paleozoic-earliest Mesozoic, clastic wedges filled sedimentary basins within geodynamic settings evolving from continental rifts, rifted-continental margins, protoceanic basins, arc-trench systems, remnant ocean basins, proforeland basin systems and back-arc basins within the circum-Mediterranean region (Critelli et al., 2008; Critelli, 2018).

The changing nature of clastic particles in these clastic wedges reflect the provenance relations from different source rocks within the spatial and temporal evolving geo-puzzle terranes, including relations between ophiolite-bearing, uplifted continental crust (both shallow to deep crust terranes), volcanic and sedimentary (particularly carbonate strata) source rocks. Typical sand(stone) suites are quartzose, derived from flexured cratonal area, followed by quartzolithic and quartzofeldspathic derived from the growth fold-thrust belt. Mixed siliciclastic and carbonate shallow- to deep-marine clastic wedges are diffuse in many filled basin systems along the Circum-Mediterranean region, as such as volcaniclastic sand(stone) that may also occur interbedded with typical quartzolithic suites, in both remnant ocean basins and foreland basins.

The variable mosaic of source terranes within the Circum-Mediterranean region, representing striking examples of proforeland sandstone suites, offered the possibility to investigate provenance relations in sandstones with a new plane of precision and sophistication, discriminating grain particles in clastic wedges using spatial (extrabasinal versus intrabasinal), and temporal (coeval versus noncoeval) distinction of detrital signals (Costamagna & Criniti, 2023). The spatial/temporal approach in deciphering particles in clastic rocks has been widely used to detail the basinal dispersal pathways in different geotectonic settings, wherever mixed silicate and carbonate terranes act as the major source rocks, from rifted-continental margins to collisional orogens.

Tectonic activity recorded by deep basin deposits: a sedimentological approach to unravel synsedimentary tectonics

Fabbi S.*[1] & Cipriani A.[2]

[1] Dipartimento di Scienze della Terra, Sapienza Università di Roma.

Corresponding author email: simone.fabbi@uniroma1.it

Keywords: mass transport deposits, Jurassic rifting, pelagic basin.

Mass-transport deposits are commonly referred to synsedimentary tectonics, but the presence of turbidites and/or calcidebrites in deep marine, fine-grained pelagic deposits, can be the result of several factors, such as tectonics, climatic events, sea level oscillations, gravitational instability among others. Here we present four cases of clastic deposits of syntectonic origin from the Jurassic and Cretaceous of the Umbria-Marche-Sabina (UMS) Apennine and Calabria. Two of them are strictly linked to the development of Early Jurassic rift faults related to the Western Tethys opening.

In UMS, the rift produced a puzzling pattern of horsts and graben, resulting in a complex Jurassic palaeogeography. Synsedimentary fault activity (earthquakes) is documented by huge megabreccia bodies sourced from footwall-blocks and deposited in rift-basin. These clastic deposits span from lower Sinemurian to lower Pliensbachian. Subsequently, the end of faulting is indicated by Pliensbachian *p.p.*-Tithonian pelagic successions lacking coarse clastic bodies (Fabbi & Santantonio, 2012), with few exceptions. In the Longobucco Basin (Calabria), the rift-related tectonic activity is continuous throughout the Early Jurassic, as recorded by megabreccias that are widespread from the Sinemurian to the middle Toarcian.

Other examples are most likely controlled by tectonic activity in passive margin, even though none of the faults producing the study clastics were directly detected. Growing evidence for Bajocian synsedimentary tectonics comes from the UMS, where megaclastic deposits occur embedded in basin-fill pelagites, and are usually associated to neptunian dykes filled with Bajocian sediments, backstepping of the footwall block-margins, the occurrence of erosional unconformities and soft-sediment deformation structures in condensed and basinal successions.

Comparable features occur in the Barremian-lowermost Aptian pelagic deposits of the UMS Basin. Megabreccias and slumps characterize pelagic units, and tectonic rejuvenation of Jurassic faulted margins coupled with neptunian dykes have been described (Cipriani & Bottini, 2019). The occurrence of "extrabasinal" loose benthic material associated with "intrabasinal" clasts of breccias provides clues to infer that synsedimentary tectonics affected margins of carbonate platforms contiguous to the UMS basin. In fact, earliest Aptian faults have been described by Fabbi et al. (2023) in carbonate platform successions.

Biostratigraphic analysis of pelagic sediment hosting megaclastic wedges or overlaying them as condensed deposits is crucial for constraining the minimum age of tectonic activity. Similarly, clast composition analysis is essential for determining the maximum age of the accumulation and, thus, the tectonic instability responsible for its formation. Intercalated clastic sediments in pelagic basins provide insights into a tectonic history that cannot be fully reconstructed through direct structural observation.

Keywords: (mega)turbi5dites, organic matter, Miocene.

The wedge-top siliciclastic successions of the Miocene Cilento Group record a complex physiography of an evolving fragmented (broken) foreland characterised by different coeval and relatively short, laterally- and longitudinally-confined, source-to-sink, likely representing mixed fluvio-deltaic-turbidite systems. This tectonic-stratigraphic framework is in turn modulated by high-frequency and high-amplitude cycles of base-level variations, and a general trend towards increased rates of erosion and sediment transport, likely including the transfer and burial of vast amounts of organic matter. In the Langhian-Tortonian interval (i.e., S. Mauro Formation), at least 5 major sedimentary events took place with a recurring time of about 1–3 Ma. These episodic events generated tens of metres thick sandy-silty-marly megaturbidite deposits (MTs) of hybrid carbonate-siliciclastic composition that can be followed across the entire basin system for tens of kilometres, from the depocentres to the margins, and possibly beyond. Their anatomy is remarkably similar to other megabeds cropping out in the foredeep record of the Northern Apennines, the Spanish and French Pyrenees, the Southern Alps, and the Dinarides, indicating common flow reflection and ponding processes. Nonetheless, their anomalous thickness variations of the finer-grained populations and complex interactions with the background siliciclastic beds reveal an interplay of processes (e.g., settling-traction vs. flocculation-emulsion) yet to be fully understood. Notably, these outsized events seem to be clustered within an interval of globally reduced carbon burial, suggesting an intimate link between these types of events and short- to long-term sedimentary and biogeochemical cycles. The calibration of such a geological archive is essential for understanding the tectonic-climatic dynamics of the central Mediterranean area and its future evolution. As part of the TOOLS project (PRIN PNRR 2022, P2022T3A4E, "**T**esting the efficiency of submarine landslides **O**n **O**rganic carbon sequestration over geologica**L** time**S**") the aim of this preliminary work is to establish a robust, field-based, sedimentological-stratigraphic baseline to constrain the role of these exceptional sedimentary flows in the local to global biogeochemical cycles from a multidisciplinary and deep-time perspective.

Low-temperature Δ47/(U-Pb) carbonate thermochronology reveals the exhumation history of the Paris Basin southern margin

Keywords: exhumation rates, clumped isotopes (Δ47), U-Pb dating.

Low-temperature thermochronology of sedimentary successions provides insights to constrain the thermal history of sedimentary basins, estimates the timing of hydrocarbon generation, determines the onset and evolution of the basin inversion, and quantifies the basin exhumation rates. Historically, these reconstructions rely on thermo-chronometers like fission tracks and (U-Th)/He analyses that are however not applicable in successions dominated by carbonate rocks. More recently, advances in carbonate geochemistry and mass spectrometry opened the possibility of quantifying the timing and duration of heating/cooling events in sedimentary basins by investigating carbonate diagenetic phases precipitated within any kind of sedimentary rock with carbonate Δ47-(U/Pb) thermo-chronometry (*sensu* Mangenot et al., 2018; Gasparrini et al., 2023).

Here we study the Middle Jurassic carbonate succession from the southern margin of the intracontinental Paris Basin that presently crops out in the Burgundy region. Basin inversion is known to have begun in the Late Cretaceous - Early Paleogene due to the onset of the Alpine orogeny (Beccaletto et al., 2011). The succession, exceptionally exposed in quarries, was sampled and macroscopic carbonate cements were analyzed using optical and cathodoluminescence petrography, O-C stable isotope geochemistry, Δ47 thermometry, and U-Pb dating via LA-ICPMS. The results reveal the sequential precipitation of four carbonate diagenetic phases (three calcites, one dedolomite) from fluids dominated by meteoric waters (δ18Ofluid between -5 and -8 ‰ SMOW) which cover most of the basin inversion period spanning from Paleocene-Eocene to Pliocene-Pleistocene. The temperature-time history reconstructed well reproduces the uplift dynamics of the basin documented via structural analyses (Beccaletto et al., 2011). It also records two compressional phases, in the Eocene and Miocene, attributable to the Pyrenean and Alpine cycles, respectively, and separated by an extensional phase in the Oligocene. The temperature-time data obtained from this study were then used to calculate the exhumation rates associated with the two compressional phases encompassing the last 50 Ma of the basin evolution and overall point at a total exhumation exceeding previous estimations (<700 m according to Barbarand et al., 2013).

These results illustrate the potential of carbonate Δ47/(U-Pb) thermo-chronometry to reconstruct and quantify low-temperature exhumation histories of sedimentary basins and mountain ranges and pave the way for applications in multiple domains of Earth sciences.

Keywords: biomarkers, microfauna, paleoenvironment.

Nowadays, the advancement in organic matter (OM) investigations led to solid results for paleoenvironmental reconstructions. Depositional settings are characterized by specific assemblages of micro-organisms, which actively contribute to the production of molecular fossils (biomarkers) in sediments. Phytoplankton is known to be the main productor of biomarkers (e.g. α-tocopherol, C27 diasterenes or shorter chain fatty acids). Therefore, terrigenous, deltaic, normal marine, and hypersaline environments usually show significant differences both in biomarker compositions and in past living organisms. The latter, such as calcareous zoo- and phyto-plankton, have been commonly used as indicators of palaeoenvironmental and palaeocenographic changes for decades. Benthic foraminifera are known to be sensitive to organic carbon (OC) content. Therefore, association changes strictly relate to OC in the seafloor. However, although both indicators have been extensively employed independently, the relationship between biomarkers and microfauna associations is not straightforward and deserves further investigation. In this work, the high preservation potential of foraminifer tests and nannofossils in marine sediments is combined with the analyses of preserved biomarkers, offering a new interdisciplinary tool to better define past environmental settings and related changes (e.g. oxygen, salinity, and organic carbon content). The new approach of correlation and combination of organic biomarkers with foraminifer and nannofossil assemblages allowed a high-resolution environmental analysis on a restricted thrust top basin in central Sicily. The studied succession of Torrente Vaccarizzo shows rich OM marly/clayey layers which deposited before the onset of Messinian Salinity Crisis, between 6.5 to 5.9 Ma. The abundance of tocopherols, steranes, hopanes, diasteranes, and fatty acids revealed a general OM immaturity, pointing to a shallow burial depth since Messinian time. The presented results are promising and pave the way for future applications in other basins and environmental systems.

Magnetostratigraphy and calcareous nannofossil biostratigraphy of upper Eocene turbidites (Ventimiglia Flysch Fm) from the western Alps foreland basin

Marini M.[1], Patacci M.*[2], Cifelli F.[3], Cipollari P.[3], Mattei M.[3] & Muttoni G.[1]

Keywords: Ventimiglia flysch, magnetostratigraphy, biostratigraphy.

The late Eocene Ventimiglia Flysch Fm (FYV) of NW Italy (Servizio Geologico d'Italia, 2012) is part of the greater Grès d'Annot system, a dominantly deep-water unit cropping out in of SE France as part of the sedimentary fill of the foreland basin of western Alps. Compared to the turbidites of SE France, FYV has received relatively little research interest to date. Yet, better understanding the chronostratigraphic significance of FYV is key, as it represent the fill of the most internal and oldest preserved depocentre of the foreland basin.

FYV constitutes the fill of a topographically complex basin. It crops out in three relatively small synclines in the west and a larger outcrop in the east, which constitutes a monocline largely dipping toward the west-northwest. The studied composite section belongs to the main outcrop of FYV which has a preserved thickness of around 1500m and is characterized by an overall sheet like architecture (Marini et al., 2022) suggestive of a confined basin-plain setting of deposition. The age of FYV is loosely constrained based on foraminiferal biostratigraphy of the hemipelagic marlstone below (late Bartonian) and an earliest Oligocene foraminiferal assemblage characterizing its upmost part. This contribution presents the preliminary results of an investigation aimed at providing a depositional age model for FYV through the integration of magnetostratigraphy and nannofossil biostratigraphy.

A total of 192 samples for palaeomagnetic analysis were collected targeting the mudstone component of a c. 1500m-thick composite stratigraphic section, previously logged bed-by-bed for sedimentary facies. Natural Remnant Magnetisation (NRM) of 168 samples was measured using a cryogenic magnetometer after subjecting samples to either alternating-field or thermal demagnetisation. Analysis of 24 additional palaeomagnetic samples from the upper half of the composite section and of a total of 25 samples for nannofossil biostratigraphy spanning the full preserved thickness of FYV is underway.

Results of NRM analysis indicate that a vast majority of samples have a relatively stable characteristic component (ChRM) of reverse polarity defined by an unblocking temperature range of 250 ~450°C that in the remaining samples is overprinted by a viscous normal polarity component resulting in great circles trending toward reverse polarity. This defines a reverse polarity magnetozone with a minimum thickness of c. 700. The current foraminiferal biostratigraphy framework (Dellagiovanna et al., 2012) suggest there are three reverse polarity chrones (i.e., the Priabonian C16r, C15r, and C13r, having durations between c. 0.2 and 1.4 ky; Ogg, 2020) representing plausible correlation targets for the identified reverse polarity magnetozone. Pending the results of the ongoing nannofossil biostratigraphy and in light of magnetostratigraphic results to date, the minimum sedimentation rate for FYV is estimated to be in the range 500-3500 m/Ma, which places it in the upper end of the range of turbidites deposited in large confined basins of tectonically active settings.

Keywords: petrography, detrital zircon ages, Lucanian external chain.

In-depth petrographic characterization of the lithic fragments coupled with detrital zircon ages allowed to obtain relevant information about supply provenance (Critelli & Martín-Martín, 2024; Fornelli et al., 2022).

Petrographic features and U-Pb spot ages on detrital zircons from turbidite sandstones of Tufiti di Tusa (TTF), Numidian Flysch (NF), Bifurto (BF), Gorgoglione (GF) and Serra Palazzo (SPF) formations, exposed in southern Italy, were detected to define provenance signatures aiming to better constrain the paleogeography and timing of the tectono-sedimentary main stages of the Apennines orogeny from Rupelian (TTF) to Burdigalian p.p. - Early Langhian (NF and BF) and Langhian-Serravallian -Early Tortonian (GF and SPF).

Detrital zircon ages from the epiclastic record of the Tufiti di Tusa Formation indicate a sedimentary basin mainly fed by Rupelian synorogenic magmatic centers located in the central Mediterranean, and by minor input from Variscan granitoids and metamorphic rocks from the Mesomediterranean Microplate.

Zircon data from Numidian and Bifurto quartz-arenites evidenced for the external Burdigalian-Early Langhian Apennines Foreland, an exclusive source area located on the Africa Craton; therefore, this sedimentary basin has not been fed by detritus from the Variscan or Alpine chain.

Detritus from both Variscan crystalline basement forming the Alpine chain (Calabria-Peloritani Terranes) and Variscan magmatic and metamorphic rocks unaffected by Alpine tectonics (like Sardinia and Corsica pro-parte block) supplied the Middle Miocene depositional domain of Gorgoglione and Serra Palazzo formations.

Based on these new petrographic, chemical, and geochronological data a revised paleogeographic history could be inferred for the Apennines foreland basins from Rupelian to Tortonian: i) in the early Oligocene abundant calc-alkaline products from a volcanic arc, probably located on the eastern domains of the Mesomediterranean Microplate, fed the internal domains of the Apennines foreland; ii) in the early Miocene the eastern domain of the Southern Apennines foreland was fed by quartz-rich sandstones coming exclusively from the African Craton; iii) important paleogeographic changes in the Middle – Miocene eastern foredeep were recorded: the Gorgoglione and Serra Palazzo sandstone composition and the detrital zircon ages indicate that their source areas were located on both internal (Mesomediterranean Microplate and Sardinia-Corso Block) and external geodynamic contexts (Fornelli et al., 2022).

Corresponding author email: damaris.montano@unimi.it

Keywords: carbonate cements, thermometry, Paris Basin.

The Upper Triassic deep (2000-3000m depth) reservoirs of the Paris Basin (PB) have been broadly exploited for oil & gas resources and are under evaluation for their geothermal potential and as CO_2 storage site. Assessing the cementation and paleo-fluid circulation history in these reservoirs is therefore crucial to predicting quality and productivity and reducing potential exploration risks. Previous authors have investigated the cementation history of the Upper Triassic succession from the depocenter of PB (Spötl et al., 1993; Worden et al., 1999). However, these studies could not rely on modern analytical tools and thus temperature, timing, sources, and pathways of paleo-fluids remained underconstrained.

This contribution aims at revising the cementation and paleo-fluid circulation history of the Upper Triassic from the depocenter of the PB (South-East of Paris) by means of analytical tools such as clumped isotope (Δ47) thermometry and LA-ICPMS analysis. Samples collected from well cores mainly consist of fluvial sandstones deposited in an arid to semiarid continental environment. Authigenic cements include calcite, dolomite and anhydrite precipitated during the Mesozoic subsidence and the Cenozoic uplift of the successions. An accurate petrographic analysis in transmitted-light, UV-light, and cathodoluminescence allowed reconstructing the cement stratigraphy. Insights on the thermal conditions and composition of the fluids responsible for each cementation event were obtained via O-C stable isotope analysis, trace element geochemistry (LA-ICPMS), fluid inclusion microthermometry and carbonate clumped isotope (Δ47) thermometry. Inferred precipitation temperatures combined with thermal curves of the investigated wells allowed proposing a possible timing for the cementations. Results from this study highlight the occurrence of multiple stages of cement precipitation from Jurassic to Paleogene times at temperatures spanning from 60 to 120°C. The fluids that precipitated these cements consisted of brines with salinities between 6 and 21% wt (NaCl eq.). The more saline brines derived from the mixing between the original formation waters and halite-saturated brines that migrated from the East during the Mesozoic subsidence. On the other hand, the occurrence of cementation from the less saline brine point to a meteoric-derived water influx within the reservoirs during the Cenozoic uplift. This study highlights that the late cementation and paleo-fluid circulation history in the investigated Upper Triassic siliciclastic reservoirs of the PB is therefore related to high saline brines that were locally diluted by meteoric waters. The timing of the cementation events and the pathways of fluid migrations, which has long been debated in literature, were more accurately defined.

Keywords: x-ray diffraction, stable isotope analysis, K-Ar dating.

Paleothermal indicators (e.g. mixed layered clay minerals, vitrinite reflectance) are used to constrain the maximum temperature experienced by sedimentary successions in orogenic belts or to assess the thermal maturity of kerogen-rich rocks, while stable isotopes analyses (e.g. C, O) are carried out to determine the origin of the involved fluids. In this research, instead, we show how mixed layers illite-smectite and H, O isotope studies from deformed siliciclastic units and basement rocks of the Carboneras fault zone (Betic Cordillera, SE Spain) can also provide valuable insights in the evolution of temperature and fluids during faulting. Importantly, the addition of K-Ar constraints on syn-kinematic illite separated from fault rocks, also allows this approach in the case of long-lived, mature faults, where multiple reactivation episodes can be discriminated and are responsible for the complex fault architecture at the outcrop. X-ray diffraction data (quantitative analysis of minerals and illite polytype determinations) allowed us to reconstruct the distribution of syn-kinematic minerals within the fault rocks and constrain their temperature of (de)formation, while geochemical results allowed us to unravel the origin of fluids during distinct events of faulting. The integration of mineralogical, geochemical, and geochronological data allowed us to build a time-constrained temperature and fluid evolutionary model for the Carboneras fault zone.

XRD results document an inherited assemblage consisting of quartz, carbonates, K/Na-micas (2M1 polytype), feldspar, chlorite, kaolinite, pyrite, and Fe/Ti-oxides, a syn-kinematic assemblage composed of muscovite-2M1 (Ms-2M1) and mixed layers chlorite-smectite (C-S) and illite-smectite (I-S, 1Md polytype), and a post-kinematic assemblage with smectite, chlorides, and sulphates. The coexistence of randomly (R0), short-range (R1), and long-range (R3) ordered I-S and discrete Ms-2M1 in adjacent fault rocks suggest for a complex history of multiple brittle-events at various temperature (from 70°C to >275°C) and depth. Stable isotope data show that meteoric fluids infiltrated within the fault zone, interacting with the host-rock at various depths, and developing R0 I-S and R1 I-S or Ms-2M1. Lastly, K-Ar dating on syn-kinematic muscovite and illite-smectite indicate that the recorded deformation occurred during three distinct thermotectonic events in the Oligocene, middle-late Miocene, and Pliocene-Pleistocene.

In conclusion, the data portray an exhumation history associated with three principal thermotectonic events that occurred at decreasing temperature and depth, where parental fluids of meteoric origin infiltrated into the fault zone, interacted with host rock at various degree, and formed distinct temperature-dependent clay minerals.

The stratigraphic record of the Ventimiglia Flysch Fm, north-west Italy (western Alps foreland basin, Grès d'Annot turbidite system)

Patacci M.*[1] & Marini M.[2]

[1] Dipartimento di Medicina clinica, sanità pubblica, scienze della vita e dell'ambiente, Università dell'Aquila.
[2] Dipartimento di Scienze della Terra "Ardito Desio", Università di Milano.

Corresponding author email: marco.patacci@univaq.it

Keywords: Alps, Ventimiglia, sedimentological logging.

The Grès d'Annot turbidite system represents the deep-water silicilastic fill of the Alpine foredeep and it crops out in a series of outliers across the Maritime Alps of SE France and NW Italy. It was deposited in a series of topographically complex basins, with the age of deposition becoming younger to the west, reflecting the advancement of the orogenic wedge and the migration of the foredeep system (Ford et al., 1999). Sediment provenance is from the Corsica-Sardinia and Maures-Esterel massifs to the south. In addition to their importance in reconstructing the Alpine chain evolution, the outcrops of the Annot and Peïra Cava sub-basins have the provided the location for some of the most influential studies of turbidite sequences from the 1960s onwards (Bouma & Ravenne, 2004). However, the close attention of the research community to the Grès d'Annot in France has not been matched by similar efforts on the Italian outcrops. These are known as the Ventimiglia Flysch Formation and consist of three relatively small synclines in the west and a large northwest-dipping monocline in the east. No high-resolution stratigraphy of the Ventimiglia Flysch has been published to date, and thickness estimates vary between a few hundreds and a thousand metres. To fill this knowledge gap, new sedimentary logging is undergoing at various locations of the monocline in the area north of Ventimiglia to reconstruct a high-resolution composite section.

Eleven sedimentary logs have been collected to date with a resolution of 0.5 cm, using a high-precision Jacob's staff (Patacci, 2016), for a total of around 1000 metres of stratigraphy. The logs are scattered throughout an area 5x10 km, elongated in the N-S direction. The succession can be interpreted as the medial part of a confined basin-plain, with sandstone beds thinning to the N-NE and mudstone caps thickening in the same direction. Bed-by-bed correlation to allow the composite log is possible thanks to the tabular geometry of the succession and to the presence of a key correlation horizon (Olivastro MTD; Marini et al., 2022), mapped across the entire study area. The high-resolution composite section logged to date encompasses roughly 2/3 of the preserved stratigraphy of the Ventimiglia Flysch, therefore suggesting a revised preserved thickness of around 1500 metres. The sequence is characterised by the presence of thick mudstone caps (thickness 1-2 times that of the associated sandstone bed) throughout the stratigraphy, indicating full confinement persisting as the basin became filled. Hybrid event beds are dominant, with the cumulative thickness of the H3 muddy sand and mudclast-rich divisions reaching 1/3 of the total sand thickness in the lower half of the stratigraphy. The new dataset will provide the basis for a revaluation of the age and sedimentary evolution of the siliciclastic fill of the Ventimiglia sub-basin and it will allow a more detailed comparison with other sub-basins of the Grès d'Annot, with the aims of expanding current palaeographic and evolutionary models of the Alpine foredeep.

Oligocene-Miocene exhumation history of the Epiligurian wedge-top basins (Northern Apennines) constrained by low-temperature thermochronology

Stendardi F.*[1-2], Viola G.[2], Carrapa B.[3] & Vignaroli G.[2]

[1] Dipartimento di Scienze della Terra, Università di Pavia. [2] Dipartimento di Scienze Biologiche, Geologiche e Ambientali, Università di Bologna. [3] Department of Geosciences, University of Arizona.

Keywords: low-temperature thermochronology, Epiligurian wedge-top basins, exhumation history.

The tectonic configuration of the Northern Apennines (NA) fold-and-thrust belt stems from the Neogene-to-Quaternary foreland-ward migration of thrust fronts coeval with the activation of post-orogenic extension at the rear of the belt in response to the eastward rollback of the subducting Adria slab. From a thermal point of view, previous works concluded that the NA experienced cooling and exhumation over the past 20 Myr at an average exhumation rate between ca. 0.3 and 1 mm/yr, with continental accretion becoming progressively younger towards the east. However, whereas low-T thermochronology has been successfully applied to the lowermost exposed structural units aiming at unravelling the timing of thickening and later dismantling of the fold-and-thrust belt, its application to the shallower wedge-top basins has remained largely unexplored and underutilised. We present new thermochronological data (apatite fission-track (AFT) and U-Th/He data (AHe)) from an Epiligurian wedge-top basin, which recorded Eocene-upper Miocene marine deposition on top of the growing NA. By analysing samples from the entire basin sedimentary succession, we aimed to better constrain the tectono-thermal record of the Epiligurian wedge-top basins, thus exploring their role in the dynamic behaviour of the NA belt. Our thermochronological results show that the studied Epiligurian basin has been exposed to a maximum temperature of ~ 90° C after deposition and underwent cooling from the early Oligocene onward**.** In particular, the lowermost Epiligurian formation (Lutetian in age) experienced significant Oligocene through Pliocene cooling which indicates that, although it was deposited under marine conditions, it experienced cooling-driven rock uplift during the structural thickening of the belt. This is consistent with the abrupt change of the depositional environment that affected the Epiligurian stratigraphic succession in the Burdigalian, when a shallowing upward trend from silica-rich marl to shelf and slope-basin facies occurred. The study shows that cooling recorded by the uppermost structural levels of the NA was not steady state but rather it occured in distinct episodes. We frame the exhumation history of the Epiligurian Basins within a two-stage tectonic scenario, including an early (Eocene-Early Miocene) overthrusting phase of the more internal units, followed by frontal accretion (middle Miocene Quaternary) during the eastward slab rollback.

Low efficiency turbidite systems controlled by the geometry of structurally-confined mini-basins (Valla and Fraschetto Systems, Oligocene, Tertiary Piedmont Basin, NW Italy)

Tinterri R.*[1], Lima D.F.[1-2] & Civa A.[1]

[1] Dipartimento di Scienze Chimiche, della Vita e della Sostenibilità Ambientale, Università di Parma.
[2] Petrobras - Petróleo brasileiro S.A. Brazil.

Keywords: turbidite systems, facies analysis, basin geometry.

This work presents a comparison between Valla and Fraschetto turbidite systems (Oligocene Molare Group) cropping out in the western part of the Tertiary Piedmont Basin, a large polyhistoric episutural basin (Mutti et al., 2002). In particular, this work aims to understand the relationship between basin geometries and flow dynamics through lateral-vertical distribution of facies, erosional structures, mudstone clasts, load structures, water escapes, paleocurrents and lastly of onlaps against the basin margins.

The Valla turbidite system represents the filling of a small WSW-ENE oriented structural depression (less than 1 km wide and few kms long) with a steep southern fault-related margin and a milder northern margin. Towards the east this asymmetric basin features a transversal paleo-topographic high related to the continuation of the NNW-SSE oriented Mioglia flexure (a fault-bend fold). The Valla system is characterized by lenticular and amalgamated beds of bouldery to pebbly very coarse to coarse grained sandstones deposited by extremely poorly organized and highly immature sediment gravity-flows resulting from the resedimentation of underlying fan delta deposits. The Valla system is a very low efficiency turbidite system in a very small basin, in which dense flows, from the west, evolve parallel to the WSW-ENE oriented fault-controlled basin margins. The lateral and vertical facies distribution is controlled by basin asymmetry and by a subtle frontal topography related to the Mioglia flexure. Dense flows deceleration against the steep southern margin forms very thick massive beds with erosional bases (often deformed by load structures) and pillar-type water escapes. Deflection and compensation processes produce a north-westward lateral displacement of the main depositional zone closely resembling that described by Tinterri & Civa (2021) in the time equivalent Fraschetto turbidite system (few kms far from study area) where the deflection of small volume dense flows against a structural high, parallel to the Mioglia flexure and oblique to the flow direction, produces laterally accreted deposits. These conclusions are also supported by comparison to other turbidite systems with higher efficiency but characterized by similar basin geometries, such as the Ranzano and Annot Sandstones (Tinterri et al., 2017).

This work is part of a broader study which tries to point out how basin geometry and confinement degree, which mainly depend on tectonic setting and tectonic structures orientation, are the major controlling factors of the efficiency degree of a turbidite system and thus of its lateral and vertical facies distribution (Tinterri et al., 2023). Growing evidence from field and subsurface data highlights that tectonic structures parallel or perpendicular to the flows can favour or hinder flow evolution respectively, and Valla and Fraschetto turbidite systems are two examples of these dynamic behaviours for the category of very low efficiency systems.

Keywords: multiphase rifting, basin inversion, geothermal energy.

Situated directly beneath one of the most densely populated regions in the Netherlands, the West Netherlands Basin emerges as an optimal location for geothermal energy exploration. Presently, the basin hosts 14 operational projects, with at least 3 more in the developmental phase. The primary target in the area are the syn-rift deposits of the Late Jurassic Nieuwerkerk Formation.

The geological history of the West Netherlands Basin is characterized by Mesozoic multi-phase rifting, followed by late-stage inversion during the Late Cretaceous. Comprehensive analysis of publicly available seismic and well data allows us to discern two rifting episodes during the Jurassic. A first phase in the Early Jurassic and a subsequent phase, partly influenced by structures of the former, during the Late Jurassic. This latter phase aligns with the sedimentation of the fluvial-deltaic Nieuwerkerk Formation.

The interplay of multi-phase rifting and fault evolution localized the creation of sedimentary accommodation space. This influenced the architecture of the fluvial system that deposited the Nieuwerkerk Formation. Consequently, the distribution of sandy facies within this formation is expressed by significant heterogeneity. This causes lateral and vertical variations in porosity, permeability, and net-to-gross ratios. Our reinterpretation offers valuable insights into the depositional environment of the Nieuwerkerk Formation, its structurally-controlled evolution, and thus, mitigating risks associated with geothermal well planning in fluvial sandstone reservoirs within inverted rift basins.

Architecture of migrating channel belts in a foreland basin: insights from the Tortonian Tachrift turbidite system, Taza-Guercif basin, NE Morocco

Zuffetti C.*, Felletti F. & Marini M.

Dipartimento di Scienze della Terra, Università di Milano.

Corresponding author email: chiara.zuffetti@unimi.it

Keywords: channel, Morocco, turbidite.

The present study focuses on reconstructing one of the distributary systems that acted as transfer pathways for clastic material from the Atlas chain to the Rifian Corridor (Morocco). The latter represents a remnant of the Rif foreland basin, a large-scale structure which was part of a series of ancient, relatively narrow seaways connecting the Atlantic Ocean to the Mediterranean Sea during the late Miocene. At present, the Rifian Corridor comprises the infill of three sedimentary basins, i.e. the Gharb, Fes-Meknes and Taza-Guercif basins.

The study area is located in the southern margin of the Taza-Guercif basin, which was established in the early Tortonian as the result of flexural loading by the advancing thrust sheets of the Rif foreland, combined with the concurrent re-activation of Middle Atlas tectonic structures.

We present the channel-levee Complex 6, one of the multiple turbidite channel-levee complexes making the Tachrift system, exceptionally exposed as part of the clastic fill of the basin. Goal is to document its 3D architecture, facies assemblages, and evolution, to be integrated with the ongoing surveys on the basin fill. The method integrates geological mapping, facies analysis on 46 logs, and 3D physical stratigraphic correlations. Statistical analyses on sedimentological variables supported quantitative comparison among depositional elements and their lateral transitions.

Complex 6, 13 m thick, consists of three sandstone-rich units, A, B, and C, that progressively increase in grain-size and are laterally stacked in a SE-ward shifting fashion. The tabular, fining-upwards sandy packages with rare concave-upwards erosional surfaces in unit A suggest a system of small sinuous and ephemeral distributary channels. Upwards, unit B and C display channel-fill deposits and genetically linked levees with different crossflow facies tracts, that record changes in flow parameters and morpho-dynamics of the parent channel. Unit B shows deposition in sinuous meandering channels, dominated by Lateral Accretion Packages (LAPs) that make transition to levees at the accreting inner bank, showing complex lateral relationship with the outer bank levee; unit C is characterized by relatively straighter channels where amalgamated sandstones (i.e., channel axis) laterally pass into sandy levee crests, then to mud-prone outer levee heterolithics. 3D stratigraphic architecture of complex 6 reveals an eastward channel belt migration and a progressive flow energy/density increase.

This detailed sedimentological study, integrated with those conducted on other channel-levee complexes outcropping in the area, together with the analysis of coeval and adjacent shallow marine, coastal, and deltaic sediments, will allow us to discern the role of interacting tectonics, climate change, and autocyclic processes controlling the deposition within the Taza-Guercif basin.

Keywords: electrical resistivity, elastic/anelastic characteristics, geothermal reservoirs imaging.

This work shows the preliminary results of the activities carried out in the framework of the project TOGETHER - Sustainable geothermal energy for two Southern Italy regions: geophysical resource evaluation and public awareness financed by European Union – Next Generation EU (PRIN-PNRR 2022, CUP D53D23022850001).

Part of the TOGETHER project activities are devoted to implementing a geophysical multi-messenger approach for improving the imaging of geothermal reservoirs in terms of temperature and physical properties of the reservoir rocks and fluids. This approach is based on the joint evaluation of complementary information carried outby subsoil electrical resistivity and elastic/anelastic characteristics from seismic waves propagation: 1) measured electrical resistivity depend on temperature, porosity, percentage of fluid saturation, and permeating fluid type (Rizzo et al., 2022); 2) VP and VS parameters result in being mainly sensitive to lithology changes, whereas their ratio (VP/VS) provides precious hints on the fluid composition and its pore pressure; 3) the anelastic parameters, described by the quality factor Q, strictly depend on some rheological properties like the temperature and the percentage of fluid saturation in rocks (Amoroso et al., 2018).

The proposed method is being tested in two test sites in Southern Italy that are appropriate for low to medium-enthalpy geothermal extraction: 1) Contursi Terme, with fluids temperatures ranging from 21°C to 30°C, and numerous wells for balneotherapy with temperatures between 25°C to 47°C (Gori et al., 2023); 2) Tramutola, situated in Agri Valley (Basilicata Region) where, during the drilling of a hydrocarbon well in 1936, AGIP oil company intercepted a confined aquifer of sulphureous hypothermal water (28 °C with a flow rate of 10 l/s) associated with gases of mantle origins, primarily CH4 and CO_2 (Olita et al., 2023).

During the first project phases, multi-scale and multi-resolution 3D subsoil electrical resistivity is being estimated in test areas using Electrical and electromagnetic geophysical methods, such as Magnetotelluric (MT) and shallow and deep electrical resistivity tomography (ERT). At the same time, both local earthquake tomography (LET) and ambient noise tomography (ANT) will be adopted; the proposed methods will aim at a multi-scale and multi-resolution elastic/anelastic subsoil imaging in terms of both 3-D P-and S- wave velocity models and quality factor estimations.

New geophysical data are acquired using cutting-edge instrumentation purchased as part of two additional scientific projects: ITINERIS (Italian Environmental Integrated Research Infrastructure System, PNRR, MUR, M4C2, Investment 3.1 RI), financed by European Union – Next Generation EU, and GRINT (Geoscience Research INfracstructure of Italy, INGV).

Comparative analysis of alarm-based earthquake forecasting models in Italy

Biondini E.*[1], D'Orazio F.[1], Lolli B.[2] & Gasperini P.[1-2]

[1] Dipartimento di Fisica e Astronomia, Università di Bologna. [2] INGV, Bologna.

Corresponding author email: emanuele.biondini2@unibo.it

Keywords: earthquakes forecasting.

The importance of studying earthquake precursor signals is undeniable, especially at a time when the quality of seismic data is constantly improving. This allows a deeper understanding of seismic phenomena and a more accurate validation of forecasting models.

In this work, we explore and compare the ability of two different precursor signals to predict potentially destructive strong earthquakes. The precursor signals analysed are the spatio-temporal variations of the b-value of the frequency-magnitude relationship and the occurrence of possible strong foreshocks, respectively.

The analysis of spatio-temporal variations in the b-value of the frequency-magnitude distribution of earthquakes can provide valuable information on the stress state and probability of earthquake occurrence in a specific geographic region. In fact, as it has been observed in many cases, the b-value tends to decrease in the preparatory phases of a strong earthquake, and suddenly increases after the occurrence of the mainshock.

Similarly, the analysis of foreshocks can provide a valuable answer in the search for precursor signals for earthquake forecasting. Earthquakes tend to cluster in space and time, and foreshocks can indicate the approach of a mainshock. After a foreshock, the relative frequency of a large earthquake in the same area increases significantly compared to quiet periods, suggesting that foreshocks can be used as a basis for a forecasting experiment.

To evaluate such a hypothesis, in this work, different alarm-based forecasting methods are implemented. The forecasting methods have been retrospectively calibrated and optimized for the period 1990-2011 to forecast Italian earthquake of magnitude larger than 5.0.

The methods have been then applied pseudo-prospectively over the period 2012-2023 and the forecasting skills have been assessed using specific tests and statistics for alarm-based models. Such models have been also compared with those of the ETAS applied using the alarm-based approach.

Exploring the Greater East Shetland Platform (Northern North Sea, UK): integration and modelling of wellbore, seismic, gravity and magnetic data to evaluate its storage potential

De Luca M.*[1], Mancinelli P.[2], Patruno S.[3] & Scisciani V.[1]

Keywords: geological modelling, seismic interpretation, gravity and magnetic forward modelling.

The reduction of anthropogenic greenhouse gas pollutants and securing new energy supplies will require sites of extensive geological storage capacity. Forward modelling of gravity and magnetic data can contribute to depicting the subsurface geological framework of underexplored areas, such as the Greater East Shetland Platform (GESP) and its intra-platform basins in the UK Continental Shelf (Northern North Sea), where data availability is limited and sparse. This region is characterized by a laterally discontinuous but locally thick (1-8 km) Devonian-to-Tertiary sedimentary sequence that unconformably overlies the Caledonian crystalline basement. The intra-platform basins are located 50-150 km from shorelines and are crosscut by pipelines, therefore representing attractive potential areas for geological storage by repurposing existing infrastructures to serve the energy transition (e.g., Leporini et al., 2019).

In this study, legacy wellbore data (i.e. lithology, seismic velocity, and bulk density) and a newly acquired 2D seismic survey have been analysed and interpreted. Furthermore, six profiles were depth-converted and served as constraints for the forward modelling of observed Bouguer gravity and magnetic anomalies.

Results suggest that the first-order contributors to the observed Bouguer gravity anomalies are related to the scattered distribution of the Mesozoic sedimentary sequences of the intraplatform basins. In particular, two gravity minima correlate with the main Triassic-Jurassic successions within the area (i.e. Dutch Bank Basin, East Orkney Basin), while shallow exposures of the basement underneath the Tertiary cover (i.e., Caithness Ridge, Fair Isle Platform) is spatially-related to gravity maxima. Furthermore, the main sources of the modelled magnetic anomalies are related to high susceptibility (≤0.05 SI units) bodies in the crustal basement that locally correspond to high reflectivity zones observed in the seismic profiles. Such deep sources are interpreted as paleo-domains inherited from the pre-Devonian tectonic evolution of the study area and assembled during the Caledonian Orogeny (De Luca et al., 2023).

Despite their scattered distribution, wellbore data analysis, when coupled with our findings, supports the interpretation that the GESP is an area offering new targets for fluid storage, either below or close to producing fields. Moreover, a potential storage area of 2000 km2 has been identified. Industry and government co-funded projects to build or re-use existing pipelines to transport carbon dioxide in areas close to the GESP have been recently proposed (e.g., Acorn and Sleipner, Pale-Blue, 2021; Furre et al., 2017) to support CCS (Carbon, Capture and Storage) and CCUS (Carbon, Capture, Utilization and Storage) activities. Thus, further investigation could define effective GESP capacity making it an area of strategic interest for future expansion of storage capacity and existing CCS projects in the North Sea.

OTRIONS seismic network during ten years of analyses: the new microseismicity catalog of the Gargano area (Southern Italy)

Ferreri A.*[1], Romeo A.[1], Giannuzzi R.[1], Cecere G.[2], Falco L.[2], Filippucci M.[1-2], Michele M.[2], Serlenga V.[3], Panebianco S.[3], Stabile T.[3], Selvaggi G.[2] & Tallarico A.[1-2]

Keywords: seismology, earthquakes, detection.

The OTRIONS seismic network (FDSN code OT) is a local network installed in the Apulia region (Southern Italy) by the University of Bari Aldo Moro. Its primary objective is to investigate the seismic activity in the Gargano area (Northern Apulia) and the Salento area (Southern Apulia). OTRIONS started to operate in 2013 and in 2019 the network migrated on EIDA. Therefore, since then is managed by University of Bari Aldo Moro and the National Institute of Geophysics and Volcanology (Filippucci et al., 2021). A first catalogue of the seismicity in the period from 2013 to 2018 was released in 2021. It comprised events both manually and automatedly detected using SeisComP3 (Helmholtz-Centre Potsdam, 2008).

After ten years of operation, at present the focus lies on the microseismicity of the Gargano area and, in particular, on compiling a new seismic database from April 2013 to December 2022. This work has been conducted by employing CASP (Complete Automatic Seismic Processor), a software for automatic event detection, picking, and location (Scafidi et al., 2019). CASP operates on a remote server managed by RECAS-Bari, the computational infrastructure jointly managed by INFN and UniBa. CASP and NonLinLoc software (Lomax et al., 2000) where set specifically for the Gargano area. As velocity model, we adopted the 1D Gargano velocity model (de Lorenzo et al., 2017).

The recorded seismic events were organized into two catalogs: an automatic and manual catalog obtained from CASP's automatic location results, and by a manual revision of P- and S-wave arrival times, respectively. The reliability of CASP algorithm was evaluated by comparing the automatic and the manual catalogs.

The final revised catalog revealed a significant increase in events detection performance with respect to the earlier version derived from SeisComP3. Furthermore, the results show that the choice of the CASP parameters allows us to lower the minimum magnitude threshold of the recorded microseismicity in the Gargano area. Moreover, the application of PhaseNet deep neural network for earthquake detection showed that the number of the detected event can be further increased with respect to CASP. Finally, the preliminary results of the seismicity distribution suggest a deepening of the earthquakes trend moving northwards in the area.

A comparison between moment magnitude scales

Gasperini P.*[1] & Lolli B.[2]

[1] Dipartimento di Fisica e Astronomia "Augusto Righi", Università di Bologna. [2] INGV, Bologna.

Corresponding author email: paolo.gasperini@unibo.it

Keywords: seismic magnitude.

Moment magnitude *Mw* was first defined by Kanamori (1977) and Hanks & Kanamori (1979) in the late 1970s, when the availability of new force balance seismometers made it possible to measure the seismic moment *M0* with virtually no limits in the frequency passband. For this reason, *Mw* does not become saturated even for the largest earthquakes ever recorded. *Mw* has been chosen in such a way that it coincides best with the previous definitions of magnitude (*ML*, *mb*, *Ms* etc.) on certain ranges of values but can deviate significantly from them within other ranges. A few years ago, a new moment magnitude scale *Mwg* was proposed by Das et al. (2019), with the aim of better reproducing the values of *mb* and *Ms* over their entire range and to better predict the energy *Es* adiated by earthquakes. In this work we show that there was no need to define such a new scale and that the latter is not even optimal to achieve the goal that the authors had set themselves.

New insights on the deep electrical structure of the Molise-Sannio region: preliminary outcomes of a Magnetotelluric survey

Kashi R.*[1], Balasco M.[2], De Girolamo M.[3], Graziano M.[1], Improta L.[3], Patella D.[1], Pigniatello G.[1], Siniscalchi A.[1], Tripaldi S.[1], Ventola I.[1], Villani F.[3] & Romano G.[1]

Keywords: Magnetotelluric, crustal model, Molise-Sannio region.

In the framework of MOlise SAnnio Integrated Crustal MOdel – MOSAICMO, a project led by the Istituto Nazionale di Geofisica e Vulcanologia (INGV), a Magnetotelluric (MT) survey was carried out to provide information about the subsurface electrical resistivity distribution of the junction zone between the Central and Southern Apennines (Molise-Sannio region).

20 MT soundings were acquired along a ~25 km long profile SW-NO oriented and extending from Piedimonte Matese toward Campobasso. Thanks to the high sampling frequency used and to the quite long lasting of the records, each of the soundings provides impedance estimations in a wide period range [10-4 s - 103s]. Dimensionality analysis performed on the whole dataset justified the use of a 2D inversion strategy which resulted in a resistivity model of the investigated area up to a depth of 12 km b.g.l.

This crustal resistivity section well match both with the surficial geological information, clearly discriminating between the Matese and the Sannio units, and with other independent deep information (i.e. the analysis of the logs of the Campobasso 1 well).

The overall information coming from the MT survey will certainly contribute to the MOSAICMO project aims being a fundamental piece for the multiscale and multidisciplinary investigation of the investigated area.

Fault (re)activation and fluid-induced seismicity: an example from the Val d'Agri intermontane basin (Southern Italy)

Lavecchia A.*[1], Serlenga V.[2], Filippucci M.[1-3], Stabile T.A.[2], Prosser G.[4] & Tallarico A.[1-3]

[1] Dipartimento di Scienze della Terra e Geoambientali, Università di Bari "Aldo Moro". [2] Istituto di Metodologie per l'Analisi Ambientale, CNR, Tito Scalo, Potenza. [3] INGV, Roma.

Corresponding author email: alessiolavecchia@yahoo.it

Keywords: Val d'Agri, numerical model, fluid-induced seismicity.

Over the last decades, the occurrence of fluid-induced, moderate-to-large earthquakes in several locations around the globe sparked interest in the relationships between fluids and seismicity. Several studies suggest that fluids can be one of the most prominent factors that can induce variations of the stress state of rocks, due to the increase or drop of the pore fluid pressure, and consequently trigger earthquakes. In this framework, the Val d'Agri is an important case study where we observe the relationships between fluids and seismic activity. In this area, the activity of reinjection of wastewater from oil extraction reactivated the Costa Molina blind thrust in the eastern sector of the valley and generated a well-defined microseismicity cluster. A few kilometers SW from this cluster, the water load associated with the presence of the Pertusillo reservoir generates and/or favors further seismic activity within the Apulian carbonatic platform. The formation, geometry and evolution of the seismically active structures in the region are still a matter of debate, especially if the polyphase compressional/extensional tectonics that characterizes the southern Apennine's geological history. As a consequence, the seismic potential in the whole region is largely unconstrained.

We built up a 2D thermo-mechanical model to define the principal mechanisms generating the present-day tectonic setting observed in the Val d'Agri and surrounding regions and to provide insight into the seismic hazard characterizing the area. We suggest the presence of a major dècollement layer decoupling the deformation of the sedimentary cover and the crystalline basement, which is constituted by the Triassic Burano Formation. Our model quantifies the stress field and allows us to estimate the Coulomb stress in the Val d'Agri crust, to assess the seismic potential of the region. We conclude that the Coulomb stress values are positive in a large part of the crust, and therefore that fluid injection is a high-risk activity for the reactivation of buried structures, especially within the Apulian carbonatic platform formation.

What is in the INGV ISIDe online database before 16 April 2005?

Lolli B.*[1], Vannucci G.[1] & Gasperini P.[2-1]

Keywords: magnitude, seismic catalogs.

The Italian Seismological Instrumental and Parametric Data-Base (ISIDe) is the recipient of earthquake data collected in real-time by the Istituto Nazionale di Geofisica e Vulcanologia (INGV), and used by the studies of earthquake forecasting and seismic hazard assessment in Italy in the last decade. When it went online, following a significant improvement of the seismic acquisition system of INGV, it was including only data since the second fortnight of April 2005. About ten years later, the data since the beginning of 1985 suddenly appeared without any prior notice than the updating of the starting date of the dataset. However, the characteristics of the added data appeared clearly different from the following period both in terms of the numbers of located earthquakes and of types of magnitudes provided. After having analyzed the numerical consistency and the calibration of magnitudes of ISIDe as a function of time from 1985 to 15 April 2005, we can say that such a dataset is incomplete and poorly calibrated compared to other catalogs of Italian seismicity (CSTI, CSI, and HORUS) available for the same period. Hence, we suggest not using it as is for statistical analyses of Italian seismicity. However, it provides some magnitudes that are missed by other catalogs and thus might be used for improving such catalogs.

Elaboration of new regional temperature-at-depth maps, aiding in the assessment of the geothermal potential in the Southern Latium

Keywords: Geothermal energy, well analyses, seismic interpretation, Southern Latium.

In the upcoming years, significant enhancements in energy production systems will be imperative to achieve the decarbonization objectives of the European economy. According to the Integrated National Energy and Climate Plan (PNIEC, 2019), Italy aims to accelerate the transition from traditional fuels to renewable sources by gradually replacing coal for electricity generation with an increasing proportion of renewables in the energy mix by 2030. In this context, geothermal energy emerges as the most promising energy source. It holds the potential to substantially contribute to the adoption of low-carbon technologies for generating electricity, as well as for heating and cooling purposes.

An initial step in evaluating the geothermal potential of an area involves understanding the distribution of temperatures at depth and the geological and structural conditions of the subsurface. At national level, the temperature reference data are the maps at different depths from ground level (i.e., 1, 2, 3 km) available in the Italian National Geothermal Database (BDNG, Trumpy & Manzella, 2017). On the contrary, the National Mining Office of the Ministry of Environment and Energy Security, through the website of the project "Visibility of petroleum exploration data in Italy" (ViDEPI Project, 2019), provides public information and data on subsurface acquired by different oil companies during past exploration activities.

In this study, subsurface data from these extensive public datasets have been reanalyzed and combined to generate new temperature-at-depth maps in the Latium and Campania regions with the aim of evaluating their geothermal potential. The newly elaborated temperature maps combine values extracted from the public hydrocarbon wells dataset of the VIDEPI Project and from geothermal wells and temperature isolines reported in the BDNG database. To reconstruct the distributions of temperatures at depth, various operational data processing were performed in a GIS environment interpolating linear and point data, and producing isothermal surfaces from 50 to 350 °C, every 50 °C.

The analyses of the preliminary results highlight some areas characterized by high temperature values in correspondence to the Bracciano, Vico, and Bolsena lakes, Viterbo city, the Campi Flegrei and Vesuvius zones, and in the southern Latium region. In this latter area, thanks to the analysis of a confidential geophysical dataset (well-logs and seismic reflection profiles) provided by ENI national energy company, we reconstructed the depth and the geometry of the regional reservoir with the aim of evaluating its temperature range. The results of the reconstructed temperature values and geodynamic and structural conditions reveal several promising geothermal areas in southern Latium. These findings enable a qualitative assessment of the area's geothermal potential for different use applications.

Keywords: crustal structure, seismic gap.

Knowledge of the crustal structure of potentially hazardous but long-silent seismic gap areas is crucial for earthquake risk mitigation. Seismic sequences occurring in those well instrumented areas provide a valuable opportunity to characterize the crustal properties of the seismogenic volume. Here we present the result of analyses of the crustal properties of two seismic gap areas: the Mt. Pollino area (Italy) and the Northern Thessaly area (Greece).

The first area was affected by a 4-year long sequence, started in 2010, characterized by more than 10,000 earthquakes with a predominant swarm-like behavior and, to a lesser extent, as a mainshock-aftershock sequence following the two main events (ML 4.3 and ML 5.0) that occurred about two years after the sequence began. In the second case study, the aftershock sequence, following three moderate-magnitude events (Mw 6.3, Mw 6.0 and Mw 5.6), dissipated in less than a month during March-April 2021.

Velocity, attenuation and focal mechanism tomographies have been performed at local scale for the Mt. Pollino seismogenic volume using the events of the 2010-2014 seismic sequence, and the detailed structures at smaller scale highlighted by relative location of microearthquakes. These results have been also compared with the most recent geological findings. The likely role of over-pressurized fluids, already suggested in previous works, the main structural barriers and the lithologic units involved have been revealed by this analysis.

With regard to the Thessaly seismic gap the lithologic units, the likely role of fluids, and the blind fluid-filled inherited structures involved in the sequence have been highlighted by the integration of seismic tomography and InSAR geodetic models. The results have been also corroborated by geological studies and focal mechanisms of the main events performed by different seismological agencies.

As highlighted by the two analyzed case studies, the integration of different techniques is fundamental for a more complete understanding of complex seismogenic volumes with the goal of reducing their associated seismic risk.

New insights in Andean geothermal exploration: preliminary results from the Tocomar geothermal system case study (Puna, Argentina)

Pedini M.*[1], Cella F.[1], Invernizzi C.[1], Mazzoli S.[1], Viramonte J.G.[2] & Filipovich R.[2]

[1] Scuola di Scienze e Tecnologia—Sezione di Geologia, Università di Camerino.
[2] Instituto de Bio y Geociencias del NOA (IBIGEO, UNSa-CONICET), Salta, Argentina.

Corresponding author email: matteopedini97@gmail.com

Keywords: geothermal, 3D Model, Andes.

The Tocomar Geothermal System (TGS), situated in the back-arc region of the Central Andes on the Puna Plateau in northwest Argentina, represents a significant potential for high-temperature geothermal fields, making it a promising site for alternative power generation. Evidence of current and past geothermal activity, including thermal springs, phreato-phreatomagmatic structures, travertines, and saline deposits, underscores its geothermal significance (Filipovich et al., 2020). The TGS, located and controlled by the westernmostsegment of the Calama – Olacapato – El Toro lineament (COT) and associated with the homonymous volcanic center, has been interpreted as fault-hosted reservoir (Filipovich et al., 2022). However, despite its potential, proposed conceptual models for the TGS have limitations and fail to fully explain the geothermal system's dynamics.

While geological studies have been conducted in the area, geophysical investigations imaging the geothermal fields and their elements are scarce. Notably, a 3-D inversion of audio-magnetotelluric data around the TGS provided insights into its main elements, including the clay cap and potential reservoir, at depths of ~1000 m. New gravity and airborne magnetic geophysical data were collected to delineate geological structures controlling geothermal manifestations and estimate the extent of the geothermal field. This data, integrated with petrophysical characterization of cap and reservoir rocks, revealed insights into the geothermal system's properties, including low permeability and thermal conductivity of cap rocks and the thermal conductivity and electrical resistivity of reservoir rocks (Ahumada et al., 2023). Probabilistic assessments estimated the power production capacity of the TGS positioning it as a significant contributor to renewable energy in the region. These findings, coupled with its strategic location and the tectonic control characterizing the Tocomar area, suggest the reservoir's potential may be larger than previously assumed(Filipovich et al.,2022).

This preliminary study proposes a comprehensive geological model of the TGS, integrating surface geological mapping, macro and reservoir-scale balanced and restored cross-sections, geoelectric and gravimetric/magnetic modeling. The resulting geologic framework model represents a significant advancement in understanding the reservoir rocks or basement of the TGS. Utilizing a macro-scale 3D geological model, the study characterizes the reservoir complexity by defining the geometry of the main tectonic elements and the depth of the host rock (basement). Further, a detailed 3D model of the Tocomar basin will be generated, facilitating the development of an integrated 3D static model depicting the spatial evolution of the rock properties. These insights provide valuable information for future evaluations, such as fluid flow simulation and updated volumetric calculations.

Keywords: magnetotelluric, space weather.

In recent years, the Magnetotelluric technique has become a potent instrument for defining the lithosphere's physical characteristics, geometries, and structures This is performed by reconstructing the distribution of the physical parameter electrical conductivity (Bahr & Simpson, 2005; Bedrosian, 2007).

The MARGE project, which stands for Geoelectromagnetic Risk Map for Central Italy, is being carried out by the Istituto Nazionale di Geofisica e Vulcanologia (INGV) in collaboration with the University of Bari and the Institute of Methodologies for Environmental Analysis of the National Research Council (CNR) and aims to create an extended map of the electrical conductivity of the subsurface of central Italy by analysing natural electric and magnetic fields.

Preliminary results from the MARGE project are presented, focusing on the collection of broad-spectrum and long-term magnetotelluric data on a grid of points approximately 50 km apart. The project has two main objectives: to study lithospheric structures and large-scale geodynamic processes in the central Apennines through 3D modelling of magnetotelluric data, and to develop geoelectric field maps of central Italy to support Space Weather modelling and the analysis of the vulnerability of critical infrastructures (Kelbert, 2020).

Keywords: GNSS, post-processing analysis, NRTK.

In recent years, many analysis have been performed to obtain three-dimensional (3D) positioning by using the Global Navigation Satellite System (GNSS) Continuously Operating Reference Stations (CORS). Nowadays this methodology is widely used all over the world in different parts of the continents (Snay & Soler, 2008) to evaluate positioning in real-time (Network Real-Time Kinematic, NRTK) and in post-processing analyses. The purposes of the developed local academic GNSS network are multiple: to support the scientific research to better understand the geodynamic phenomena taking place in the Apulian region; provide support to university educational activities, through apprenticeship and degree theses; for private and public users that could enquire the GNSS data. These objectives were achieved by realizing a new infrastructure composed by GNSS- CORS, managed from the "Dipartimento di Scienze della Terra e Geoambientali" (DiSTeGeo) of University of Bari in collaboration with INGV (Istituto Nazionale di Geofisica e Vulcanologia). This network has been implemented starting from 2022 and is actually composed by four stations named DSTG, MARU, MOTT and TARD, respectively located at Bari, Maruggio, Mottola (two countries near Taranto) and Taranto. In the context of data sharing, DSTG station is part of the RING (Rete Integrata Nazionale GPS), the national GNSS network managed by INGV. The development of this network allows to obtain three-dimensional (3D) positioning, both in real-time (Network Real-Time Kinematic, NRTK) and in post-processing analyses. For the real-time service, through the NTRIP protocol (Networked Transport of RTCM via Internet Protocol) the RTK/DGPS differential corrections are distributed. For the post-processing service, the data are shared with the FTP protocol, international standard for the geodetic community. The first data analyses enabled to verify the network operating service and the quality of the recorded data during the first period of functioning of the infrastructure (2022-2024).

Snay R.A. & Soler T. (2008) - Continuously operating reference station (CORS): History, applications, and future enhancements. Journal of Surveying Engineering, 134(4), 95-104, https://doi.org/10.21163/GT_2020.151.05.

New insights from analyses of geophysical data in the Northern Apennine buried structures for evaluation of their geothermal potential

Tesauro M.*[1-2], Cortassa V.[1], Gola G.[3], Galgaro A.[4] & Manzella A.[3]

[1] Dipartimento di Matematica, Informatica e Geoscienze, Università di Trieste. [2] Department of Earth Science, University of Utrecht. [3] Istituto di Geoscienze e Georisorse, CNR.
[4] Dipartimento di Geoscienze, Università di Padova.

Keywords: geothermal energy, geophysical data, InGEO project.

Geothermal energy is arguably the most attractive of low-CO_2 renewable resources, being broadly distributed and available in every period of the year. The main aim of the InGEO project (*Innovation in GEOthermal resources and reserves potential assessment for the decarbonisation of power/thermal sectors*) is to develop an innovative exploration workflow integrating geophysical data and other direct and indirect information, organized to make available a sort of decision support system of geothermal projects. To this purpose, we chose as a target area the Northern Apennine buried structures belonging to the Romagna and Ferrara Folds (RFF). This area extends from the termination of the Emilia Folds in the West to the Adriatic coast in the East and from the outcropping edges of the Northern Apennines in the South to the undeformed Po foredeep in the North. The RFF area has been the subject of previous geothermal studies revealing relatively low geothermal gradients within the deep carbonate units (on average 14 °C/km) and more significant thermal gradients (on average 53 °C/km) in the overlying impermeable formations (Pasquale et al., 2013). This feature in temperature distribution with depth is clear evidence for fluid thermal convection occurring in the deep-seated carbonate units of Mesozoic age, which constitutes the local geothermal reservoir. The shallow crust of this area has been investigated by several previous studies and through a total of 535 deep exploratory wells (VIDEPI database: https://www.videpi.com/videpi/videpi.asp), having final depths ranging from 0.5 up to 6.5 km below ground level. They provide essential information, concerning lithostratigraphy, temperatures measured during drilling stops and geophysical logs, commonly electrical resistivity, gamma ray and sonic. Several geophysical investigations, recently carried out in the Alps and Po plain, revealed both the shallow ad deep structures of the study area, in terms of lateral variations of Bouguer anomalies, seismic velocities, and main discontinuities (Nouibat et al., 2023; Zahorec et al., 2021). The analyses of the data collected revealed a good correspondence between the low seismic velocities, characterizing the shallow crust of the RFF, and the negative Bouguer anomalies. We reconstructed the Moho depth of the area, estimating the depth of the iso-velocity contour of 4.1 km/s (Nouibat et al., 2023) and observed its deepening from NE to SW, towards the Apennines, from ~27 km to ~48 km. Seismic tomography of the upper mantle (Rappisi et al., 2022) reveals that the velocity in the shallow and deep lithosphere is low in the central part of the study area, possibly related to a local asthenospheric upwelling and tends to increase beneath the Apennines. The results of this ongoing research will be the input of the thermal model and contribute to the development of an open-source and web-based GIS tool, and to the calculation of the deep geothermal energy potential for both hydrothermal resources and deep heat exchangers.

Reliable long-term CO_2 storage as clathrate hydrates in seawater and marine sediments: the CO_2-RESTO project

Tinivella U.*[1], Giustiniani M.[1], Castellani B.[2], Giovannetti R.[3], Zannotti M.[3], Nicolini A.[2] & Rossi F.[2]

[1] Istituto Nazionale di Oceanografia e di Geofisica Sperimentale, Sgonico (TS). [2] Dipartimento di Ingegneria, Università di Perugia. [3] Chemistry Interdisciplinary Project ChIP, Scuola di Scienze e Tecnologie, Sezione di Chimica, Università di Camerino.

Corresponding author email: utinivella@ogs.it

Keywords: CO_2 clathrate hydrate, laboratory measurements, modeling.

CO2-RESTO project aims at developing a technological solution for the carbon dioxide (CO_2) sequestration as clathrate hydrate, both in seawater and under the seafloor. Clathrate hydrates are nonstoichiometric solid compounds formed by cage-like crystalline structures of water molecules where a guest molecule – in this case CO_2 - is entrapped under proper conditions of temperature and pressure. The CO_2 storage as clathrate hydrate has been chosen in accordance with their desirable properties if compared to other geological storage pathways, such as higher density than seawater (resulting in a negative buoyancy effect); stability at moderate oceanic depth, storage in solid form, less susceptible to perturbations than fluid flow; storage within porous media (as the sediment of the ocean floor) with a cementing effect. CO_2-RESTO addresses some crucial issues, being devoted to obtaining a body of knowledge, significantly beyond the state of the art on engineering, chemical and geophysical aspects of CO_2 clathrate hydrate science. The project will investigate the proper approaches of CO_2 storage as clathrate hydrate, through in-lab experimental activities for the understanding of hydrodynamics, thermodynamics/kinetics, stability of CO_2 clathrate hydrate formation/dissociation, microscopic characterization of CO_2 clathrate hydrate, the effect of salinity, other chemical compounds and of the presence of other gaseous components. A theoretical model applicable to a CO_2 clathrate hydrate reservoir will be developed to characterize a possible natural site for CO_2 clathrate hydrate storage and help the choice and an efficient technological solution for CO_2 injection will be proposed. The project addresses important national long-term PNRR targets. One of the further objectives to 2040 is the installation of CO_2 capture and sequestration plants, both in the electricity and industrial sectors, to bring the energy system to complete decarbonization by 2050. In addition, the option to store CO_2 as clathrate hydrate is particularly relevant to those economies that produce substantial amounts of CO_2 in their industrial and power operations, but do not have proper local geologic storage. The estimates completed so far show that there is a huge capacity for clathrate hydrate storage worldwide, including Europe.

Seismic-electromagnetic effect in the Pollino area: measurements, analysis and numerical modelling

Ventola I.*

Dipartimento di Scienze della Terra e Geoambientali, Università di Bari "Aldo Moro".

Corresponding author email: ivana.ventola@gmail.com

Keywords: seismic-electromagnetic, fluids, modelling.

Seismic-electromagnetic is the name given to the phenomenon where seismic and electromagnetic fields are coupled. Two main conditions are required: porosity and fluids. This coupling ensures an exploration potential of both fluids and media characteristics, jointing seismic resolution and electromagnetic sensitivity. Even if in literature numerical modelling and laboratory / active experiments are present, the phenomenon earthquakes related is less explored. Here we present a systematic analysis of the seismic-electromagnetic effect recored during the Pollino seismic swarm (Southern Italy | 2011-2014). The acquisition was made up by magnetotelluric and seismic station in the same place. The analysis that will be discussed has been conducted in the time-frequency domain. Similarities and differences between seismic and electromagnetic waves will be described. Digitalisation problem will be discussed. Moreover, pre-seismic electromagnetic signals were observed: we used numerical modelling to explore the nature of these signals.

Characterising rainfall-runoff processes and recharge rates in Mediterranean ephemeral streams with small impoundment dams

Agius B. & Mamo J.*

Institute of Earth Systems, University of Malta.

Corresponding author email: julian.a.mamo@um.edu.mt

Keywords: infiltration, field saturated conductivity, mediterranean ephemeral streams.

Three main features characterise Mediterranean catchments: limited water resources because of high spatiotemporal variability of precipitation, dry summers and high-intensity rainfall events that generate flash floods (Zribi, Brocca et al. 2020). Understanding the relationship between rainfall, evapotranspiration, recharge, and runoff is critical in quantifying the water cycle at different time scales and understanding how the changing climate will impact local hydrological regimes and water resource availability in Mediterranean catchments. Monitoring hydrological processes within the unsaturated zone is difficult and expensive (Castiglione et al., 2005), but given the importance of groundwater in the region, characterising the unsaturated zone and understanding factors controlling infiltration and quantifying recharge will provide invaluable insights to inform water management decisions.

The proposed work aims to utilise the methodologies developed by Caputo, De Carlo et al. (2010), which employed large diameter infiltration tests on bedrock alongside geophysical techniques to monitor the unsaturated zone in carbonate rock formations. Characterising this zone is challenging due to its inherent heterogeneity and cracks and fissures in the rock. This work utilised infiltrometers installed directly on the rock surface within the valley bed to measure the field-saturated hydraulic conductivity. These results were compared to infiltration rates obtained through monitoring of the fill and recession rates of water behind retention dams built across dry valley systems to harvest stormwater for recharge and agriculture over these outcrops and corresponding climatic parameters to measure precipitation and calculate losses through evapotranspiration.

Seven consecutive basins were studied, with the first two situated above exposed Lower Coraline Limestone and the others downstream overlying Globigerina Limestone. The low-cost setup consisted of a gauge board and trail camera for each basin (with infrared for night photos). The volume of each basin at each stage was measured using a consumer drone to produce a digital surface model through photogrammetry using aerial photographs. Processing the stage height at a frequency of 10 minutes allowed the generation of hydrographs for runoff reaching each of the basins during rainfall events. Monitoring the recession rate was used to estimate recharge after attributing evaporation losses by using climate data.

This study underscores the complexity and variability of hydrological processes in Mediterranean catchments and demonstrates the critical role of field monitoring in enhancing our understanding of these dynamics. The research provides valuable insights into the interactions between rainfall, evaporation, and recharge processes by employing cost-effective techniques such as trail cameras to monitor multiple points along dry valley systems.

Evaluation of recharge sources and nitrates origin in a karst spring: a case study from the F.na Nurighe spring (NW Sardinia, Italy)

Arras C., Calia M.*, Biddau R., Murgia A. & Da Pelo S.

Dipartimento di Scienze Chimiche e Geologiche, Università di Cagliari.

Corresponding author email: mara.calia@unica.it

Keywords: karst spring, nitrates, ZVN.

According to the European and Italian regulation, the threshold for nitrates contamination in groundwaters addressed to human consumption is set to 50 mg/l. Identification of nitrates sources is not easy to assess and detailed hydrogeological investigations are required to delimitate Nitrate Vulnerable Zones (ZVN).

Miocene limestones and calcarenites from the Mores Formation, which widely outcrop in the Logudoro basin (NW Sardinia, Italy), host a karst aquifer that gives rise to several springs. One of these, the Funtana Nurighe spring, supplies the Cheremule's municipal aqueduct, a small village of about 400 inhabitants. Results of the hydro-geochemical monitoring carried out by the Regional Agency for Environmental Protection of Sardinia (ARPAS) since 2013 have highlighted continuous exceedances of the nitrate threshold value in the spring waters. This implies a significant impact on the water supply of the municipality and on the inhabitant's health.

Based on the ARPAS monitoring results and the reconstruction of a detailed geological model of the area, a preliminary ZVN has been defined, which currently constrains over a wide area. The main goal of the present research is to deepen the hydrogeological knowledge of the study area and to provide useful information for the re-delimitation of a more effective ZVN. The study includes i) a comprehensive review and interpretation of chemical analysis from the ARPAS monitoring, ii) the collection of new samples from springs located in the nearby area (June 2020 and June 2023), and ii) a new monthly monitoring of flow rates and the sampling of the spring waters since June 2023 for the determination of nitrates, major ions, trace elements, and water isotopes.

Multi-temporal geochemical analyses from ARPAS show that chemistry of the F.na Nurighe spring is characterized by a bicarbonate alkaline-earth type during the winter/spring period and a chloride-bicarbonate alkaline-earth type during the summer-autumn period. Compared to nearby springs, which are also fed by marls and basalt formations, the compositional ratios of the F.na Nurighe waters (i.e., Mg/Ca vs. SO_4/Cl; Mo/U vs. SO_4/Cl) indicate significant mixing processes, and therefore possible lateral recharge from other hydrogeological units, especially during the dry season.

Flow rate measurements collected so far are representative of the baseflow recession curve (BRC), with yield decreasing from 5,4 to 2,9 l/s, and the initial part of the subsequent rising limb where yields have reach values of 18 l/s. Nitrates show a progressive increase from 71 to 120 mg/l during the BRC, followed by an abruptly collapse to 49 mg/l; this value remains almost constant during the recharge period and then rise sharply to over 100 mg/l in the late Aprile measurement. Such preliminary results have provided useful information about the possible alimentation sources of the spring. However, the lack of a clear correlation between flow rates and nitrates concentration requires further investigations and monitoring.

Review of laboratory-scale studies to assess factors affecting the fate of microorganisms in porous media

Keywords: laboratory tests, groundwater contamination, microorganisms transport.

Groundwater has traditionally been considered the water resource least susceptible to microbial contamination, because active biological and filtration processes in the subsurface reduce the load of microbial contaminants before they reach groundwater. This belief was once supported by the assumption that groundwater could not harbor microorganisms. In addition, knowledge of groundwater microbiology was poorly understood until the 1970s due to the lack of reliable methods for sampling groundwater environment. In recent decades, scientific evidence of groundwater contribution to waterborne diseases has been documented (Murphy et al., 2017). Indeed, microorganisms capable of causing waterborne diseases has been detected in groundwater. The detection of pathogens in groundwater is primarily due to the release of illicit or inadequately treated wastewater on soil or surface waters, the application of manure to enrich soils, or the reuse of wastewater for irrigation. Physical, chemical, and biological factors influence the presence of microorganisms in the soil and affect their transport and fate in the subsurface environment (Bitton & Harvey, 1992). Specifically, soil texture controls microbial survival by affecting water holding capacity, while the availability of organic matter creates favorable conditions for their survival (Obayomi et al., 2019). Structural heterogeneity, instead, can influence hydraulic properties such as water content and hydraulic conductivity. Chemical parameters such as ionic strength, ion valence, and pH play an important role in microbial retention; biological factors such as cell type, hydrophobicity, surface charge, and bacterial type contribute to mechanical and physicochemical processes (Bai et al., 2022). Since the interaction of these multiple factors and variables are very complex and poorly understood across spatiotemporal scale, recently scientific research is facing this topic by means of both field and laboratory studies, aimed at understanding how these factors may affect the microorganisms transport through a porous media. Specifically, this scientific contribution presents a systematic review of laboratory-scale studies published in the period from 2013 to 2022. This study was carried out in the framework of the SCA.Re.S. (Evaluation of Health Risk Related to the Discharge of Wastewater on the Soil) project, funded by the Regional Government of Apulia (DGR 1346, 04/08/2021) to evaluate the risk of groundwater contamination due to the discharge of wastewater treatment plant effluents into drainage trenches. The objective of this research is to contribute to a more realistic assessment of the risk of microbiological contamination of groundwater, as well as to increase current knowledge regarding environmental remediation.

Integrated assessment of climate impacts on ecosystem functions and productivity of critical-zone eco-hydrology: the Italian case study of the INTERACTION project

Caputo M.C.[1], De Carlo L.[1], Doveri M.[2-3], Giamberini M.S.[2], Giordano R.[1], Masciale R.[1], Menichini M.[2], Portoghese I.*[1], Turturro A.C.[1] & Passarella G.[1]

Corresponding author email: ivan.portoghese@cnr.it

Keywords: water-scarce critical zone, coastal aquifer salinization, wetland.

This presentation reports the main advances of the project titled "Integrated Assessment of Climate Impacts on Ecosystem Functions and Productivity of Critical-Zone Eco-Hydrology"- INTERACTION, funded by the Belmont Forum's Collaborative Research Action (CRA). The project, involves international research team from Italy, Qatar, and the USA. It offers a novel approach to managing the environmental risks, climate change, and anthropogenic impacts on Water-Scarce Critical zones (WSCZ) combining scientific research with stakeholder engagement. To tackle this challenge, INTERACTION adopts a multi-disciplinary approach involving heterogeneous expertise ranging from environmental and socio-economics analysis, numerical modeling, soil and groundwater hydrogeology, and climate change modeling and assessment. More in detail, INTERACTION deals with coastal aquifers in arid and semi-arid regions affected by high population density, extensive groundwater usage, climate change impacts, and rising sea levels which result in groundwater quantity and quality degradation, salinization of agricultural soils, disruptions of coastal wetlands, and consequently ecosystem degradation. The long-term effects of anthropogenic activities on these systems are not yet fully understood, hindering their management. Traditional approaches tend to study the components of such a system in isolation, overlooking their nonlinear relationships. INTERACTION adopts a holistic perspective considering relationships among physical, anthropogenic, and socio-economic factors to provide more effective solutions for integrated management in water-scarce coastal areas. The Italian case study is focused on the Torre Guaceto protected wetland in Apulia, South Italy. In this area, soil and groundwater salinization issues exist mainly induced by the intensive agricultural activities in the surrounds, critically encroach upon the evolution of coastal wetlands and water management measures. The area is characterized by a dry sub-humid climate, but trends towards more arid conditions have been identified. The location, morphology, and hydrogeology of the area, together with the observed changes in the rainfall regime and overexploitation of groundwater for irrigation, explain the critical level of groundwater salinity. The unwanted scenario is a relevant water scarcity risk that may affect agricultural activities as well as wetland conservation. INTERACTION, through integrated monitoring of the main natural elements of the site, stakeholder involvement, and suitable system dynamics modeling carries out an in depth analysis of current and alternative land use and water management strategies to cope with the changing dynamics of water demand and supply and prevent further deterioration of groundwater dependent ecosystems.

Column test to study the influence of lithological characteristics of rocks on the hygienic-sanitary quality of groundwater

De Giglio O.[1], Savino A.F.*[1], Bagordo F.[2], Grassi T.[3], Brigida S.[3], Triggiano F.[1], Apollonio F.[1], Colella D.[1], Turturro A.C.[4], De Carlo L.[4], Caputo M.C.[4] & Montagna M.T.[1]

Corresponding author email: antonellasavino8@yahoo.it

Keywords: laboratory test, microorganisms fate, saturated rock.

Groundwater is an important source of water supply to meet drinking and irrigation needs. They play a crucial role in regions, such as Apulia, where particular geological features, such as the extensive outcrops of fractured and karst rocks, determine surface water scarcity (Maggiore & Pagliarulo, 2004).

However, groundwater is also the most vulnerable resource to contamination from surface pollution sources, including wastewater treatment plants in case of malfunction or poorly managed increase in incoming load. In these situations, pathogenic microorganisms can be detected in inadequately treated effluent, which by reaching groundwater, pose a serious risk to human health (Montagna et al., 2020; De Giglio et al., 2022). In this regard, the Apulia Region has funded the SCA.Re.S. (Assessment of the hygienic-sanitary risk related to the discharge of wastewater on the ground) project (DGR 1346, 04/08/2021).

This study, part of the SCA.Re.S. Project, aimed to investigate the migration behavior of microorganisms in a saturated rock column to figure out the impact of the different rock lithotypes on the contamination, due to the infiltration of treated wastewater through the subsoil. In the last decades, many studies have been conducted to investigate transport processes of microorganisms through porous media (Madumathi et al., 2017). In the present research, laboratory-scale tests were carried out to investigate the interaction of pathogenic microorganisms with different carbonate rocks, by monitoring over the time the microbial load. Specifically, the experimental column test was set up using a saturated porous rock sample (ø=10 cm, h=50cm). A suspension (500mL) of *E.coli* of known titer (2.4x106ufc/mL), followed by a sterile saline solutions, were poured at the top of the core sample. The percolated water, collected every half hour for 3 consecutive days was subjected to quantitative analysis of the microorganisms. The experiment was repeated three times under the same laboratory conditions (T=23°C). Overall, a suspension containing 3x109 *E.coli* cells was poured onto the porous rock sample. On average, 8x106 cells were eluted at the end of the experiments with a decrease of 97.2%. The study increased the knowledge on the interaction occurring between the type of microorganism and the physical and hydraulic parameters of the rock, in order to minimize the impacts of microbiological contamination in groundwater and consequent risk to human health.

High-altitude minor springs in Central Italy tapped for drinking supply: hydrogeological characterization and aquifer potentialities evaluation

Di Giovanni A.*[1], Di Curzio D.[2] & Rusi S.[1]

[1] Dipartimento di Ingegneria e Geologia, Università "G. d'Annunzio" Chieti-Pescara.
[2] Department of Water Management, Delft University of Technology.

Corresponding author email: alessia.digiovanni@unich.it

Keywords: spring, groundwater.

In central Apennines' high altitude villages the water used drinking purpose is guaranteed by springs with seasonal and limited discharge.

The small villages located in the south-eastern portion of the Abruzzo region's mountain area and the north-western part of Molise region, also known as Alto Sangro area, have reached self-sufficiency because of the presence of many springs located at altitude higher than 1100 m and tapped for drinking purpose; some lack in water availability during summer season were point out, this is due to the impossibility of tap into lower elevations' springs which are used for the more urbanized coastal areas supply.

Despite the strategical position of these springs, the managing companies have preferred different exploitation and distribution policies; currently, water supply from springs or well fields with major potentials is chosen, even if it require more effort for water distribution.

In this work, these high altitude aquifers were deepened, defining their characteristics, potentialities and residual capabilities. The geological and tectonical framework is peculiar because the relationships between litholigies are mainly due to faults and low angle thrusts. Consequently, the hydrogeological set-up reflects the geological one, the low angle thrusts put in contact terrigenous lithologies with different permeability (i.e. Gamberale-Pizzoferrato formation), within the so-called Molise units, with the carbonatic succession of the central Apennines and the Sicilidi calcareous-clayey formation (Festa et al., 2014).

In this complex hydro-geological framework, groundwater is allowed to emerge as spring: usually, the calcarenites within Molise units, or the Apennines limestone formations work as aquifer, while the clayey complex of the *Sicilidi* or clay within Molise units, as aquiclude. In some cases, even coarse slope deposits work as aquifer, they were found over the impermeable complex, originated from carbonate deposits located at higher altitude. Analyzing the hydrogeological set-up, these springs were mainly classified as "for permeability limit" (Civita, 1973).

These high-altitude springs have an average discharge between 1 l/s and 2 l/s, and the preliminary results about groundwater potentialities were obtained through infiltration coefficient: the found recharge volumes were about 100 Mm3, over a 615 Km2-wide area.

Corresponding author email: linda.franceschi@igg.cnr.it

Keywords: extreme events, small island, groundwater recharge.

In the recent decades, the frequency and intensity of rainfall extreme events are increasing due to climate changes (Fowler & Ali, 2022). Increased temperature and extreme precipitation can have a significant impact on groundwater recharge, modifying the relationship between superficial and groundwater and causing a deterioration of the resource, in terms of both quantity and quality. Several studies show that groundwater recharge is decreasing in many areas around the globe. However, a few researchers highlighted an increase in recharge under certain conditions (Pulido–Velazquez et al., 2015 and references therein). Insular aquifer systems are the ones that mainly suffer the effects of climate changes in terms of atmospheric temperature and precipitation regime, and the Mediterranean region has been identified as one of the climate systems most responsive hotspots in relation to the increasing of greenhouse effect, particularly due to marked warming and large decrease in precipitation (Diffenbaugh et al., 2007).

In this frame, Pianosa Island represents a strategic site to study the effects of climate changes on aquifer systems along a significant period and a good proxy for the whole Mediterranean area. The importance of Pianosa is due to the very low anthropic pressure, a consequence of the closure of penal colony in 1996 and controlled tourist access in spring and summer. Pianosa is characterized by medium-low annual rainfall (about 550 mm/year on average). The mean annual atmospheric temperature is about 17°C and windy conditions are present during most part of the year. Despite its relatively dry climate, its small extension, and a flat morphology (max altitude of 28 m a.s.l.), significant freshwater resources are stored in a shallow unconfined aquifer and in some deeper aquifer layers in confined/semi-confined conditions (Doveri et al., 2012). The study of the aquifer system and processes in the unsaturated zone is of paramount importance to better understand the recharge mechanisms as well as the evolution of water availability, thus supporting a correct management of groundwater resource. The study was carried out through (1) analysis of continuous monitoring data of rainfall, temperature, piezometric level, infiltration water, and soil humidity, (2) analysis of chemical composition, and (3) isotopic signature of water. The study focused on the analysis of the hydrogeological processes occurred during extreme rainfall events on the island. The most significant one occurred since 2014 is that of 25 November 2022, with a cumulative rainfall of about 276 mm in a few hours. During this event, groundwater recharge was efficient, since the piezometric level increased and maintained values higher than that recorded before the event. The timing of water quantity transit through soil and unsaturated zone of the aquifer, as well as the evolution of electrical conductivity, chemical and isotopic signals in water, suggested the rapid response mechanisms of the system to extreme rainfall.

Corresponding author email: ilaria.fuoco@cnr.it

Keywords: membrane processes, heavy metals, groundwaters.

The main challenge of the present day is to provide consumers with safe water for daily use. The increase in industrial activities represents a real problem regarding water resource protection. However, in some specific sites, natural pollution plays a predominant role in water contamination. When pollution is associated with anthropic activities, the possibility of site restoration can be possible assuming that a critical condition has not already been reached. Instead, when pollution has a natural origin, the high concentration of pollutants represents a natural background level, and the issue cannot be solved at its root. For instance, groundwater contamination due to the natural rock-to-water release of heavy metals such as Chromium or Arsenic represents a primitive environmental issue that cannot be solved because the natural process cannot be stopped. However, using valid techniques to produce safe water could represent a solution in naturally polluted sites, providing safe water to people who live in the surrounding areas. In the frame of PNRR project (CUP B83C22003980006), a multidisciplinary study was proposed. The main topic of this specific action (Spoke 2, PP2, Action 7) is the geochemical investigation and mapping of potential pollutants in Calabro-Lucanian aquifers coupled with membrane treatment processes. Based on strong-based geochemical information, representative polluted waters were selected for laboratory tests. Subsequently, the most suitable site will be identified to install a prototype membrane-based and energy self-sufficient to purify the contaminated water, providing a safe product for drinking and/or agricultural purposes. Among available membrane techniques, nanofiltration (NF) was chosen as the most valid technique to achieve the project's objective (Figoli et al., 2019; Fuoco et al., 2020).

The project can have a positive scientific and applicative impact. It can be realized in other polluted sites, allowing the reuse of waters that cannot be used for drinking or agricultural purposes in their natural state.

The authors thank the project "Tech4You—Technologies for climate change adaptation and quality of life improvement"—National Recovery and Resilience Plan (NRRP), Mission 4, Component 2, Investment 1.5, funded from the European Union–NextGenerationEU, Identity code: ECS 00000009, CUP B83C22003980006.

Keywords: bioodiversity, cave biology, springs.

Organisms inhabiting caves are usually described as lacking biological cycles, since they exploit environments with largely constant conditions. However, recent evidence is emerging on the rhythmicity of cave-dwelling animals, with experimental, observational and genetic analyses. There are still many uncertainties, as some organisms may have regular or irregular rhythms, and some others seem to lack them. In this study, we analysed the activity of two groundwater-dwelling species: the European cave salamander (*Proteus anguinus*) and the crustacean isopod *Monolistra pavani*. Both species are usually thought to be arhythmic and exclusively found in caves; however, for the cave salamanders, recent studies have described the non-random activity in surface freshwater springs. We used GLMMs and N-mixture models to test the relationship between abundance and detection probability of cave species and both external cycles (circadian, lunar, and seasonal) and flooding events (upstream cumulated rain), analysing in two different models the surface and underground sites. We found that cave salamanders are generally more abundant during the night. Their detection probability in springs was higher during the night, with higher moon illumination (i.e., full moon) and after upstream rains; in caves, detection probability was higher during winter. For isopods, the detection probability was higher in early summer and in the evening. Our results suggest that depigmented cave-dwelling organisms are vulnerable to sunlight and tend to avoid it, exploiting the spring environment during the night, when ecological conditions are more similar to caves. Higher activity in springs may as well be related to food availability, as floods may foster it. Future studies to clarify these patterns are needed, and a molecular approach may be necessary to finally disentangle the role of adaptations and plasticity. These results are in accordance with previous studies on cave-dwelling invertebrates. In conclusion, cave animals may exhibit a rhythmic behaviour both in springs and in caves.

Evaluation of nitrate leaching processes during infiltration and transport in the unsaturated zone

Lobina F.*[1], Da Pelo S.[1], Biddau R.[1], Coppola A.[1], Vacca A.[1], Hassan M.B.S.[2], Arras C.[1] & Porru C.[1]

Keywords: nitrate, unsaturated zone, monitoring.

The increase in intensive agriculture and animal husbandry has led to the large-scale application of organic and chemical fertilizers to the soil. This use has led to the release of various chemical pollutants into the soil, which then enter the water table through the leaching of rainwater and irrigation water. Despite the implementation of strict regulations laid down in the Nitrates Directive, groundwater quality has not significantly improved in many Nitrates Vulnerable Zones.

Studies on vulnerability to aquifer contamination often focus more on the groundwater body negleting the unsaturated zone. The vadose zone is a fundamental part of the hydrological cycle, capable of storing water, providing water for vegetation, transporting solutes, and breaking down pollutants before they reach the aquifer.

The study area is the Arborea plain (Sardinia), designated as an NVZ since 2005 due to heavy nitrate contamination in its aquifer. Consequently, the research aimed to monitor nitrate leaching during infiltration and transport through the unsaturated zone and evaluate any processes of natural attenuation.

In the plain, an agricultural field was selected as a pilot site where an unsaturated zone monitoring system was set up to obtain information on the processes taking place through the soil profile to the saturated zone. TDR probes were installed to measure volumetric water content, while suction cups were placed at different depths to sample pore water for the analysis of ionic nitrogen species and nitrate isotopes. The experimental approach was coupled with the use of a physically based flow and transport model in the unsaturated zone FLOWS (Coppola et al., 2014, 2019; Hassan et al., 2023) for the simulation of the flow and transport of nitrate in the pilot site.

Monitoring the unsaturated zone combined with models are a useful factor in assessing the vulnerability of the aquifer and contribute to a better understanding of the processes occurring in the transported solute, thereby optimizing agricultural practices and measures to protect groundwater resources.

Keywords: seawater intrusion, alluvial aquifer, coastal aquifer sustainability.

Magra River flows for 70 km between Tuscany and Liguria regions and is one of the main estuarine rivers in Italy. It drains a watershed of 1700 km2 and its terminal path is characterized by the confluence with Vara River. After the confluence, the Magra River feeds one of the most important aquifers, currently exploited for drinking water purposes. The aquifer is set on an asymmetric Graben, with a N-S development, marked by La Spezia normal fault, which represents the west boundary. The Val Magra aquifer is composed of recent fluvial sediments, such as coarse-medium sand, and gravels and Pleistocene non-consolidate conglomerates deposited as alluvial fans by secondary tributary. The absence of a continuous surface clay layer makes it an unconfined aquifer. The vulnerability of the aquifer has been partially tested by Critelli et al. (2023). The groundwater over-exploitation and the proximity to the seacoast make it vulnerable to climate change (Costall et al., 2020). In particular, the most dangerous effect linked to climate change is the seawater intrusion phenomenon, which could compromise the quality and quantity of groundwater, damaging agriculture and gradually desertifying the territory. This phenomenon may be accelerated by poor water management. Innovative studies are therefore needed to better understand the vulnerabilities related to the aquifer. A good reconstruction of the alluvial and coastal aquifers and a 3D hydrogeological model is necessary. In this study, a new hydrogeological model of the lower Val Magra aquifer is developed. The model realized in MODFLOW was calibrated using PEST against hydraulic head records. It is based on geological sections which are elaborated thanks to borehole stratigraphy and seismic surveys. Marine intrusion's spatial and temporal evolution has been strongly monitored from 2022 to 2023 through water electrical conductivity measurements and water sampling campaigns, for successive water isotope analysis (Sabattini et al., 2024) to evaluate groundwater mixing following the approach reported in Ronchetti et al. (2023). The results obtained in this study will enable us to: a) identify the most vulnerable groundwater exploitation sites; b) formulate detailed rules about seawater wedge intrusion and understand its effects on the coastal aquifer; c) predict the evolution of aquifer water flow related to climate change consequences. All these observations will help stakeholders to implement a future water management plan.

Keywords: innovation, soil decontamination, bio-based solution.

Teseco Bonifiche, Department of Biology (UNIPI), CNR-IRET and CEBAS-CSIC (ES) have developed a technology for the remediation of contaminated soils and aquifers, which is based on an original chemical-physical-biological and on the use of a system specifically designed for its on-site application. The process, for which a patent has been filed, is registered under the name Soil-Omic ®. Soil-Omic ® is a protocol that uses omics sciences and advanced environmental engineering tools and exploits, amplifying it exponentially, the ability of the indigenous soil microbiota to degrade and remove recalcitrant and persistent contaminants.

The technology was designed for the in situ decontamination of soil and groundwater, which are used as a medium for an original biological and chemical flushing concept named BIOflushing ®. The technology is site-specific, meaning its development and effectiveness are connected with in-depth knowledge of the characteristics of soil and groundwater of the site.

The conceptual model of the site is built starting from the acquisition of a variety of data, obtained from chemical, physical and mineralogical analyses, which involve all the natural components and contamination factors, and through the examination of the microbiota, its evolution during treatment, and its metabolites.

Soil-Omic ® consists of the integration of consolidated physico-chemical approaches with metagenomics and culturomics, to evaluate and govern the process of abatement of organic and inorganic pollution in environmental matrices.

The protocol also analyses and models the forms in which the organic contaminant is adsorbed to the matrix, thus determining the best conditions to make it bioavailable even when it has been subject to aging processes.

At the same time, through original sequential extraction protocols developed directly on site-specific matrices, the technology allows the development of chemical solutions suitable for the desorption, transformation and solubilization of inorganic contaminants.

The Soil-Omic® process and the BIOflushing® system were designed and validated during full-scale pilot tests for the abatement of recalcitrant organic environmental contaminants deriving from anthropic activities, such as Hydrocarbons (TPH) (Di Gregorio et al., 2016; Becarelli et al., 2019), polycyclic aromatic hydrocarbons (PAH), polychlorinated biphenyls (PCBs) (Siracusa et al., 2017), volatile chlorinated compounds and BTEX -benzene, toluene, ethylbenzene and xylene, organochlorine compounds, and for the removal of metals and metalloids, such as Pb, Cd, Zn, Ni, As, Cu, Cr. The technology was designed to operate on both the unsaturated and saturated zone of the soil.

The technology was developed and tested following the awarding of the pre-commercial contract POSIDON PCP, financed by the European Horizon 2020 Program (Grant agreement No. 776838).

Keywords: unsaturated zone, evapotranspiration, effective infiltration.

Climate change significantly influences water resources and the hydrological cycle (Held & Soden, 2006). To comprehensively evaluate the potential effects of climate change on groundwater resources, it is crucial to understand and quantify changes in groundwater recharge (Doveri et al., 2016). Groundwater recharge, the process through which groundwater is replenished by the effective infiltration and seepage of surface water, plays a fundamental role in maintaining water supplies. However, accurately estimating recharge rates requires access to high-quality and spatially distributed data. For this reason, it is important to identify tools and methods to explore the complex interactions between atmosphere, soil's unsaturated zone, and groundwater. This is essential for sustainable water management and for developing effective adaptation strategies in response to the challenges posed by climate and global change.

The recharge of aquifers is influenced not only by climatic conditions and by the characteristics of the aquifer itself, but also by the properties of the overlying layers. Various methods, including the analysis of land cover, surface water data, and the characteristics of the unsaturated zone, can be employed to estimate both current and future recharge rates (e.g., Brussolo et al., 2022).

In this study, the focus is specifically on two surface-subsurface processes concurring in groundwater recharge: evapotranspiration (ET) and effective infiltration (EI). Experiences on the small Mediterranean island of Pianosa (Tuscan Archipelago) are described. The island hosts the Pianosa Research Base (www.brp.cnr.it), managed by the Istituto di Geoscienze e Georisorse (IGG) of the National Research Council of Italy (CNR). The island is equipped with an extensive hydrological and hydrogeological monitoring network. Among other features, this network includes the measurement and characterization of total and effective infiltration water and precipitation. To obtain these measurements, the network uses specialized equipment such as a rain-gauge sampler and a high-precision lysimeter equipped with probes for soil moisture, soil tension, and soil temperature at various depths. Additionally, portable and automatic customized non-steady-state dynamic flux chambers, paired with Infrared Gas Analyzers (IRGAs), were employed to measure ET (Raz-Yaseef et al., 2017).

Preliminary results are presented, comparing various approaches, including both theoretical methods and experimental techniques. The data as a whole indicate that the ET process predominates in contrast to EI, which occurs only for a short period during the winter-spring months. This suggests a strong seasonal pattern in the occurrence and intensity of EI.

ERT characterization of treated water pathways from large infiltration trenches in unsaturated fractured/karstified calcarenite

Peruzzo L.*[1], De Carlo L.[2], Caputo M.C.[2] & Cassiani G.[1]

[1] Dipartimento di Geoscienze, Università di Padova. [2] Istituto di Ricerca sulle Acque, CNR, Bari.

Corresponding author email: luca.peruzzo.1@unipd.it

Keywords: infiltration trenches, preferential pathways, geophysical methods.

In Italy, during the last decades, infiltration trenches have been increasingly used to spread and buffer effluent in the subsurface, because of its natural filtering capability against organics, chemicals and contaminants.

This unconventional water source can provide an unintentional recharge of water to aquifers but, according to the Italian regulation, a monitoring of the chemical and physical parameters of the mixed water is crucial to avoid potential contamination sources.

In this context, geophysical methods are a powerful tool to identify preferential pathways in the unsaturated subsurface.

Such methods are non-invasive and cost effective, they have high applicability in challenging environments, being capable to cover wide areas with a high level of resolution.

Despite imaged targets cannot be directly observed, the water flow can be tracked over space because of the significant contrast in resistivity between the conductive plume and the surrounding rock.

In the framework of the DY.MI.CR.ON Project, financed by European Union - Next Generation EU, an Electrical Resistivity Tomography (ERT) survey has been performed in an area near the wastewater treatment plant of Carpignano Salentino, where domestic effluent is spread in infiltration trenches dug into the calcarenite rock.

Clear evidences of the presence of preferential paths outside the trench are observed: despite a high daily flow rate, a negligible amount of water accumulates in the trench after several months.

Several ERT profiles were carried out to track infiltration patterns and support the network of wells to be monitored.

EMI and ERT characterization of plant-scale irrigation and ET: an orange orchard-case study and methodological challenges

Peruzzo L.*[1], Werban U.[2], Pohle M.[2], Cassiani G.[1], Consoli S.[3] & Vanella D.[3]

[1] Dipartimento di Geoscienze, Università di Padova. [2] Department of Monitoring and Exploration Technologies, Helmholtz Centre for Environmental Research - UFZ Leipzig, Germany.

Keywords: agriculture, irrigation, geophysics.

EMI allows time-lapse profiling of electrical conductivity (EC). In recent years, progress was made in the study of the intra-field variability and soil-plant correlations at the scale of a few meters. On the contrary, some methodological challenges still hinder the possibility to resolve the spatiotemporal complexity at smaller scales. These smaller scales are typically associated with irrigation and evapotranspiration (ET) dynamics and thus central to the agroecosystems and precision agriculture, particularly in orchard farming. This EMI study characterizes the 3D EC variability in an orange orchard in eastern Sicily (Italy).

To the best of our knowledge, this is the first 3D investigation capturing both irrigation and ET effects at the meter scale. The characterization successfully distinguishes plant rows, interrows, and quaterrows. The conductivity in the plant rows increases upwards, from the drier root-water-uptake region to the drip irrigation region above. In the interrows, the conductivity increases downwards from the drier evaporation-dominated layer to the deeper soil where the irrigation water accumulates without significant ET. The quaterrows show yet another conductivity profile, being surprisingly homogeneous and relatively conductive. Local effects, such as the plant size, further complicate this conceptual model and add both inter- and intra-row heterogeneity. While the characterization results confirmed the EMI potential, the following methodological challenges were equally important. First, a Geophex GEM-2 and a CMD Mini-Explorer were used, the latter in vertical and horizontal configuration. The choice of instruments and surveys appears now suitable for this field site but it is surely not obvious a priori and/or always possible. It is highlighted how the use of a single instrument would surely lead to misinterpret the root water uptake or the evaporation contributions. Second, the quantitative use of the two instruments required alignment and joint inversion. However, the standard GPS systems did not provide a reliable alignment of the surveys. Time-consuming GIS corrections were needed for both intra- and inter-dataset shifts.

Third, after the GPS alignment the surveys were interpolated over a common grid to allow the joint inversion. Because of the strong anisotropy of the agroecosystems, this required the careful parametrization of a Kriging algorithm.

Fourth, the individual EMI datasets also differed because of their drift and calibration. The lack of convenient alternatives initially motivated an ERT-based calibration, but ultimately two of the twelve datasets were discharged. Fifth, noise and errors required the use of a moving median. This common practice poses a trade-off between smoothing and resolution that hinders high-resolution surveys. Sixth, a sub area of the orchard was investigated in much higher detail. This proved fundamental for the identification of the quaterrows and other meter-scale details. Again, the implications of a particular survey design are hard to predict, also considering the successive effect of smoothing and grid interpolation. Overall, this study presents a state-of-the-art EMI application that focuses on small-scale aspects that were less considered in previous studies. The presented challenges explain the lack of similar studies and should be considered when discussing the EMI convenience and adoption.

Assessing surface water-groundwater exchange dynamics for managed aquifer recharge design: a case study in Muravera, Southeastern Sardinia, Italy

Piscedda F.A.*[1], Wanty R.[2], Arras C.[1], Porru M.C.[1], Biddau R.[1], Musu F.[1], Podda F.[1] & Da Pelo S.[1]

[1] Dipartimento di Scienze Chimiche e Geologiche, Università di Cagliari.
[2] Colorado School of Mines, Department of Geology and Geological Engineering, Golden, US.

Corresponding author email: fabrizioa.piscedda@unica.it

Keywords: managed aquifer recharge, manage groundwater resources, hyporheic zone.

Climate change requires early planning of mitigation and adaptation strategies to effectively manage groundwater resources. The implementation of managed aquifer recharge systems can help mitigate the effects of climate change and alleviate the need for withdrawals, particularly under conditions of imbalanced natural recharge. In the coastal plain of Muravera (southeastern Sardinia, Italy), already affected by significant salinization phenomena, understanding the dynamics between surface water and groundwater is central for managing hydrodynamic balance and assessing potential managed aquifer recharge projects (Porru et al., 2024). As part of the Project eINS Ecosystem of Innovation for Next Generation Sardinia (Code ECS0000038 - CUP F53C22000430001), we investigated the exchange dynamics between surface water (SW) and groundwater (GW) within the hyporheic zone of the Muravera coastal aquifer. Mini piezometers of two lengths (100 cm and 200 cm) as those described by (Wanty & Winter, 2000) were deployed along transects moving from upstream towards the sea, and an additional transect with five mini-piezometers was installed orthogonal to the SW flow direction at the groundwater discharge zone. Parameters including temperature, specific electrical conductivity (C.E.S.), redox potential (Eh), and pH were measured, with water samples collected for chemical analysis. To evaluate potential leakage into the aquifer from a channel receiving treated wastewater from the Muravera wastewater treatment plant, a sodium chloride (NaCl) tracer test was conducted. Additionally, groundwater samples from nearby wells were analyzed for the presence of gadolinium, a contrast agent typically found in domestic wastewater discharges, as it is not removed during the treatment process in wastewater treatment plants (Cidu et al., 2013). Our findings revealed areas where groundwater flows into and out of the Flumendosa River within the hyporheic zone, with water quality exhibiting layering even on a small scale. This study significantly advances our understanding of surface water and groundwater interactions in the lower part of the Flumendosa River basin, particularly exchange processes in the lower valley. By exploring the hyporheic zone, where dynamic exchanges occur between surface water and groundwater, we identified chemical and physical properties, pressure heads, and gradients that distinguish discharge direction between SW and GW.

Methodological approach to simulate the evolution seawater intrusion with climate change

Porru M.C.*[1], Davids T.[2], Arras C.[1], Oude Essink G.H.P.[3], Piscedda F.A.[1] & Da Pelo S.[1]

[1] Dipartimento di Scienze Chimiche e Geologiche, Università di Cagliari. [2] Groundwater management department, Deltares, Utrecht, The Netherlands. [3] Utrecht University, Physical Geography, The Netherlands.

Keywords: climate change, numerical modelling, seawater intrusion.

Seawater intrusion is a major environmental problem in coastal areas around the world, significantly contributing to the depletion of water resources. Even a small amount, less than 1% of seawater intrusion in an aquifer, can render freshwater unfit for drinking. Furthermore, locally, water quality impairment can also lead to soil degradation, limiting its use or causing land abandonment.

In the framework of the Return project (founded by the Next-GenerationEU, NRRP), this paper presents a new methodology for simulating seawater intrusion, accounting for the decrease in natural recharge caused by climate change.

To simulate the coupled effects of groundwater density and solute transport, this study utilizes iMOD-WQ software developed by Deltares. This software incorporates SEAWAT, a well-established tool for modeling density-dependent interactions between freshwater and saltwater in aquifers. iMOD itself is a modified version of the source code specifically designed for parallel processing. This approach significantly accelerates computations by up to two orders of magnitude, depending on the available computer resources. This efficiency is crucial, especially when simulating long time periods essential for studying climate change impacts. While iMOD offers a graphical user interface, Python scripting was chosen for this study due to its superior data manipulation capabilities.

A Soil Water Balance code was used to quantify the impact of climate change on natural recharge. This code, implemented by the USGS, allows the variation of recharge to be simulated in both time and space. In addition to climate data, the code is based on soil characteristics. Four inputs are needed: land use, available water capacity, hydrological soil group and Flow direction.

The area under study where this approach was applied is the coastal plain of Muravera (Sardinia, Italy), where the problem of seawater intrusion has been causing not only environmental but also socio-economic problems for more than 50 years. Thanks to a large dataset base, all the necessary inputs to the codes used are derived from measurements obtained on the field over the years.

This approach can make an important contribution in water resource management by enabling the development of effective strategies to mitigate salt intrusion under anticipated climate change impacts. Its applicability to similar areas makes it a valuable tool for broader water resource protection.

Acknowledgements: This study was carried out within the RETURN Extended Partnership and received funding from the European Union Next-GenerationEU (National Recovery and Resilience Plan – NRRP, Mission 4, Component 2, Investment 1.3 – D.D. 1243 2/8/2022, PE0000005).

Monitoring saltwater intrusion in the area surrounding the Grado lagoon (NE Italy)

Surian B.*, Forte E. & Zini L.

Dipartimento di Matematica, Informatica e Geoscienze, Università di Trieste.

Corresponding author email: benedetta.surian@PHD.UNITS.it

Keywords: saltwater intrusion, electromagnetic induction (EMI) techniques, climate change.

Coastal aquifers are heavily influenced by seawater intrusion, a phenomenon exacerbated by current climate change, which is affecting the availability of freshwater for drinking and irrigation purposes. This occurrence also leads to a progressive salinization of agricultural lands, adversely affecting crop yields.

Despite the importance of groundwater salinization management for coastal agriculture in the Friuli Venezia Giulia region (NE Italy), there is currently a lack of detailed study on the topic. To partly fill this gap, a first field campaign was carried out in the inland areas surrounding the Grado lagoon, as part of an ongoing PhD project focusing on the regional issue.

The Grado lagoon is a low energy environment characterized by higher salinity compared to the Adriatic Sea and the nearby Marano lagoon, due to shallower depth and limited presence of freshwater tributaries. In the inland regions of the Grado lagoon, which are mainly situated below sea level and predominantly utilized for agriculture, ensuring environmental sustainability rely heavily upon effective water resource management. In order to tackle this challenge and manage the water resource effectively, it is crucial to establish a comprehensive hydrogeological model of the area.

Non-invasive geophysical investigation techniques have commonly been employed for this purpose in similar contexts. In this study, Electromagnetic induction (EMI) technique has been utilized for studying saline intrusion in the subsurface, thanks to its ability to explore large areas in relatively short times, detecting depth and lateral variations in electrical conductivity which can be associated with soil salinity changes. During this campaign, more than 30 km electrical conductivity profiles were collected along the lagoon margin, highlighting electrical conductivity variations, directly linked to the presence of saltwater in the aquifers closer to the saltwater body.

The data obtained from EMI surveys were validated through Electrical Resistivity Tomography profiles performed in selected location and through direct sampling of groundwater, conducted via manual boreholes drilled to varying depths relatively to the groundwater level. The material retrieved from the drillings also enabled us to obtain short stratigraphic logs, which have contributed to a better understanding of the salinity distribution in the coastal aquifers.

The combined approach has demonstrated its worth by providing crucial insights into the extent of salinization in the coastal phreatic aquifers. A thorough understanding of seawater intrusion is essential for future strategic planning of water resource management and agricultural development in the study area.

Renewable energy application: sustainability techniques in Torino Urban City

Taddia G.*, Gizzi M., Berta A. & Lo Russo S.

Corresponding author email: glenda.taddia@polito.it

Keywords: groundwater heat pumps (GWHPs), urban sustainability, aquifer protection.

Italy is one of the top 10 countries for geothermal electricity generation and among the first 15 for heating and cooling applications. In 2021, there were 226 active installations in Italy for the exploitation of direct geothermal energy for the sole heat production purposes. These are, in most cases, individual heating and thermal plants.

For about 2 years, Torino has been among the 100 European cities and the 9 Italian cities that have the objective of achieving an 80% reduction in CO_2 emissions by 2030 compared to 2019 values. The journey started long ago when the European Union's Mission Smart and Climate-Neutral Cities was launched, with the aim of accelerating the transition towards climate neutrality in 100 selected European cities as a reference by 2030 (anticipating 2050 foreseen by the Green Deal) and opening a call aimed at all European cities. Torino was thus one of the selected Italian cities. The priority objective of Torino and the other selected cities was the preparation of the so-called Climate City Contracts (CCC) (Comunicato Stampa Comune di Torino, 2024), i.e. contracts which, although having no legal value, will serve to formalize a clear, transparent and well-defined political commitment towards the Commission and national/regional authorities, including citizens, research organizations and the private sector.

In this context, Groundwater Heat Pumps (GWHPs) are an efficient solution for reducing carbon emissions in heating and cooling systems in urban areas with favourable geological conditions (Taddia et al., 2019). These systems draw water from shallow aquifers, undergo heat exchange processes, and return water at a modified temperature. It is important to preserve the groundwater quality of aquifers, which serve as renewable energy sources, for urban sustainability. In order to promote the adoption of GWHP, urban planning should be carried out while ensuring the long-term protection of groundwater. Torino Urban City has an alluvial shallow aquifer that is a valuable source of low-enthalpy geothermal energy (Berta et al., 2024). However, it is essential to conduct a comprehensive site assessment to evaluate the environmental impacts, taking into account well characteristics, locations, pumping rates, and thermal effects on local groundwater resources. The thermal plumes, which are shaped by water extraction and reinjection rates, have an impact only on downstream neighbouring plants. Accurate hydrogeological characterization is crucial for constructing new facilities, as positive aquifer responses to long-term disturbances demonstrate. The proposed urban-scale model is a valuable tool for experts and authorities, enabling the assessment of thermal disruptions at both localized and urban levels. Using this tool ensures the sustainable use of aquifer resources in complex systems, promoting informed decision-making for urban heating and cooling strategies.

Keywords: hydrogeological modeling, groundwater recharge, seawater intrusion

Groundwater, a vital resource for meeting domestic and agricultural water demands, faces imminent threats in coastal aquifers from seawater intrusion and declining recharge rates. This study focuses on the Metaponto coastal aquifer in south Italy, where rising seawater levels and increased evapotranspiration contribute to both seawater intrusion and reduced groundwater recharge. Addressing the interconnected impacts of these phenomena requires a variable-density hydrogeological model to comprehend the current and future status of groundwater resources. One significant challenge in modelling the water balance and groundwater together is the bidirectional interaction between surface water budget and groundwater models. While conditions from the surface water budget model inform the groundwater model, feedback from the groundwater model to the surface water model is often overlooked. To address this challenge, this study combines the modelling of the surface water budget and groundwater, with the results of the water budgeting implemented as boundary conditions for the groundwater model at each time step. The novelty of this research is the consideration of agricultural irrigation contributing to groundwater recharge along with other factors. The regional model for the Metaponto coastal aquifer was developed using the MODFLOW code for steady-state groundwater flow and the SEAWAT code for salt transport. The objective of this study was to evaluate the impact of climate change on salt concentrations in the Metaponto coastal region over an 80-year period, encompassing all aspects of the hydrologic cycle. The methodology involved in this research integrates a regional-scale three-dimensional groundwater model with variables such as sea level rise, changes in agricultural practices, shifts in groundwater demand, increasing sea salinity levels, and reduced river flow and upstream flux. The results of this study demonstrated a comprehensive hydraulic head and salinity distribution in three dimensions by combining diverse influences of climate change and human activities. This study offers valuable insights into potential future scenarios, proving beneficial for both scientific research and practical water resource management in the Metaponto region.

Use of GPR imaging for early detection of water leaks in pipelines

Torres D.[1-2], Zambrano M.*[1] & Baena J.G.[2]

Keywords: water leakage simulations, ground penetrating radar (GPR), early detection.

Italy faces significant challenges related to excessive water consumption, a substantial portion of which is attributed to leakages in distribution networks. These leakages have serious repercussions on water supply and social, infrastructural, and environmental dimensions. Traditional leak detection methods, such as pressure/flow monitoring and acoustic detection, often only identify advanced leakages and are hindered by their low resolution, particularly in urban settings (Tavera, 2008; Ahmed Negm et al., 2023). This study explores the efficacy of Ground Penetrating Radar (GPR), a non-destructive geophysical method, for the early detection of water leaks in underground distribution networks. The accuracy of GPR was evaluated using laboratory (real data collected in controlled environments) and simulation (synthetic profiles generated from a Finite-Difference Time-Domain, FDTD, electromagnetic wave model) experiments as analogues for water leaks in pipelines. Previous studies suggest that GPR can accurately locate leakages and provide detailed information about their extent and severity, surpassing conventional methods (Tavera, 2008; Lai et al., 2015; Liu et al., 2022).

Moreover, these findings highlight the need for more empirical evidence and case studies to corroborate the effectiveness of GPR under various conditions (Gamal et al., 2023). The outcomes of this research underscore the potential of GPR to significantly enhance early leak detection, suggesting a promising direction for more efficient water management and conservation in both urban and rural areas. At the same time, it seeks to delineate the challenges and limitations of the method in environments affected by water infiltration, which may serve as a reference for future research.

Keywords: Managed Aquifer Recharge (MAR), geophysical techniques, hydraulic characterization.

In coastal areas, saltwater intrusion due to overexploitation of the groundwater and sea level rise induced by climate change effects, causes a reduction of drinking and irrigation freshwater supplies. Mitigation and adaptation strategies are strongly encouraged in order to preserve water quality and quantity. Among these, Managed Aquifer Recharge (MAR) is an increasingly used water management strategy to protect and enhance stressed groundwater resources. Severe EU regulations control the implementation of MAR plants in order to avoid negative impact on the resource by ensuring the protection of the groundwater. Conversely, technical aspects concerning the planning of a MAR scheme, require the integration of several experimental approaches at different scales.

At this regard, an accurate definition of the geo-hydrogeologic model of the area of interest and, at the same time, the description of hydraulic parameters is crucial for modeling water flow and transport processes in the critical zone of the study area.

An integrated approach that combines traditional hydrogeological measurements and innovative unconventional techniques, has been applied in the Pwales Valley of Malta Island, where a MAR scheme is being planned.

A field-scale geophysical survey based on Electromagnetic Induction (EMI) technique allowed to define the geological setting and the spatial extension of the saltwater intrusion (De Carlo et al., 2024). At the same time, infiltration test performed on the outcropped filtering medium, provided information on the main hydraulic properties (the field saturated hydraulic conductivity, Kfs, and the average infiltration rate).

In addition, laboratory tests, performed on rock samples constituting the studied aquifer, provided water retention and hydraulic conductivity functions crucial to develop a local groundwater-flow numerical model to predict different environmental scenarios and visualize potential effects of the MAR scheme in the Pwales Coastal Aquifer (Caputo et al., 2024).

Keywords: porous aquifer, microbial transport, groundwater contamination.

Groundwater is one of the main sources of water supply for human, agricultural and livestock needs. It becomes essential in areas where surface water is limited or insufficient to meet all needs. However, over-exploitation, due to increasing water demand and climate change impacts, is causing groundwater depletion. In addition, groundwater quality worsening, due to the infiltration of contaminated water from anthropic activities, can impact human health causing epidemics. The geological characteristics of aquifers, especially when the unsaturated zone consists of highly permeable or karst or fissured rocks that activate preferential flows, can influence pollutant transport increasing the risk of groundwater contamination. In these cases, a better understanding of the transport and fate of microorganisms through the unsaturated zone is essential to safeguard groundwater and prevent aquifer contamination. The irrigation of horticultural crops with poor quality water, coming from contaminated groundwater or low-quality treated wastewater, could pose a health problem due to the presence of pathogenic microorganisms, especially in case of consumption of raw or undercooked foods. The aim of this project, financed by European Union - Next Generation EU, is to improve knowledge on groundwater contamination through a novel interdisciplinary approach based on the integration of microbiological, geological and agronomic skills. Two sites in Puglia and Sicily have been chosen for a total of 5 sampling points, of which the chemical-physical characteristics of soil and water such as pH, temperature, electrical conductivity, dissolved oxygen, solids, have been well determined. The collected samples are filtered by membranes and specific bacteria are detected by culture methods. An additional volume of water is concentrated for the detection of human pathogenic viruses by molecular methods. Coliphages are also quantified, and the presence of protozoa is determined. Moreover, in the Sicilian sampling points, to test any virus adsorption on vegetables, samples of plants irrigated by target water sources are collected to identify and quantify the above-mentioned viruses. To study the transport of microorganisms in unsaturated porous media, laboratory experiments will be carried out on selected rock samples and used to validate a transport model to predict at large scale the migration of pathogens under different environmental conditions. In particular, the project provides methodological tools which, applied in different fields, can help to evaluate anthropic pressures and their impact on environmental matrices like plants, soils, rocks and groundwater. The results of the project permit to modulate anthropic activities, by considering the geological and hydraulic characteristics of the territory, in order to minimize the impacts of microbiological contamination on the environment and on agri-food activities and, consequently, the risk for human health.

Groundwater - lake interaction in a mediterranean coastal aquifer: the Alimini lake case study (Southern Italy)

Volpe A.*, De Carlo L., Masciale R. & Caputo M.C.

Istituto di Ricerca Sulle Acque, CNR, Bari.

Corresponding author email: angela.volpe@ba.irsa.cnr.it

Keywords: coastal aquifer, hydrogeochemical indicators, saline intrusion.

The current study is focused on the characterisation of a coastal water system located in the Apulia Region, Southern Italy. The study site lies in the context of a semi-arid region, and comprises a freshwater lake fed by a multi-layer shallow porous aquifer. Groundwater is the main freshwater resource of the area, and suffers from an intensive exploitation that rises dramatically during summer, due to the increase of both population, caused by the massive presence of tourists, and the demand by agriculture. This study is intended to provide insight into the interactions between groundwater and lake water, in view of the potential lake water exploitation for drinking purposes, in order to help efficient and sustainable water management by local authorities.

Four monitoring campaigns were carried out throughout one hydrological year to collect a set of water samples both from the lake and wells in its nearby surroundings. Geochemical interpretation of water quality data was performed by comparing a set of hydrochemical indicators that can suggest the processes controlling the chemical composition of groundwater, with special attention to the potential seawater intrusion. The applied indicators included a number of correlations involving major ions concentrations and a few physico-chemical parameters relating thereto, e.g., total dissolved solids, and seawater fraction. Groundwater and lake water quality were then compared, particularly considering the standard values for drinking water. Data processing was aimed at bringing out potential seasonal variations of groundwater quality, due to the increased withdrawal from wells in the summer season, and the consequent potential impact on lake water quality.

Results suggested that groundwater chemistry was mainly controlled by the dissolution of carbonate minerals, with almost no contribution of cation exchange mechanisms, and a minimal impact of saltwater intrusion only into the wells closer to the coastline. The extent of intrusion showed no significant variation throughout the year. Lake water quality closely mirrored that of the feeding groundwater. Data analysis suggested that either biological and chemical processes occurring in the lake ecosystem, or anthropic activities in the area, did not have an impact on drinking water quality standards.

Keywords: geodetic monitoring, hydrocarbon exploitation activity, GNSS & InSAR.

In 2014 the Italian Ministry of Economic Development (MiSE) established a Working Group that drafted a document (Dialuce et al., 2014) providing indications and guidelines (ILG) for the monitoring of subsurface hydrocarbon exploitation activities with high safety standards in seismically active zones and in areas where they can produce ground deformations. The ILG describes the main technical aspects for implementing the monitoring, and the guidelines for its management and control as well as the actions to be undertaken under different scenarios of variation of the monitored parameters. In the following years, the ILG was tested on some pilot sites for which the National Institute of Geophysics and Volcanology (INGV) was involved as the Monitoring Responsible Structure (SPM).

As regards ground deformations, the ILG recommends the joint use of the main satellite techniques (GNSS and InSAR) to measure and analyze the spatio-temporal variations of these signals with respect to the background conditions, in turn identifying any surface deformation phenomena possibly linked to the anthropic activities.

With reference to different case studies embedding hydrocarbon production and storage, in this contribution we illustrate:

– the presentation of the data available at each test site;
– a synthesis of the observations and outcome of the measurements ;
– the critical issues and potentials of individual projects;
– possible future studies.

The high variability in the quantity and quality of data available for each site has made it very difficult to evaluate the impact of hydrocarbon cultivation activities on ground surface deformations, highlighting the need to standardize the planning and implementation strategies of the monitoring. Nonetheless, in some specific cases the available measurements have allowed us to identify specific signals due to the exploitation activity, thus underlining the importance of high-quality GNSS networks for characterizing deformation signals along the three displacement components.

The results thus far obtained evidence several critical issues, which make the monitoring of ground deformations, according to the indications of the ILG, a challenging goal. Nonetheless, we confirm that a rigorous conduction of deformation measurements may provide useful information on both the impact of the industrial activities, and the movements related to ongoing natural phenomena such as hydrological and tectonic processes, or sediment compaction.

Lithosphere heat flow and subsidence of the Tyrrhenian back-arc basin

Chiozzi P., Bonorino L. & Verdoya M.*

Dipartimento di Scienze della Terra, dell'Ambiente e della Vita, Università di Genova.

Corresponding author email: massimo.verdoya@unige.it

Keywords: marine heat flow data, ocean lithosphere, marginal basins.

The presence of active seafloor spreading in some marginal and back-arc basins formed the basis for the hypothesis that their geodynamic evolution and lithosphere thermal structure are similar to oceanic plates. Since the 1980s, it was argued that the heat flow with age in back-arc basins, including the Tyrrhenian Sea, followed the same relation for the oceanic lithosphere created at midocean ridges. It was also argued that the seafloor depth increases with age but differently to major oceans a subsidence excess of about 1 km was generally observed in back-arc basins. In the Tyrrhenian Sea, determining the conductive heat flow has been particularly challenging due to buried, high-conductivity salt structures and localized hydrothermal activity linked to the seafloor reliefs. Although the heat-flow data showed a large scatter, an increase from the Magnaghi–Vavilov Basin towards the younger Marsili Basin was generally recognised. This paper reviews the whole heat-flow database of the Tyrrhenian Sea. We critically assess the thermal measurements and correct heat-flow data for sedimentation and climatic changes to infer the purely conductive terrestrial heat flow. Finally, we discuss the thermal pattern and the seafloor depth compared to the modern oceanic cooling models obtained from the analysis of global heat flow and bathymetry data from oceanic, marginal and back-arc basins.

Geological modelling and CO_2 flow simulation: an integrated approach for basin scale storage in a saline aquifer

De Luca M.*[1-2], Mackay E.J.[2], Good T.R.[2], Scisciani V.[1], MacBeth C.[2] & Patruno S.[3]

[1] Dipartimento di Ingegneria e Geologia, Università "G. d'Annunzio", Chieti-Pescara. [2] Institute of GeoEnergy Engineering, Heriot-Watt University. [3] Department of Engineering, University of Nicosia.

Corresponding author email: mattia.deluca@unich.it

Keywords: geological CO_2 storage, regional flow simulation, saline aquifer.

Theoretical studies and successful industrial projects have emphasise the significant role played by Carbon Capture and Storage (CCS) in tackling global climate change; however, such projects have mainly been limited to field-scale operations (e.g. Eiken et al., 2011).

The regional saline aquifer of the Triassic Bunter Sandstone Formation (BSF) in the UK Southern North Sea has been identified as a promising area for multiple large-scale CCS activities (Noy et al., 2012; Williams et al., 2013). Understanding the fate of the CO_2 plume during and after injection in such a large interconnected system (extending to about 9000 km2) is crucial for both risk assessment and regulatory compliance, and is also relevant should there be the economic opportunity to increase storage capacity (Patruno et al., 2024).

A comprehensive study has been conducted to analyse features that could impact the overall storage, such as plume migration, seabed connectivity of the reservoir, and petrophysical heterogeneities. Composite and wireline logs, core measurements, and 2D and 3D seismic data were analysed, interpreted, and converted to the depth domain, to create the reference geological models subsequently used to generate various flow scenarios using reservoir simulation. Injection of 1 Mt/yr/well for 50 years via 14 injection wells distributed throughout the BSF has been simulated. Results indicate that plume migration may continue for centuries after Cessation of Injection (CoI) and that existing pressure gradients affect its evolution. Poro-perm heterogeneities enhance the residual trapping mechanism by allowing plume spreading beneath low permeability baffles imposed by low local Kv/Kh ratios. During the injection phase, the plumes are mainly driven by viscous forces and exhibit a circular spreading pattern around the wells. After CoI, the plumes are displaced by gravity forces and tend to migrate following the shape of the top reservoir structure. However, differing migration paths have been observed by varying model boundary conditions. In the open scenario (i.e. with flow connection at the reservoir seabed outcrop), a persistent viscous gradient between surrounding traps and the reservoir outcrop displaces the CO_2 plume toward the outcrop; this effect is also observable to a lesser extent in faraway closures. Conversely, in the closed boundary case there is a reduction in plume migration across the whole model, allowing traps to be completely filled. This investigation underlines the complex interactions between geological settings and heterogeneities, boundary conditions and pressure connectivity, hydrogeological fluxes, and force dynamics. This understanding is crucial not only during the expected operational timeframe but also on a long-term scale during carbon storage in large-scale saline aquifers. Understanding the impact of long-term plume migration will lead to new approaches in optimising geological carbon storage at the basin scale.

Carbon sequestration potential of abandoned fractured reservoirs in Northwest Zagros, Iran

Dinani P. *[1], Bigi S.[1], Conti A.[2] & Moallemi A.[3]

[1] Dipartimento di Scienze della Terra, Sapienza Università di Roma. [2] Istituto di Geologia Ambientale e Geoingegneria, CNR. [3] Research Institute of Petroleum Industry (RIPI) Tehran.

Keywords: carbon sequestration, carbonate reservoir, Zagros.

Achieving NetZero by 2050 will be possible if contributors to CO_2 emissions take action. In this context, providing an atlas of CO_2 storage in countries that contribute to carbon dioxide emissions is necessary. Evaluating the potential of reservoirs in the Zagros area, a main foreland basin hosting oil and gas and consequently contributing to CO_2 emissions, could be a significant step toward creating a database for future storage plans. Specifically, the presence of carbonate reservoirs in various geological provinces worldwide necessitates their evaluation.

In this study, we conducted an in-depth analysis of the potential of a Late Cretaceous carbonate reservoir situated in the Lurestan area in Iran by formulating the geological model of the Ilam Formation (top of the Bangestan Group). Our target formation for storage is the Bangestan Group, mainly comprised of the Ilam and Sarvak formations, separated by the Surgah Formation in the middle. The study area covers approximately 52 km by 45 km and is located in the northeastern part of Lurestan. For further analysis in the site characterization process, we focus on the Ilam reservoir within the specific structure in the studied area.

The first step in constructing the geological model involved seismic interpretation, utilizing data from well logs and existing geological maps of the area. The target formation is predominantly limestone, with dolomitic limestone present at the top of the reservoir, as determined by interpretation of sonic, Gamma, and Neutron logs. Another reason for considering this structure for carbon sequestration is the presence of a thick layer of the Gurpi Formation serving as a caprock. Composed mainly of marls from the Campanian to Maastrichtian age, this caprock varies in thickness from 900 to 1100 meters and increases from southeast to northwest, providing a barrier for CO_2 migration.

Since[PS1] our structure is laterally bounded by two reverse faults, we formulated two different geological models for this site. Firstly, we considered ‘safe storage,’ focusing only on the top of the reservoir as the exploitable part. Secondly, we considered the volume of the reservoir bounded by these faults. The base case model has dimensions of 48 km × 7 km × 300 m and was discretized into 220×126×15 cells. We present a detailed outline of static estimation, utilizing the proposed equation of USDOE for the Ilam reservoir, followed by the Monte Carlo simulation method to generate multiple realizations of the reservoir performance by randomly sampling input parameters according to their probability distributions.

Carbonate reservoirs, such as the Ilam Formation, are well-known for their consistently low porosity levels. In our reservoir, this characteristic is confirmed by forecasted porosity values, indicating a maximum porosity of 15%. Natural fractures likely play a significant role in the tight carbonate effective permeability due to their low matrix porosity/permeability. Therefore, in this study, Electromagnetic Imaging (EMI) data were utilized to construct a stochastic discrete fracture network (DFN) using Petrel. Subsequently, we upscaled the DFN using the Oda method to assign grid porosity/permeability values to the model.

National energy policy: a focus on georesources targets at 2050

Fagiani A., Antoncecchi I.*, Corneli D., Sofia R. & Sterpa S.

Div V., ex-Directorate General for Infrastructure and Energy Security of Italian Ministry of Environment and Energy Security – MASE.

Corresponding author email: antoncecchi.ilaria@mase.gov.it

Keywords: natural gas production, CCS, hydrogen.

International energy policies, such as Paris Agreement (COP 21) and Regulation (EU) 2021/1119, already integrated into the national regulatory framework, boost decarbonization efforts through energy transition with the aim to achieving climate neutrality by 2050.

The targets of the national energy policy are described in the Integrated National Energy and Climate Plan - NECP (art.14 Regulation (EU) 2018/1999) updated on 2023 (PNIEC_2023.pdf (mase.gov.it).

Therefore, Italy is equipping itself with various planning tools to enhance environmental sustainability, safety and energy costs accessibility, while promoting a just transition.

Among these initiatives, transition to renewables is fundamental and passes through the central role of natural gas, while encouraging a new development of the geothermal sector, the possible exploitation of solid minerals in the sea, with particular reference to critical minerals, considering the Regulation (EU) 2024/1252 establishing a framework for ensuring a secure and sustainable supply of critical raw materials, and adoption of new technologies such as, for example, CO_2 capture and storage as well as the promotion of hydrogen as an energy carrier.

An example of an innovative project is the experimental CO_2 storage program in Porto Corsini field. The project, approved by Ministerial Decree of 26th of January 2023, aims to initially store 1 Mt of CO_2 starting from 2024, with plans to scale up to 50 Mt by 2050, potentially making the field as a possible CO_2 storage hub in the Mediterranean level (proposal relating to the PCI project).

In recent years, numerous provisions have been issued to maintain and optimize natural gas production and storage, such as the approval of the so-called Energy Decree, as a tool for revitalizing the sector.

In the geothermal sector, reference is made to the forecasts of the Ministerial Decree of 30th September 2022 which describes the methods for installing closed-circuit geothermal probes, providing simplified authorization procedures to speed up the administrative process, where possible.

For all the different sectors mentioned, the maintenance of high safety standards is fundamental, which is guaranteed at a national level also through specific and advanced integrated monitoring techniques (e.g. Dialuce et al., 2014). In particular, to face up to the growing technical specialization of the sector, scientific partnerships have been carried out with highly qualified research bodies, universities, and government institutions in order to address the main scientific open questions in the context of safety with the energy industy (e.g. Antoncecchi et al., 2023).

Enhancing the Italian geothermal data infrastructure: integrating geothermal data and potential assessment tools

Galione M.R.*, Criscuolo L., Manzella A. & Trumpy E.

Istituto di Geoscienze e Georisorse, CNR, Pisa.

Corresponding author email: martina.galione@igg.cnr.it

Keywords: geothermal database, underground data management, potential assessment.

Geothermal energy is a sustainable and renewable energy, offering significant potential in mitigating climate change and reducing dependence on fossil fuels. Identifying geothermal resources involves the acquisition, processing and analysis of a large quantity of data. Geothopica1, the Italian Geothermal Data Infrastructure (https://geothopica.igg.cnr.it), through a web portal created in 2007 and renewed in 2023 by the Institute of Geosciences and Earth Resources of the National Research Council (CNR-IGG), provides a rich portfolio of geothermal information whose beating heart is represented by the updated National Geothermal Data Base (Banca Dati Nazionale Geotermici, BDNG) (Trumpy et al., 2017).

Geothopica, developed in compliance with national (RNDT 2.0) and international (INSPIRE) regulations, provides data, documents and web services (OGC) to guarantee access, interoperability and re-use of the available information. CNR-IGG maintains and upgrades the infrastructure, updating its contents thanks to different assessment projects. Recently, two main national geothermal projects coordinated by CNR, "VIGOR" and "ATLANTE Geotermico", gave the opportunity to update geothermal information for nine regions in central-southern Italy, however now CNR-IGG has enriched the database also in other regions. The new collected data were obtained by the boreholes masterlog made available by the VIDEPI2 project (funded by the Ministry of Economic development)(https://www.videpi.com), which provided data referred to Marche, Veneto, Friuli Venezia Giulia, Trentino Alto Adige regions and a few locations in the Po Plain. A second new dataset stems from historical data gathered during the geothermal exploration that took place in the 1990s in Larderello and Monte Amiata: about 50 folders with paper documents related to geothermal wells were analysed, and digitalized. The collected data include stratigraphic logs, chemical analyses of geothermal fluids and gases, drilling mud density and temperature data. For some wells, drilling reports were also attached to the boreholes when available.

Geothopica has also been empowered with a web application for computing the geothermal potential in an area of interest. This tool, called ThermoGIS, uses the volume method and geological reservoir information as input to elaborate maps of geothermal potential suitable for several applications, including power generation, district heating, district heating and cooling. The ThermoGIS code was initially developed by the Dutch Geological Survey (TNO) (Van Wees et al., 2013) and then adapted to the Italian geothermal conditions in a collaboration between CNR and TNO.

GeoThopica, the largest and most comprehensive repository of geothermal data in Italy, is useful not only for research and development in the geothermal energy sector but also for thermal and CO_2 storage projects or for the exploration of economically strategic minerals (e.g. lithium, rare earths) favouring the energy transition.

Keywords: permeability, CO_2 storage, friction.

Underground CO_2 storage involves injecting fluids into a reservoir aquifer, leading to artificial changes in the subsurface stress field. The implications for fault-seal and caprock integrity need to be understood to establish safe operational pressures and monitoring / mitigation procedures in case of leakages along faults and induced seismicity during fluid-assisted fault reactivation. For faults cutting across sedimentary rocks, clay concentration into the fault core can significantly alter the fault frictional properties and reduce or create strong anisotropy in permeability. Here we show that the increase in shale content within a quartz-rich experimental fault promotes a fabric evolution from a load-bearing granular framework to an interconnected foliated and clay-rich network causing a significant reduction in strength, enhanced frictional stability, and a marked decrease in permeability. Fault stability is favored by fault dilation associated to a reduction in pore fluid pressure within the low permeability, clay-rich faults. For a shale content > 30% we also observe that the permeability parallel to the foliated fault fabric is 1.5-2 order of magnitude higher than permeability parallel to the foliation. Our data suggest that while the enhanced stability within pressurized clay-rich faults matches well with observations of aseismic slip during hydraulic stimulations of shales, the documented increase of permeability in the fault parallel direction demands a more comprehensive characterization to better predict possible up-fault leakage during CO_2 injection for storage.

A potential site to store Hydrogen in the subsurface in Northeast Italy

Lorenzet R.[1], Corradetti A.[1], Del Ben A.[1], Franceschi M.[1] & Bonini L.*[1-2]

Keywords: energy transition, hydrogen, underground hydrogen storage.

The ongoing transition to a low-carbon economy is pushing the development of renewable energy sources. These latter, however, are characterized by intermittent energy production that causes energy excesses or deficits, thus requiring long-term storage, which poses significant challenges. Increasing emphasis has recently been put on hydrogen as an energy carrier, and Underground Hydrogen Storage (UHS) has emerged as one of the most promising storage solutions.

Preliminary analysis of potential UHS in northeast Italy (Mattera et al., 2023) identified a perspective reservoir-and-caprock system in the Miocene Cavanella Formation (reservoir) and Marne di San Donà Formation (caprock) in the subsurface of the Treviso area.

We used well and seismic data on the Cavanella and Marne di San Donà formations to reconstruct a three-dimensional static model of a buried anticline (Arcade Nervesa anticline) that represents a well-promising structural trap. Then, we computed the volume of the reservoir, to verify its potential as a storage site. The structural trap has a volume of around 1 billion cubic meters, and the reservoir is around 200-300 million cubic meters.

The feasibility of hydrogen storage in this site is then evaluated by computing a storage feasibility index, assigned through a dedicated scoring matrix based on the characteristics that literature identifies as required for hydrogen storage. Results suggest that the Arcade Nervesa anticline area could be considered a potential UHS site

Sealing potential of the messiniaN SALT from IODP Expedition 402

Keywords: physical properties, Messinian salt, Tyrrhenian.

During the International Ocean Discovery Program Expedition 402, which took place from February to April 2024 in the Tyrrhenian Sea, six deep sites were drilled along two orthogonal transects. The expedition targeted the transition between the continental crust of Cornaglia and Campania terraces and the oceanic domain of the Vavilov Basin. Two of these sites are located on the conjugate margins of the basin, two terraces, where the Messinian Salinity Crisis (MSC) deposits are present. The drilling at sites U1613 and U1617, located at the Cornaglia and Campania terraces respectively, allowed us to recover the evaporitic sequence from gypsum-enriched terrigenous sediments through anhydrite to halite layer. We performed a series of physical property measurements of the recovered cores on board of the JOIDES Resolution drillship that included P-wave velocity, density, magnetic susceptibility, and natural gamma ray. In addition, we analyzed representative discrete samples to measure the P-wave velocity measurements in different directions, as well as bulk density, grain density and porosity. These physical properties allowed us to define with high accuracy the sealing properties of sediments deposited during the MSC. In fact, MSC deposits become the best seal for gas or oil when halite which has zero porosity is present. This capacity can be modified by salt tectonics, typical of these sediments, which decreases the thickness of the salt layers and impacts their lateral continuity by introducing a secondary porosity represented by faults and fractures. Thanks to the great opportunity offered by the IODP program Exp. 402, the physical properties of the entire MSC sequence will be analyzed in detail and correlated with seismic and sedimentological data.

Linking an outcrop analogue to a deep potential CO_2 storage site with 3D geological model: an example from southwestern Sicily

Maiorana M.*, Rizzo G.F., Todaro S., Gasparo Morticelli M., Agate M. & Sulli A.

Corresponding author email: mariagiada.maiorana@unipa.it

Keywords: carbon capture and storage, outcrop analogue, seismostratigraphy.

The southern Sicilian sector is notoriously rich in geological traps explored since ’70 by oil and gas companies. Taking also into account the presence of numerous industrial emitters in the near Gela, this area is configured as potentially suitable for CCS (Carbon Capture and Storage) projects.In the area near Sciacca thick carbonate successions outcrop and it is characterized by a sequence of shallow water limestone covered by condensed pelagic limestones, all Jurassic in time. Seismostratigraphic, structural and sedimentological analysis carried out in the Sciacca area through 2D seismic reflection profiles and borehole data collected from public databases, confirmed the presence of potential reservoir and seal for CO_2 storage in correspondence of the Jurassic carbonates. The reservoir is represented by the Lower Jurassic peritidal limestones belonging to the Inici Formation consisting of grainstone-packstone with bivalves and benthic foraminifera with primary porosity. Analysis of facies and terrain analogs identified also a high secondary porosity in the upper part of the Inici Formation due to the fracturing, dolomitization, and paleokarstic processes. The seal is, instead, represented by the Middle-Upper Jurassic condensed pelagic deposits referable to the Buccheri Fm. known as Rosso Ammonitico. These condensed pelagic deposits consist of mudstone-wackestone with ammonites showing low porosity, due to the fine grain texture. The new collected data confirmed that in the area the outermost deformed portion of the western Sicilian chain outcrops composed of a double verging compressional structure delimited by NNE-SSW-trending left-lateral transpressive faults. In the offshore sector the seismic profiles interpretation highlighted the presence of a NE-SW-oriented ramp-anticline, bounded by high-angle deformation with transpressive kinematics. By combining seismostratigraphic and structural results with those derived from geological survey and samples analysis, we generated a 3D geological model defining thickness, lateral extension and fault boundaries (with their leakage potential) for reservoir and seal. This interpretation of the regional structure suggests a potential structural traps within buried antiformal stacks. This study, therefore, presents new data at the regional scale regarding the presence of reservoirs and seals (both onshore and offshore) potentially suitable for CCS purposes. By retrieving the parameters defined by the European Geocapacity Project, the CO_2 storage suitability for the area investigated has been estimated.

Caprock genesis in hydrothermal systems via alteration-controlled fault weakening and impermeabilization

Marchesini B.*[1-2], Pozzi G.[3], Collettini C.[1], Carminati E.[1] & Tesei T.[4]

[1] Dipartimento di Scienze della Terra, Sapienza Università di Roma. [2] Istituto di Geologia Ambientale e Geoingegneria, CNR, Roma. [3] Istituto Nazionale di Geofisica e Vulcanologia, Roma. 4 Dipartimento di Geoscienze, Università di Padova.

Keywords: hydrothermal systems, caprock, permeability, friction.

The mechanical and hydraulic behavior of faults in geothermal systems is strongly impacted by circulation of aggressive fluids. This, in turn, affects our ability to model the properties of subsurface structures in both reservoirs and caprocks to assess reservoir behavior and potential hazard during geothermal exploitation. However, the effect of alteration on the mechanical properties of faults in geothermal systems is severely under documented. To fill this gap, we studied the rocks from the caprock of a fossil hydrothermal system in the Apennines, developed in acid volcanic effusive rocks during the Upper Pliocene extensional stage and associated magmatism. We combined field structural observations, XRD analyses, friction experiments, and permeability tests. We document fault weakening induced by the combined effect of mechanical comminution and hydrolytic alteration resulting to strong enrichment in clay minerals (70-80 wt%) along fault cores. Argillic rocks (kaolinite-alunite-quartz-rich), are much weaker (friction coefficient $0.26 < \mu < 0.45$) than the unaltered protolith (trachyte $\mu = 0.55$), favoring strain localization. The enrichment of clays along fault cores induces a local decrease in permeability of three orders of magnitude respect the protolith, promoting an evolution of fault behavior from initial conduit into barrier. The efficiency of this process is demonstrated by the cyclic development of fluid overpressure in the altered volcanic rocks, as highlighted by distinct explosive breccias and hydrofracture networks. Permeability barriers also enhance the lateral flow of hydrothermal fluids, promoting the lateral growth of the caprock. As highlighted by the velocity-strengthening frictional behavior of the studied rocks, hydrolytic alteration promotes stable slip of faults with crucial consequences on the evaluation of the risk of induced seismicity during the exploitation of geothermal reservoirs.

Alteration-controlled repeated breakage of hydrothermally altered marly-limestones seals, Fenice-Capanne mining area (Tuscany, Italy)

Keywords: hydrothermal alteration, fluid-rock interaction, caprock; fluid inclusions.

Hydrothermal alteration may promote formation of efficient caprocks above reservoirs, limiting the upward movements of hot convective fluxes and thus granting, below it, the high-pressure and -temperature conditions required for exploitation of the geothermal energy. Characterization of the secondary (structurally-controlled) evolution of caprocks is thus crucial to evaluate their seal efficiency. The hydrothermally altered marly-limestones of Ligurian affinity exposed in the Neogene mining area of Fenice-Capanne in the hinterland of the Northern Apennine chain provide an exhumed analogue of the caprocks sealing the geothermal systems of the Tuscan Latium region. In this regard, our study is aimed at assessing the paleo-thermal and paleo-hydraulic conductivity properties of the Ligurian caprocks through an integrated approach that combined field, mineralogical and geochemical studies with fluid inclusion analysis (i.e., microthermometry, micro-Raman and analysis of noble gases). The increase in volume (up to 98%) due to massive silicification of marly limestones favored the initial embrittlement of the calcsilicates-rich rocks, enhancing circulation of hydrothermal fluids along a complex pattern of faults and fractures. Repeated injections of hot hydrothermal fluids (T = 180°C -350°C) caused element remobilization and vein sealing reducing secondary permeability. Cycles of breakage and sealing of the cap rocks are documented by textural relationship between calcium-pyroxenes (solid solution between diopside and hedenbergite), Fe-actinolite, epidotes, sulphides (e.g., pyrite, chalcopyrite, covellite), sulphates and Fe-oxides, which are mutually substituting each other. We interpret this alteration pattern as evidence of cyclic reducing and oxidizing conditions in the system.

Why it is important to perform a fully integrated basin-scale modeling of CO_2 storage in saline aquifers? Insights from the Paris Basin (France)

Mattioni L.*[1], Armitage J.[1], Christ A.-B.[1], Granjeon D.[1], Lemgruber-Traby A.[1], Pujol A.[1] & Bourgeois F.[2]

Keywords: geological storage, basin modelling, energy transition.

Successful CO_2 storage in deep saline aquifers rely on functional 3D numerical models of the storage complex with the real geometry and conditions. Most of the research performed in recent years on CO_2 storage has focused on a reservoir scale, with the aim to put more light on the migration and trapping of CO_2 in storage formations, and on potential leakage into shallow aquifers. However, much less effort has been put on studying transport and migration of CO_2 at a scale of sedimentary basins and on the impact of CO_2 injection on the geomechanical properties of the target reservoir and its caprock. Nevertheless, basin-scale phenomena may become particularly important when we are dealing with large-scale objects like saline aquifers. O&G industry has a large experience on 3D basin modelling techniques. Basin models are widely used in exploration and development to simulate the history of sedimentary basins through time.

In this context, the question that has driven our work was: how can we use traditional 3D Basin modeling techniques to help assess current and future carbon storage sites? Having in mind this, we developed an efficient workflow for constructing an accurate geological basin model for the evaluation of CO_2 storage capacity and simulate the injection of CO_2 and its long-term effects on the pressure field.

This study presents an efficient workflow for constructing an accurate geological basin model for the evaluation of CO_2 storage capacity in saline aquifers. This workflow has been developed in the general framework of a jointed IFPEN-TotalEnergies collaboration on a CCUS project focused in the Paris Basin (France). The Paris Basin is one of the most mature areas in the Western Europe in terms of the oil and gas exploration, with approximately 100 producing oil fields and more than 850 exploration wells, which can be used nowadays for other disciplines such as CO_2 storage. For this reason, we selected the Paris Basin as an ideal case study, the aim being not to use it to inject CO_2, but rather to test and validate our approach.

Our multidisciplinary and integrated workflow covers three main steps. Firstly, we built a 3D basin model simulating the evolution of the Paris Basin through time, by integrating diverse geological, geochemical and reservoir engineering data. The 3D basin model was then coupled with a comprehensive 4D forward stratigraphic model, which gives greater insight into the facies architecture and the distribution of potential reservoir rocks of the Bathonian reservoir through geological time. Finally, we performed an advanced 3D geomechanical analysis in the model, that allowed us to simulate the present-day distribution of fundamental basin parameters such as 3D stress tensor, porosity, pore-pressure and temperature. The resulting 3D basin model was then used for reservoir modelling purposes, and as input to model the injection of CO_2 and its long-term effects on the pressure field.

CMS@INGV: An operational monitoring center for risk mitigation related to anthropic underground operations in italy

Keywords: induced seismicity and subsidence, geophysical monitoring.

In 2014 the Italian Ministry of Economic Development issued the guidelines (*Indirizzi e Linee Guida*, ILG) outlining procedures, responsibilities, and roles for monitoring the effects of subsoil activities — focusing on gas storage, hydrocarbon extraction, wastewater injection and geothermal energy production. The need had arisen to respond to public concern regarding the potential effects of underground anthropic activities on earthquake occurrence, ground deformation, and related phenomena. The guidelines define standards for monitoring microseismicity, ground deformation,and pore pressure, and provide guidance on implementing a 4-level traffic light (TL) protocol as a decision support tool for managing possibly induced seismicity. The TL system uses monitoring information such as location, magnitude, and peak ground motion of recorded seismicity, and it is used to take decisions if seismicity is recorded within the monitoring domains. It may be worth noting that it is automatically applied exclusively for wastewater injection. Following the introduction of this regulatory framework, in 2017 the Italian *Istituto Nazionale di Geofisica e Vulcanologia* (INGV) established the Center for the Monitoring of Subsurface Activities (CMS, http://cms.ingv.it/), entirely devoted to collecting and analyzing data associated with exploitation of georesources. In this contribution we present the structure and operational principles of the CMS, its IT architecture, and the organization of the monitoring procedures. We also present the ongoing monitoring projects, that include (1) The two Italian high-enthalpy geothermal power plants (Larderello-Travale and Monte Amiata); (2) Europe's largest onshore oilfield, in Southern Italy; (3) A gas production plant in the Po-plain; and (4) Italy's first off-shore Carbon Capture and Storage plant (Northern Adriatic Sea). These case studies are discussed with reference to the main pending challenges, which concern (i) the distinction between natural and triggered seismicity, that is particularly relevant in a tectonically-active country like Italy; (ii) the comprehensive estimate of uncertainties on parameters derived from monitoring; (iii) the unbiased assessment of background seismicity when exploitation activities are already operational; and (iv) the establishment of reliable and physics-based thresholds for defining the transition between alert levels.

Stochastic and thermophysical modelling for geothermal resource assessment: the case of the Po Basin

Nanni T.*, Chiozzi P., Miola M., Verdoya M. & Vetuschi Zuccolini M.

Keywords: stochastic modelling, transient thermal modelling, geothermal resources.

Few studies have explored the geothermal potential of the Po Basin. This work aims to contribute to the knowledge of the thermal state of the western sector of the basin. A new thermal database was compiled, and the underground thermal structure was modelled to identify areas with potential geothermal resources. Initially, available thermal data from various sources were collected and new data were added. The data included bottom hole temperatures (BHT), temperatures from drill stem tests (DST) and thermophysical properties measured in the laboratory on cores extracted from wells. The temperature data were interpolated with an original algorithm to obtain a 3D stochastic distribution model, temperature maps at different depths and the 2D thermal field along selected geological cross-sections with strata mainly characterized by a homoclinal structure. Subsequently, temperature-depth profiles and the basal heat flow were calculated employing transient 1D geothermal models for the deeper boreholes located along the cross-sections. The 1D models were based not only on BHTs and DSTs but also on the measured thermophysical properties. A sensitivity analysis indicates that thermal conductivity and porosity mostly control the modelling results. The 1D thermal calculations and the temperatures inferred from the stochastic model are in good agreement in the 1000-5000 m depth range. Thus, in the case of a relatively simple structural setting, as it occurs for the selected cross-sections, the stochastic model can provide a reliable picture of subsurface temperature distribution, since thermal refraction effects are likely negligible. The geothermal gradient inferred from the stochastic model between 1000 and 5000 m varies from 20 to 27 mK/m. The geothermal gradient calculated with the 1D thermal models confirms such values (21-26 mK/m) and the basal heat flow ranges from 55 to 64 mW/m^2. The stochastic modelling highlights that the highest geothermal potential occurs W of Milan with the highest temperatures (about 180°C) at about 6 km depth.

A mineralogical and geochemical approach to evaluate the redox capacity of basaltic glass and crystals via experiments

Keywords: water-rock interaction, CCS, supercritical CO_2.

The levels of greenhouse gases, particularly CO_2, rise globally. To tackle this problem, scientists and engineers have been exploring carbon capture and storage (CCS) technology to reduce CO_2 concentrations in the atmosphere. Mineral carbonation is a promising CCS technique that involves CO2 reacting with Ca-Mg-Fe bearing basaltic rocks to store it in the rocks as carbonate minerals. The CarbFix project in Iceland is an excellent demonstration of this approach. However, much remains to be discovered about the intricate physicochemical connections between water, dissolved ions, and crystal growth in complex multicomponent systems at the atomic and nanoscale. These factors are vital for the successful deployment of CCS in basaltic reservoirs.

This research explores the use of supercritical CO_2, which is achieved by exceeding the critical temperature and pressure of 30.97°C and 73.773 bar, respectively. In this state, CO_2 exhibits the properties of both a gas and a liquid. The study presents the results of an experiment conducted on basaltic crystals and glasses under varying temperatures (between 100 and 200ºC) and pressures (64 to 79 bar) to investigate the reaction between CO_2 (sc), water, crystals (mainly forsterite) and basaltic glass. The results highlight the partial dissolution of mineralogical phases and the formation of new alteration phases, in addition to the precipitation of carbonates containing Ca, Mg, and Fe. Furthermore, the composition of the post-reaction gases will be analyzed to evaluate the redox conditions occurring in water-CO_2-basaltic glass and water-CO_2-basaltic crystal reactions.

Development of a site-screening method for hydrogen storage purposes and its application to an industrial dataset of Italian reservoirs

Ridolfi R.M.*[1], Azzaro S.[2], Beaubien S.E.[1], Da Pra A.[2], Pontiggia M.[1] & Bigi S.[2]

[1] Dipartimento di Scienze della Terra, Sapienza Università di Roma. [2] Eni S.p.A., San Donato Milanese.

Corresponding author email: riccardomaria.ridolfi@uniroma1.it

Keywords: underground hydrogen storage (UHS), site-screening method, multi-criteria decision-making (MCDM).

The use of hydrogen as an energy carrier will require effective storage solutions, and depleted hydrocarbon reservoirs offer a safer and cheaper large-scale option compared to other possibilities. The selection of a site for underground hydrogen storage (UHS) entails considerable responsibilities and expenses, and specific tools should be employed to facilitate and optimize the decision process. Thus, a site-screening method was developed to rank depleted and almost depleted hydrocarbon reservoirs for UHS, with subsequent testing on a confidential dataset of 48 production sites from Italy provided by Eni. A set of 27 screening parameters was selected from a wider dataset and a weight for each one was defined by reproducing the Analytic Hierarchy Process (AHP) (Saaty, 1987, 2008) and gathering expert judgements from both academic and industry following the Delphi technique (Dalkey & Helmer, 1963; Hsu & Sandford, 2007). This was performed from the points of view of HSE (health, safety, and environment), geotechnical performance (GP) and economic performance (EP), dividing the individual parameters among these three supergroups and normalizing the diverse kinds of dataset records to be used in the calculation procedure. The method resulted in three preliminary rankings based on the sites' HSE, GP and EP scores and a comprehensive ranking obtained through the aggregation of these three scores for each site, with penalties applied if specific, adverse features exist for UHS purposes. For sites with incomplete data, an estimation of the potential score was derived based on average values calculated from the dataset and attached as additional information to the screening scores without affecting the ranking. The AHP results highlighted a major role for Faulting Description, Mineralization Type, Onshore/Offshore, Wells Number, Reservoir Architecture, Datum Depth and Initial Pressure at Datum, even though other factors made significant contributions. The result consists of a set of scores ranging from 29 to 72 out of 100. To assess the reliability of the method, two blind tests were conducted on a minor proprietary dataset containing well-known sites from North Africa, the first involving a subset of the sites and the second using all sites. The results yielded a good match with the existing ranking performed by Eni. The developed method can be adjusted for a variety of decision-making scenarios, to accommodate changes in the screening purposes or advancements in research. In this configuration, it consists of a highly effective tool for an objective and transparent screening of sites for UHS purposes.

Keywords: UGS, Collalto seismic network, Cornegliano Laudense seismic network.

Underground gas storage - UGS is a facility strategically designed to follow the fluctuations in supply and demand of methane gas, by storing it in the summer when demand and price are low, and withdrawing it in the winter when demand is high. UGS is also among the human activities that produce ground deformation in response to the stress changes around the reservoir when the gas is injected or extracted, therefore it can trigger seismicity.

OGS is responsible for the monitoring of two UGS plants in northern Italy, namely Collalto Stoccaggio and Cornegliano Stoccaggio, both of which are operated without exceeding the original reservoir pressure.

The Collalto UGS has been in operation since 1994 and has been monitored by the Collalto Seismic Network – RSC (Priolo et al., 2015) since 2012. This network consists of 10 boreholes seismic stations installed near the reservoir and a GNSS station installed directly above it. The data collected by the RSC is integrated with seismological and geodetic data from other stations existing in the area, the former to distinguish between local and regional events and to constrain earthquake locations, the latter to compare local deformation rates with those of the surrounding area. In about 12 years, the RSC seismic catalog has recorded >3,500 earthquakes (-0.9 The Cornegliano UGS has been operational since 12/12/2018, but has been monitored by the Cornegliano Laudense Seismic Network – RSCL (Priolo et al., 2019) since 1/1/2017, 2 years before the start of storage operations. We have opted for such a monitoring strategy because the company managing the UGS has chosen to follow the Ministerial Guidelines for the monitoring of underground industrial activities (MiSE, 2014), which recommend the measurement of background levels of seismicity and ground deformation as references to show the impact of human activities. The RSCL was designed according to the same criteria as the RSC (10 seismic stations, 1 GNSS station, seismological and geodetic data integrated with those of other stations), but unlike the RSC, ground deformation is also monitored by satellite radar interferometry. After 7 years, the RSCL seismic catalog contains 33 events (0.7

Keywords: geothermal, syn-tectonic, granitic.

Elba Island is in the northern Tyrrhenian Sea and represents a crustal section of the inner zone of the northern Apennines exhumed during the Miocene extensional tectonics that opened the Tyrrhenian Basin. The island hosts two magmatic complexes, mainly represented by monzogranite intrusions and related sills and dikes swarms, exposed on the western and eastern sides of the island: the Monte Capanne (8.5-6.9 Ma) and Porto Azzurro (6.4-5.9 Ma) plutonic complexes, respectively. For this reason, Elba represents a natural laboratory for investigating the relationships between structures related to extensional tectonics and the emplacement of magmatic bodies. This presentation deals with the structural setting of an area east of Monte Calamita, where the Porto Azzurro monzogranite metamorphic aureole formed by micaschists and quartzites, it is widely exposed. It is also intruded by peraluminous leucogranite dykes dated at 6.2 Ma and veins, both showing strike roughly N-S and dip steeply to the east. After emplacement, the dykes were deformed by top-to-east HT shear zones associated with low-angle normal faults. The deformation occurred during the cooling of the magmatic system, as indicated by a ultramilonite texture, which is overlain by ultracataclastic domains testifying the change in the rheological behavior of the fault zones. This deformation occurred in the footwall of the regional normal fault known as the Zuccale Fault. Preliminary fluid inclusion analyses carried out in quartz from veins and leucogranite dykes highlighted homogenization temperatures spanning from 250 to 350°C with high salinity values. To conclude, the study area contributes to a better understanding of tectonic vs. magmatism in the inner Northern Apennines, and on a wider scale to improve our knowledge on the strict connection between faulting and dyke intrusion and cooling in upper crust domains.

Potential sources of Li-rich fluids in Northern Apennines (Italy): first results on lithium distribution in pelitic rocks

Salvadori M.*[1-2], Pennisi M.[1], D'Orazio M.[2] & Dini A.[1]

[1] Istituto di Geoscienze e Georisorse, CNR, Pisa. [2] Dipartimento di Scienze della Terra, Università di Pisa.

Keywords: lithium enrichment, unconventional resource, isotope geochemistry.

Global lithium demand related to the ongoing energy transition has grown exponentially in the last decade and is estimated to increase up to 20-folds by 2050 (Xu et al., 2020). Production from conventional deposits, as well as recycling, need to be increased and development of new unconventional resources considered. Conventional deposits (e.g., pegmatites, salars) are not represented in Italy, while some promising sources of lithium have been identified in low-enthalpy Li-rich fluids (up to 370 mg/L) issued from sedimentary sequences along the Apennine compressional front (Dini et al., 2022). The high concentration of lithium in these waters (up to 164 mg/L in Salsomaggiore Terme area; Boschetti et al., 2011) is possibly controlled either by fluids expelled by sediments during diagenesis or by later water-rock interactions. The advantage of Li-rich fluids is represented by the possibility to exploit lithium using Direct Lithium Extraction techniques (Li et al., 2019). Despite the high scientific and economic potential, the knowledge on these systems in terms of chemical and isotopic data and genetic processes is limited. This study is part of a PhD project funded by ITINERIS (Italian Integrated Environmental Research Infrastructures System project) and aims to fill this data shortage to understand the source(s) and processes controlling the lithium occurrence, both in rocks and fluids. For this purpose, an extensive sampling of the main sedimentary formations of the Apennine chain in Emilia Romagna region has been conducted, with particular interest for argillite-clay sequences. Mud from sedimentary volcanoes, widespread along the Apennine margin, has also been sampled as representative material of the deep sedimentary formations and waters. Samples have been characterized for major and trace elements. Lithium concentration ranges from 13 to 194 mg/kg, with the higher values observed in argillites and clayey formations. Boron and strontium isotope ratios (as δ11B and 87Sr/86Sr) have been also determined for the most Li-enriched samples. XRD analyses have provided the main mineralogical composition and SEM-EDS imaging and chemical maps have been used to unravel mineralogical-chemical zonation. Zoned samples have been further investigated with LA-ICP-MS to quantitatively trace lithium variability and identify the most enriched mineral phases. A leaching experiment, conducted with different solutions (deionised water, NaCl, CaCl2, HCl), has been also done to quantify the release of Li from rocks over time. To trace the water-rock interaction a lithium isotopes analytical procedure and purification method have been developed for MC-ICP-MS in Neptune-TIMS lab at IGG-CNR. The data on rock and sediment samples will be integrated with analogous chemical and isotopic data from the ongoing water sampling to develop a conceptual model of lithium cycle and enrichment processes in this complex geological context. These findings could provide the basis for a sustainable lithium resource exploitation in the Northern Apennines and in other similar environments, supporting the targets that EU sets with the Critical Raw Materials Act (CRMA 2023).

Keywords: inverse modelling, shallow hydrothermal vent, passive hydroacoustics.

Submarine hydrothermal systems emit huge amounts of both elements and energy, in terms of gas, thermal water and solid deposition. The interest of the scientific community on these extreme environment is increasing, especially in the last few years. Moreover, direct measurements can be challenging due to the extreme environmental conditions (e.g. high temperature, low pH) (Longo et al., 2021).

In this framework, passive hydroacoustics may represent a sustainable and safe method for both short- and long-term monitoring, since the typical source mechanisms present in the hydrothermal fields radiate sound pressure following different acoustic modes directly related to ascending fluids release (Dziak et al., 2012).

Here we present preliminary results obtained by applying a spectral method [Roche et al. 2022] for estimating the gas flow emission rate starting from the acoustic dataset collected on a stationary flux vent (Leifer, 2010) located at ~1.8 metres depth, inside the shallow hydrothermal field at Baia di Levante in Vulcano Island (Aeolian Islands, Italy).

To carry out the estimation of the gas volume emitted by the hydrothermal vent we implemented an inverse modelling algorithm based on the formulation of a forward model for the sound radiated by the bubbles plume, then the path is backward analysed to obtain an estimation of the flow emission rate.

High-resolution audio frames were recorded by using an autonomous smart hydrophone, able to collect and store digitised audio frames in the frequency band [1 - 12800] Hz.

The hydrophone was moored close to the investigated hydrothermal vents, collecting 4 bursts of ~10 hours each at the maximum sampling frequency, between 1 and 2 September 2022.

The collected dataset was preliminarily analysed by employing various techniques of both spectral and waveform analyses, in order to obtain a characterization of the source, thus defining the vent spectral signature. Power Spectral Density (PSD), Power Spectrum and Spectrogram show different persistent energetic frequency peaks which are compatible with the typical mechanisms connected to the dynamics of the hydrothermal field. Among these, the most energetic one is centred around a frequency of ~100 Hz.

Direct optical observations confirmed the presence of bubble radii up to 0.03 m, generating the main energetic peak at ~100 Hz, along with smaller bubbles producing less energetic peaks up to 2000 Hz. Therefore, the inversion algorithm was applied to the dataset, considering the frequency range from 60 to 2060 Hz.

The estimated flow emission rate, which assumes a mean value of 4.51 liters per minute, is in good agreement with the direct observations. This confirms that passive acoustic methods represent a valid and robust tool for both monitoring and research activity in submarine hydrothermal fields, providing to be also a long-lasting instrument for the sustainable management of georesources, as it can detect the fluctuations connected to such natural systems.

Keywords: Gorno district, Alpine-type deposits.

The strata-bound, carbonate-hosted Pb-Zn-Ag (± fluorite ± baryte) districts of Gorno and Piani Resinelli belong to the Alpine metallogenic province located between Italy, Austria and Slovenia. The orebodies are hosted in the lower Carnian stratigraphic succession of the Lombardian Basin (Southalpine Domain, N Italy), mainly composed of peritidal limestones. The aim of this study is to constrain the ore-forming conditions using petrography, geochemistry, fluid inclusion microthermometry, and radiometric datings on both ore minerals and associated diagenetic products.

Petrographic studies reveal that the mineralization was preceded by dolomitization, silicification, and brecciation events. Thermometric data from primary fluid inclusions in dolomite, sphalerite, and fluorite indicate the involvement of moderately hot (T between 70 and 150 °C) and high-salinity fluids (up to ~20 wt % eq NaCl) during ore precipitation. Radiometric dating performed on associated diagenetic minerals which pre- and postdate the sulfide mineralization reveals that the precipitation of the ore minerals occurred during the LateTriassic. Moreover, *in situ* analyses (EPMA, LA-ICP-MS) of trace elements on sphalerite will be presented here, including their implications for ore-forming conditions.

Several similarities between Gorno and Piani Resinelli in terms of diagenetic evolution of the host rock, temperature and composition of the fluids, and timing of the ore precipitation highlight the possibility that both districts could be related to a unique, widespread Late Triassic hydrothermal system, in which metal-rich fluids flowed upward through faults and associated fractures. This circulation in the Upper Triassic stratigraphic succession caused major modifications in the host rocks such as multiphase dolomitization, silicification, dissolution, and brecciation, as well as the precipitation of ore minerals in a shallow burial setting.

Characterization of dual porosity in bioturbated carbonates: A case study of Cenomanian-Turonian platform carbonates from the Southern Apennines (Italy)

Keywords: bioturbated carbonates, Thalassinoides, petrophysical analysis.

Bioturbated carbonate sequences present considerable challenges in characterizing reservoirs for hydrocarbon exploration and exploitation, and for CO_2 storage. Bioturbation strongly influences the petrophysical properties of hosting rocks, creating sedimentary heterogeneities and often enhancing porosity-permeability properties. This study focuses on a detailed investigation of Upper Cenomanian-Lower Turonian bioturbated carbonate succession (75m thick) from the Apennine Carbonate Platform (Southern Italy).

A multidisciplinary approach has been applied, integrating facies, ichnological, and petrophysical analyses using non-invasive techniques such as Computed Tomography scanning (CT, Micro-CT), and Nuclear Magnetic Resonance (NMR). The objective was to explore and characterize the abundance of burrows, their connections, and describe pore-size distribution. Furthermore, geochemical (trace elements), mineralogical, and petrographic analyses (Scanning Electron Microscopy) were integrated to understand the correlation between bioturbation, poro/perm characteristics, and diagenetic processes.

The investigated sequence displays a boxwork pattern of burrows organized with a preferential horizontal network featuring vertical shafts exhibiting Y- or T-shaped branching morphology in a firmground substrate, indicating the dominance of *Thalassinoides* ichnotaxa. *Thalassinoides* traces and porosity increase upwards in the section. CT images reveal low tortuosity of burrow conduits, characterized by preferential vertical and oblique straight paths with circular to elliptical cross-sections. In the most bioturbated strata, approximately 39% of the total rock volume consists of burrows, predominantly filled with dolomite, exhibiting substantially higher porosity than the muddy matrix. Porosity estimated within bioturbation traces ranges from 1.8 to 17.7%, while matrix porosity ranges from 1 to 4.8%. Pore Size Distribution, estimated via Hg-porosimetry coupled with NMR, indicates larger pore sizes (up to 50 μm) in more dolomitized samples, while the smallest pores (0,01-1 μm) are found in the calcitic matrix. Micro CT images offer detailed visualization of pore sizes and pore network in both traces and matrix, facilitating the future fluid flow modelling. Finally, isotopic signatures of C and O in the burrows differ from those in the matrix.

The multidisciplinary dataset we present highlight the relevance of the combination of several methodologies to characterize heterogeneous carbonates to predict fluid flow, fluid-rock interaction and diagenetic evolution. Understanding these processes is fundamental for any subsurface storage project.

New paradigms for an energetic independence and sustainable development of minor volcanic islands in Sicily: opportunities from the geothermal resources

Urso S.*[1] & Viccaro M.[1-2]

Keywords: geothermal energy, sustainability, volcanic islands.

This study delves into the possibility of geothermal exploration to attain energy autonomy on small volcanic islands. Our case study is centered on the minor volcanic islands pertaining to Sicily (Southern Italy), i.e. those of the Aeolian Arc and Pantelleria, located respectively in the Tyrrhenian Sea and Sicily Channel. Importance of this issue relies on the energy challenges in the context of global energy demands and the imperative shift towards sustainable resources. This research strives to provide a comprehensive examination of the potential, benefits and potential drawbacks in adopting geothermal energy as the primary resource to establish self-sufficiency within ecosystems of small volcanic islands.

Foundation of this research is based on the present energy landscape on Aeolian Islands and Pantelleria, predominantly reliant on fossil fuels and only sporadically renewable resources. To address these challenges, a polyhedric research approach is adopted, encompassing resource assessment to identify and quantify geothermal potential (Floridia et al., 2022; PRIN 2022 PNRR P2022ZN4XP and CUP E53D23022050001), evaluation of existing infrastructure's compatibility with geothermal integration, environmental impact analysis. Investigation is aimed at assessing the environmental, social and economic implications, the technological feasibility evaluation for identifying the most suitable condition for the geothermal energy exploitation, and the analysis of legal and regulatory frameworks necessary to support and incentivize geothermal energy development.

The study finally endeavors to deliver a holistic view of opportunities and challenges associated with implementing geothermal energy solutions in the distinct context of small volcanic islands. The research underscores the critical importance of understanding economic feasibility and social impact of transitioning to geothermal energy captured in volcanic areas.

Corresponding author email: giovanni.vespasiano@unical.it

Keywords: geothermal resources, Calabria Region, thermal model.

The assessment of the geothermal potential of the subsurface is mainly based on the evaluation of the thermal and mechanical conditions of the lithosphere. Investigating thermal regimes demands a comprehensive understanding of geological features and their operational mechanisms (Floridia et al., 2022). This approach is particularly pertinent in complex and active geodynamic contexts such as the Calabria region (Italy, central-western Mediterranean), serving as a critical case study due to its largely unexplored geothermal potential. In the framework of the PNRR 2023-2026 projects (Tech4You), an effort was made to reconstruct the lithospheric state of Calabria to quantify its shallow and medium-depth thermal regime. Beginning with modelling including the entire Calabrian territory, the main geological units and their lithology-dependent properties were defined to create a 3D geological model consistent with available geological and geophysical datasets. This geological model served as the basis to compute the current thermal conductive field in a steady state. By incorporating physical properties like thermal conductivity and radiogenic heat production for individual lithological units (*e.g.*, Di Sipio et al., 2014), the temperature at each point in the study domain was modelled. Finally, the results obtained from the thermal modelling were validated by comparing them with measured temperatures derived from historical datasets from hydrocarbon exploration (VIDEPI Project). While strong assumptions were made for high-enthalpy resources, the identification of favourable areas for exploiting medium-to-low temperature gradients has been achieved. Maximum temperatures of 90°C at a depth of 3 km along the Ionian sedimentary basins and orogenic domains have been observed, with differences of about 20°C for the Carbonate units (~70 °C) in the northern sector. According to various studies on the geothermal potential in Calabria, Carbonate units represent the main geothermal reservoir (Vespasiano et al., 2023). The model suggests that other units hosted in the sedimentary covers and the crystalline basement may also represent important geothermal systems that require further studies. Future research will focus on transient thermal numerical simulations in a regional context and rheological models coupled with convective heat transport to achieve a more realistic approach to thermal response.

Keywords: Tertiary Piedmont Basin, geothermal reservoir, basin structure.

Geothermal energy, as a renewable and green source for energy production and heating/cooling activities, has a great development potential in many European countries. The dynamic tectonic history of Italy provides a favorable geologic framework for geothermal resources to be formed. Besides some volcanic regions, characterized by significantly hot manifestations, there are many low enthalpy geothermal fields. Only a few of them have been addressed and are mainly exploited directly as heat. Within this context, less evident and more complex systems suitable for developing new geothermal projects, become key areas for the energetic transition. Nevertheless, their exploration and future exploitation can only occur through the implementation of multidisciplinary methodologies, leading to a detailed characterization of the reservoirs.

Our main goal is to determine the geothermal potential of the Tertiary Piedmont Basin (TPB, north-western Italy) by revealing the thermal structure of the region, as well as the heating mechanisms and heat flow controls in the basin. The TPB records the dynamic evolution of the Alps-Apennines junction. It accommodates on average 3 km of sedimentary units (Eocene to Pliocene in age), which show marked lateral facies variations and tectonically-controlled depositional architectures (Di Giulio et al., 2024 and reference therein). These units and the underlying Alpine basement experienced multiple pulses of deformation, developing kilometric structures over a stretched lithosphere, which likely had a key role in increasing the geothermal gradient of the area (Amadori et al., 2023). Several hot springs up to 70°C (e.g., Acqui Terme) and moderately high surface heat flux, between 62 and 84 mW m-2 (Pasquale et al., 2014) have been observed in the TPB, evidencing its potential as a new geothermal resource. The location of the hot springs, north to the metamorphic basement outcrops, identify the last one as the recharge area of the meteoric water. Furthermore, the presence of a thin crust (30-35 km), revealed by recent seismic tomography studies (e.g., Nouibat et al., 2023), enhances the role of the deep structures in the formation of the geothermal reservoir.

In this study, we display the results of the first field campaign, carried out in the TPB, and the analyses of the available geological/geophysical data. These include the recognition of key lateral and vertical facies variations of the stratigraphic units and of first order structures present in the basin. These outcomes, together with the measurements of petrophysical parameters and fluid inclusion micro-thermometry from the sampled rocks, will be the main input for the implementation of the initial geological model. This workflow based on stratigraphic and structural analyses, as well as diagenesis, will be crucial for the evaluation of the geothermal potential of the TPB and could be applied on similar basins.

Keywords: basalt, CO_2, mineralization,

Carbon Capture and Storage technologies can help reaching Paris Agreement's temperature increase of no more than 1.5-2 °*C* from pre-industrial level. To meet this target, 10 Gt of CO_2 should be sequestered every year starting today and until mid-century. Most of the research is focus on sedimentary basins for their large storage capacity but CO_2 mineralization (which proved to be the safest process to sequester CO_2) in sedimentary basins can take thousands of years. On the contrary, basalts, due to mafic minerals (olivine, pyroxenes) presence, can provide faster reaction rates thanks to release divalent cations release (Fe^{2+}, Mg^{2+}, and Ca^{2+}) promoting carbonate precipitation.

CO2 injection in basalts has big prospect since it has been demonstrated that CO_2 carbonation occurs in less than 2 years (Iceland, Matter et al., 2016). Success of this pilot project encouraged researchers to focus more and more on injection in basalts. Despite the large interest of these last years, several aspects are still under investigation given especially the high variability of this kind of rocks. "Ageing tests" carried out in reactors to mimic reservoir conditions (high temperature and pressure) are valuable tools to understand the main processes driven by CO_2 injection.

In this research, we focused on basaltic rocks coming from Al-Birk and Harrat-Lunayyir regions in Saudi Arabia. We conducted a series of ageing experiments in a micro-reactor for different durations (2h, 16h, 48h) with Milli-Q water and powdered basalt (120- 250 μm- 2mm) at 110°*C* and 40- 50 bar CO2 pressure to understand the effectiveness of carbonation reactions in these short times. Mineralogic characterization (SEM and XRD) of solid samples and water chemical analysis were conducted before and after experiments to quantify mineral and liquid changes. Preliminary results confirm that CO_2 strongly promoted olivine dissolution; furthermore, pyroxene and plagioclase altered with consequent Ca release and calcite precipitation.

Mass balances calculations/estimates were performed to point out the main reactive processes occurred in the micro-reactor. Existing geochemical database will be enhanced with new site-specific mineral phases for olivine, pyroxene and plagioclases and geochemical model were done using PhreeQC (USGS, 1999). Geochemical models are used to predict long-term behaviour of injected CO_2 and together with Reactive Transport Model (RTM) are used to investigate the dynamics of CO_2 migration and mineralization pattern in reservoir. The results of this study can provide a quantitative indication of the potential efficiency of large-scale subsurface carbonation in basaltic rocks.

Keywords: exhumed geothermal system, hydrothermal mineralisation, Elba Island.

Migration and storage of geothermal fluids in the upper crust are mostly controlled by permeable rock volumes corresponding to crustal sectors affected by brittle deformation. Understanding how hot (250°-350°C) to super-hot (>350°C) fluids circulate and interact with host rocks in fault-controlled upper continental crust is a challenging task. The results from structural, fluid inclusion, Sr isotope, petrographic and mineralogical studies of the Terranera Fe-hydrothermal mineralisation, considered an exhumed palaeo-geothermal system, describe how hot to super-hot fluids were controlled by the increased permeability resulting from the interplay between low-angle normal faults and high-angle oblique-slip faults, the latter being part of a regional transfer zone (Zucchi et al., 2024). The study area is located in the eastern Elba Island (northern Tyrrhenian Sea, Italy), where the emplacement of a Messinian felsic intrusion has allowed hydrothermal fluids to circulate in relation to a fault-related permeability of the order of 10-15 to 10-13 m2. Magmatic fluids reacted with the host rocks (carbonate and phyllite) to form Fe-ore deposits hosted within the fault zones that controlled the fluid flow. Fluid inclusions trapped in quartz crystals indicate that the fluids consisted of saline solutions (salinity from 18.0 to 26.6 wt.% NaCl eq.), which later mixed with low salinity waters of probable meteoric origin. The fluid temperature during the main hydrothermal stage ranged between about 300° and 360°C under an estimated maximum hydrostatic pressure of 28–30 MPa. In contrast, the maximum possible temperature was about 400°C at a lithostatic pressure of 89 MPa. The hydraulic breccias formed as a result of the transient fluid pressurisation up to lithostatic values, due to the self-sealing process and the subsequent pressure drop, down to hydrostatic values, as framed in the hydrofracturing processes. The results provide useful input for the identification of geothermal and ore body targets in those geological settings where fluids of magmatic and meteoric origin are controlled by active faults in an extensional tectonic regime.

Desertification risk assessment using the modified MEDALUS model in the Alta Murgia karst plateau (Apulia, Southern Italy)

D'Ettorre U.S.*, Liso I.S. & Parise M.

Dipartimento di Scienze della Terra e Geoambientali, Università di Bari "Aldo Moro".

Keywords: desertification risk assessment, GIS, karst environments.

Desertification is nowadays among the most severe environmental problems in many countries, and threatens the integrity of natural environments and the sustainability of related natural resources. This work aims to assess the proneness to desertification in the Alta Murgia karst plateau (Apulia, Southern Italy) through the integration of the modified Mediterranean Desertification and Land Use model (MEDALUS, Kosmas et al., 1999) within a GIS-based approach. The model includes among its indexes: climate, vegetation, soil and management, all combined for assessing environmentally sensitive areas (ESAs) to desertification. Considering the karst features of the study area, the management index has been modified in order to evaluate the degree of disturbance in such a fragile environment. This was made by adding the Karst Disturbance Index (North et al.., 2009), consisting of many environmental indicators contained within five broad categories: geomorphology, hydrology, atmosphere, biota, and cultural. According to the model, preliminary results indicated that the whole area falls within a range from "Fragile" to "Critical" ESAs type, with no area that results "Non affected" or "Potential". This could be justified, more than by climatic or ecological factors, by a series of anthropogenic activities carried out over the years that strongly modified and disturbed the original karst landscape, causing a high negative impact on the Alta Murgia karst.

A global overview of desertification in karstlands

D'Ettorre U.S.*, Liso I.S. & Parise M.

Dipartimento di Scienze della Terra e Geoambientali, Università di Bari "Aldo Moro".

Corresponding author email: umberto.dettorre@uniba.it

Keywords: desertification, karst, human impacts, climate change.

Desertification in karst is an effect of climate change and not sustainable anthropogenic activities, the combination of which, however, causes the gradual loss of karst natural resources, such as soil, vegetation, and groundwater. A considerable percentage of global karst areas is found in drylands, characterized by negative water balance and scarce presence of soils. High fragility of the karst environment, and its vulnerability to land degradation and pollution because of the peculiar anisotropic setting, environmental dynamics, and of the direct connection between the surface and the subsurface, are at the origin of the severe problems deriving from desertification processes in karst. In addition to natural drivers, such as geology and topography, karst desertification is generally due to four main factors, mostly or partly related to human activity: deforestation, improper land use, groundwater overexploitation, and climate changes. Through the analysis of a collection of studies conducted in several karst territories around the world, the present work aims to provide an overview of the processes leading to desertification risks in karst areas. Emphasizing the need to preserve these fragile environments, characterized by peculiar features and precious freshwater resources, this review summarizes the main situations at the global scale of rocky desertification in karst, at the same time providing indications for developing innovative and multi-disciplinary approaches addressed toward mitigation of the risk related to desertification in karst.

Keywords: mineralization, thermal water, mineralogy, geochemistry.

In Albania, the presence of high mountain chains and active fault systems favors the ascent of deep waters producing several thermo-mineral springs. The most important springs are located in the Kruja Province and rise from deep karst aquifers. The Kruja tectonic zone (central Albania) consists of elongated anticline structures of Cretaceous–Eocene limestones and dolomites covered by Oligocene flysch deposits. It is affected by longitudinal NW-SE faults intersected by some transversal faults. The carbonate rocks have been buried up to ca. 10 km depth, and are underlain by Triassic-Permian evaporites. In the Kruja Zone, the geothermal gradient ranges from 7 to 11 mK/m. Five deep wells are present in the area (depth range 2000-3000 m) tapping thermal waters of carbonate aquifer. Three of these wells, namely Ishmi-1b, Kozan-8 and Galigat-2, are the most important as concerns water quality, temperature and curative values. Thermal waters in the central area of the Kruja province are of the Cl–SO4–Na–Ca type, with temperatures up to 56 °C for springs and 65 °C for wells, and high H2S concentrations (Eftimi & Frashëri, 2016).

Recent scientific activities carried out at the Kruja Province focused on Kozan-8 well (1837 m depth) at Elbasan locality, including water and deposited minerals sampling. Thermal waters discharge exhibits EC = 6400 microS/cm, temperature of 55.4 °C, pH = 6.73, and reducing Eh. Water composition shows similar high Na and Ca contents among cations, and high Cl and SO_4 among anions. According to previous studies (Eftimi, 1998; Reimann & Birke, 2010), this water composition can be related to the presence of deep fluids with long/deep circulation in the local anticline structures, involving Mesozoic carbonates (which contain also pyrite) and the underlying Triassic evaporites. Together with H2S (Eftimi & Frashëri, 2016), enrichment in CO_2, CH_4 and He has been also detected. At the emergence, the water results oversaturated with respect to Ca-Mg carbonates, and slightly undersaturated with respect to sulphates. Around the water discharge abundant mineral deposits are present, consisting of banded encrustations of different colours (white, grey, black, pale yellow, orange-yellow) formed from the outgoing hot fluids. Such mineralization was never analysed before. Combined optical microscopy and X-ray powder diffraction analyses evidenced that the studied encrustations mainly consist of micrometric-sized crystals of Ca- and Mg-sulphates (gypsum, $CaSO_4 \cdot 2H_2O$; bassanite, $CaSO_4 \cdot 0.5H_2O$; anhydrite, $CaSO_4$; epsomite, $MgSO_4 \cdot 7H_2O$), calcium carbonates (aragonite and calcite $CaCO_3$), and sulphur (S_8). Furthermore, Na-, K-, and Fe-sulphates (metavoltine, $K_2Na_6Fe_{2+}Fe_6^{3+}O_2(SO_4)_{12} \cdot 18H_2O$; sideronatrite, $Na_2Fe_{3+}(SO_4)2(OH) \cdot 3H_2O$) were sporadically found.

Terzaghi's effective stress principle and hydrological deformation of karst aquifers detected by GNSS and inSAR measurements

Leone G.*, Esposito L., Ginolfi M. & Fiorillo F.

Keywords: Terzaghi's principle, hydrological deformation, coefficient of earth pressure at rest.

Studies have shown a strong correlation between spring discharge variations and horizontal ground displacements measured by GNSS (Global Navigation Satellite Systems) stations located in karst areas of the Apennine chain (Italy), revealing that karst massifs undergo deformation in response to groundwater level variations (Silverii et al. 2019; Leone et al. 2023b). We investigated the relationship between the hydrological stage of karst aquifers and crustal deformation in the area of Matese massif (southern Italy). To this scope, we analyzed spring discharge, GNSS, and InSAR (Interferometric Synthetic Aperture Radar) time series. Unlike GNSS, which provides a local measurement of the ground motion, InSAR allows for monitoring more or less extensive areas, making it more effective in detecting vertical crustal deformation due to hydrological processes. Our analyses highlighted that contraction and dilatation phases of the karst massif are associated with decreasing and increasing phases of the spring discharge occurring at annual and multi-annual time scales. Various authors have explained this phenomenon by the widening and closing of sub-vertical water-filled fractures dissecting the rock mass due to varying hydraulic heads within these discontinuities, neglecting the role of the pore water pressure acting in the aquifer's saturated zone. In particular, given Terzaghi's effective stress principle, pore fluid pressure is a fundamental component of the in-situ stress field (Zoback, 2007). In the specific case of karst aquifers, pore water pressure variations up to thousands of KPa are expected to occur at depth primarily in response to water table fluctuations, inducing variations in the state of stress acting in a vast rock volume. We present new equations derived by Leone et al. (2023a), relating strain to pore water pressure variations due to water table fluctuations. These equations explain the observed deformational phenomenon in its generality and are based on Terzaghi's effective stress principle (Skempton's generalization) and linear elasticity. The proposed equations were derived assuming unconstrained and constrained conditions of the karst aquifer. In the first case, the karst aquifer is free to expand laterally, and the hydrological strain depends on the overall elastic properties of the karst rock mass and the coefficient of earth pressure at rest, $K0$. In the second case, an elastic aquitard laterally constrains the karst aquifer, and the strain induced by the change in pore water pressure also depends on the elastic properties and dimensions of the aquitard. The resulting strain is thus a fraction of the unconstrained hydrological strain. We show that karst aquifer hydrological deformation can be compared to the thermal expansion of solids. In particular, the hydrological deformation is due to changes in the pore water pressure that occur at depth and affect the aquifer's saturated zone, primarily, and the epiphreatic zone.

Short- and long-term changes in the discharge of the Caposele karst spring (Southern Apennines, Italy): statistics and modeling to understand their causes

Leone G.[1], Jourde H.[2], Ginolfi M.*[1], Esposito L.[1], Ventafridda G.[3] & Fiorillo F.[1]

Keywords: karst spring discharge, atmospheric warming, snow processes.

Decreasing trends have been detected in the time series of the Caposele karst spring (Cervialto massif, southern Apennine, Italy) since 1920. On the other hand, annual precipitation appears stationary over a long period in the area (Fiorillo et al., 2021). Considering this premise, we applied statistical analysis and hydrological modeling to investigate climate change in the karst area of the Cervialto massif and its possible impact on the groundwater resource. Statistical methods were employed to analyze short- and long-term trends in secular time series of climate and hydrological variables and correlations. As observed in other Mediterranean areas, the NAO (North Atlantic Oscillation) and NAM (Northern Annular Mode) large-scale atmospheric circulation patterns affect local precipitation and the occurrence of meteorological dry (drought) and wet periods. Statistical analyses also highlighted that annual spring discharge can be described by an autoregressive-cross-regressive linear model (Kresic, 2010), where the discharge in a given year is affected by precipitation and the discharge of the previous year. Although precipitation and memory effect explain most of the spring discharge variance, they do not explain the observed hydrological trend, suggesting that it must depend on other factors and complex processes. To investigate these aspects, we employed a lumped parameter reservoir model (KarstMod; Mazzilli et al., 2019) to simulate the recharge-discharge process of the Cervialto aquifer on a daily scale and to predict the response of the Caposele spring to various climate scenarios by simulation experiments. Given the topographic features of the spring catchment, the hydrological model was coupled with a snow routine, whose calibration and validation involved the analysis of climate data and Sentinel 2A satellite images. The hydro-meteorological model showed high performance in both calibration and validation periods and reliably simulated the overall hydrodynamic behavior of the Caposele spring catchment. Using the model, we investigated the specific impact of atmospheric warming on the recharge-discharge processes. Simulation experiments suggested a key role of temperature in the karst spring discharge regime. In particular, the 1.5°C atmospheric warming observed since 1999 would contribute to the decreasing spring discharge in the last decades. The analyses highlighted that the groundwater resource depletion observed since 1920 can be mainly explained by the combined effects of recent droughts (last three decades), the aquifer memory effect, and atmospheric warming. This work provides a comprehensive analysis of hydro-meteorological processes affecting the Caposele spring catchment and attempts to clarify the impact of atmospheric warming on karst groundwater resources in southern Apennine. In this region, karst aquifers are widely extended and are a primary source of drinking water.

Karst hydrology and geomorphology of the Matese and Alburni Massifs, (Southern Italy), focusing on dolines and endorheic areas

Leone G.[1], Liso I.S.[2], Michele G.*[1], Esposito L.[1], Parise M.[2] & Fiorillo F.[1]

Keywords: karst geomorphology, hydrological features, karst landform mapping.

Karst environments are peculiar settings characterized by a deep interaction between groundwater circulation and surface hydrology and landforms. Small- to large-scale morphological features typified karst terrains, such as ponors, shafts, dolines, poljes, caves, endorheic basins, etc. All these features play an important role in hydrological processes, as they control meteoric water runoff/infiltration, the transferring of water into the underground, and thus groundwater recharge. In this context, mapping the karst landforms and understanding their hydrological role represent the starting point for many investigations, including hydrological modelling of the surface runoff and groundwater recharge, delineation of protection zones for wells and springs, simulation of point source contamination, and artificial test planning. This contribution presents the results obtained from mapping studies that focused on the karst hydrological features of the Matese and Alburni massif (Southern Italy), illustrating landforms of typical karst environments from the hydrological perspective. The hydrological analysis of high-resolution Digital Elevation Models (DEMs) in a GIS (Geographic Information System) environment has represented the primary method used in map making, which has driven the identification of the dolines and poljes, first, and has allowed for the delineation of small- and large-scale endorheic areas, then. From the point of view of surface hydrology, an endorheic area constitutes a closed watershed with internal runoff, which conveys meteoric water toward ponors, dolines, and poljes, representing the most depressed points or areas of the watershed. Therefore, endorheic areas are peculiar parts of a spring catchment from which meteoric water cannot escape (Fiorillo et al., 2015, 2022). Using specific GIS-tools, all the closed depression in DEMs were automatically identified (Leone et al., 2022). The comparisons between morphometric features of mapped depressions and known dolines allowed a first distinction between real karst landforms and false sinks. Then, a visual inspection of various informative layers, including Google Earth images and DEM-derived contour maps and hill-shade, was carried out to support dolines delineations. Based on mapped doline location, endorheic areas were automatically delineated using the well-known Watershed GIS-tool. This contribution provides new insight into the hydrological karst features of Matese and Alburni carbonate reliefs controlling the infiltration and, thus, groundwater recharge. These aspects are of extreme interest for water resources management and protection.

Keywords: caves, karst, hydrogeology.

Underground water are precious freshwater resources especially in karst settings where often it represents the only available for local communities in many countries of the world (Stevanovic, 2015). Given the high vulnerability to pollution (Goldscheider & Drew, 2007; Ford & Williams, 2007) and fragility of such a resource, karst groundwater has to be protected and properly managed. To reach the goal, a deep knowledge of the geological and hydrogeological features can be considered the starting point to develop best practices and to plan good actions toward protection of underground water resources.

In karst, the integration of traditional geological approaches at the surface with direct exploration and surveying within the caves, by means of speleological techniques (Liso et al., 2020) guarantee a proper characterization of the environment.

In Apulia Region, the biggest karst areas in southern Italy, the freshwater resource flows within the fractured and karstified limestones. Among the over 2000 caves registered in the Regional Inventory, only two directly reach the water table far from the coastline. They have therefore begun open windows to the water table, ideal sites to perform in situ investigations and hydrogeological research. Moreover, close to the coastline, another cave reaching the water table is monitored, since it is located at the transition between fresh and marine water. In this contribution we present our efforts, performed through direct explorations in cooperation with cavers, to combine surface/subsurface data to enrich the available information about hydrogeology of Apulian karst systems, and to contribute to a better understanding of its main features.

A flank margin cave along the Adriatic side of Apulia, Southern Italy

Lorusso F.[1], Liso I.S.[2], Mastronuzzi G.[2] & Parise M.*[2]

[1] Gruppo Speleologico Ostunese GEOS, Ostuni.
[2] Dipartimento di Scienze della Terra e Geoambientali, Università di Bari "Aldo Moro".

Corresponding author email: mario.parise@uniba.it

Keywords: karst, coastal caves, flank margin.

Flank margin caves are caves developed in typical coastal mixing zones, following the model initially proposed by Mylroie & Carew (1990) for young eogenetic limestone rocks in the Bahamas and other carbonate islands in the Caribbean and the Pacific. Later on, the model has been proved effective also as concerns speleogenesis in coastal areas with hard carbonates. Among the main features of flank margin caves, the following may be mentioned: lack of fluvial sediments, and of evidence of running waters, such as scallops along the rock walls and vaults; typically rounded and smoothed cave morphology, with a spongework pattern in plan view; presence of many dissolutional notches along the walls. Overall, the caves result in interconnected passages and rooms at intersections about parallel to the coastline, with passages tapering out inland, moving progressively away from the mixing zone.

Apulia Region, in southern Italy, with about 900 km of coastlines, is certainly a sector of great interest for the analysis of ancient flank margin caves, produced in the past along the mixing zone and nowadays present at different altitudes above sea level, thus becoming markers of past highstands, and gaining importance in sea level change studies.

The Murge plateau is dissected by the Murgian Escarpment, a NW-SE striking direct fault bounding it toward the Adriatic Sea, and with significant morphological expression. The local bedrock, consisting of the Upper Cretaceous Altamura limestones, is overlain by the fossiliferous Ostuni limestones (upper Campanian-Maastrichtian), forming a stepwise morphology of a set of terraces lowering to the coast (Delle Rose & Parise 2003; Parise 2011). At the foot of one of such cliffs, the Sant'Angelo cave system opens at altitude of 150 m asl. The cave system has an overall length of 1.5 km, with main NW-SE striking passages developed along a fault-line; to this, anastomosing wide and low passages showing the typical mixing-corrosion morphologies are present, marked by rounded walls and swiss-cheese morphologies, and with absence of stream sediments or scallops; due to its present elevation, age of the system may be hypothesized as Lower Pleistocene (Arriolabengoa et al., 2017).

Observing evidence of coastal mixing-corrosion, that includes rounded wall morphologies, notches, anastomosing passages, and the lack of signs of sediments within cave systems, may demonstrate their origin as flank margin caves. In cases where these are found in areas rather far from the present coastline and at much higher altitudes, they are good indicators of past sea level, and quite often are better preserved than any other marker at the surface. Determination of their age can therefore provide new clues on Pleistocene sea level changes and/or in understanding coastal uplift along the western Mediterranean coast.

Keywords: hydraulic conductivity; fracture analysis; x.ray tomography.

Discontinuities in rock formations play a crucial role in various subsurface engineering and environmental scenarios, influencing groundwater movement, contaminant transport, as well as slope instability and strength reduction. This impact is particularly significant in heterogeneous and anisotropic fractured media. To accurately assess hydraulic conductivity, various laboratory permeability tests are commonly employed, such as head permeameter tests, falling head permeability tests, radial flow tests, and pulse tests. However, despite advancements in these methods, challenges persist due to limited understanding of the characteristics of rock discontinuities. These characteristics, including fracture aperture, roughness, orientation, and mineral coatings, can vary considerably and have a significant impact on hydraulic conductivity and groundwater movement. In this study, geo-structural and geo-mechanical analyses at the laboratory scale are coupled with 3D x-ray tomography and flexible wall permeameter to assess sample hydraulic conductivity variation among different samples of the Scaglia Rossa geological formation (central Apennines, Italy), one of the principal aquifers in the Umbria-Marche domain. The fracture analysis encompassed the microstructural classification of various tectonic features such as stylolites, veins, joints, and filling materials, along with the measurement of fracture roughness and aperture. Our proposed methodology provides a promising approach to assess fracture conductivity within individual rock samples, thereby enabling the development of mathematical models for water flow in fractured rock formations. These models can subsequently be validated against field measurements, offering valuable insights into subsurface hydrology and aiding in the sustainable management of groundwater resources of similar carbonate aquifers.

Estimation of recharge to the karst Scirca spring (Central Italy) by using conventional and modified APLIS methods: a comparison

Manucci A.*[1], Cambi C.[2], Fronzi D.[3], Liso I.S.[4], Mazzocca M.[5], Mirabella F.[2], Parise M.[4], Casadei S.[2], Tazioli A.[3] & Valigi D.[2]

Keywords: karst spring, effective infiltration, recharge.

Mean annual recharge to the karst Scirca spring, in the Umbria Marche Apennines, was evaluated for the 2010-2022 period, both by traditional methods based on the estimation of actual evapotranspiration on a monthly (Thornthwaite-Mather) and on an annual (Turc) scale, and by the multiparametric APLIS method (Andreo et al., 2008). This last determines the recharge to carbonate aquifers by combining five parameters: altitude, slope, lithology, soil type and infiltration landforms. Based on these parameters, a coefficient is calculated which is independent on the climatic conditions and represents the percentage of rainfall contributing to recharge.

All methods were used in a GIS environment. This allowed to spatialize both input data and results over the spring recharge area. As we dealt with a mountainous region, the contribution of snow was considered in the precipitation data. The limits of the recharge area were revised with respect to former studies (Valigi et al., 2012; Tamburini & Menichetti, 2020) by carefully updating the geological information and by using as a base five newly drawn geological cross sections intersecting with each other. Since a highly developed karst system and numerous normal faults are present in the Scirca spring recharge area, the modified version of APLIS (Errahmouni et al., 2022) was used, in which the parameter related to infiltration landforms is determined as a function of three factors, one of which is the distance from faults. A further factor influencing this parameter was here considered the presence of surface karst landforms.

Results obtained by the Thornthwaite-Mather and the Turc methods were similar to each other and indicated that the mean annual water surplus over the spring recharge area is slightly higher than 60% of mean annual precipitation. Such amount corresponds to the average annual discharge of the spring. This indicates that the water surplus contributes entirely to the aquifer recharge and that the runoff is negligible, which is consistent with the geological characteristics of the area.

The modified APLIS method shows results which are coherent with those obtained by the traditional methods and indicate that recharge to the aquifer feeding the spring corresponds to 62% of mean annual rainfall.

The findings of this study update and partially modify those or former investigations on the same area (Valigi et al., 2012) and indicate that the whole water surplus contributes to the aquifer recharge, unlike previously assumed by using climatic and discharge data less reliable than those now available.

It can be noticed that the APLIS method indirectly estimates the water amount not contributing to recharge but, unlike the traditional methods, does not give any information on the way this amount is split in runoff and ETR. Besides, APLIS represents a viable alternative to traditional methods when reliable temperature data are not available, which is often the case of karst mountains areas.

Keywords: doline, karst, hydraulics.

In karst environments, dolines (sinkholes) represent one of the most typical landforms. Beside their genesis, and the mechanisms at the origin of their formation (Gutierrez et al., 2014), an interesting aspect to explore is that dolines play a very important role as concerns the possibility of subsoil infiltration for surface water, and therefore for the recharge of karst aquifers (Stevanovic, 2015). Starting from these considerations, this contribution is intended to deal with the hydraulic role of dolines in different karst settings. To this aim, we will describe some situations in karst environments of Apulia, southern Italy (Pisano et al., 2020, 2022), where dolines have been mapped and classified according to the main sinkhole classification by Gutierrez et al. (2014). In detail, the dolines mapped in the main polje of central-southern Apulia, Canale di Pirro, are of remarkable importance for allowing the slow infiltration of water underground, given that the majority of dolines belong to the suffusion and solution categories (Pisano et al., 2020). On the other hand, in another sector of Apulia, the Salento peninsula, most of the dolines belong to the category of collapse sinkholes (including both cover-collapse and caprock collapse sinkholes; Pisano et al., 2022), with a quite different behaviour as regards the hydraulic functioning.

Seawater intrusion and coastal karst aquifers in Apulia: status, challenges and future scenarios

Mostafa M.F.*, Liso I.S. & Parise M.

Dipartimento di Scienze della Terra e Geoambientali, Università di Bari "Aldo Moro".

Keywords: seawater intrusion (SWI), karst, modeling, Apulia and, climate change.

One of the most difficult and pervasive environmental issues threatening the sustainable use and quality of fresh groundwater supplies in coastal aquifers is seawater intrusion (SWI). Karst aquifers present a significant challenge due to their unique and complicated properties that set them apart from other types of aquifers. Large voids, leading to high flow rates, and water velocities up to several hundred meters per hour, are expressions of the great heterogeneity controlling karst groundwater movement. Therefore, the hydrogeological approach tools, like piezometric measurements, pumping tests, potentiometric maps, and hydraulic data tests, derived from well observations are largely ineffective in proper evaluating the hydrodynamics in karst terrains. Apulia Region, with over 800km of coastline and a semi-arid Mediterranean climate, represents the most remarkable karst regions in southern Italy. It hosts the amount of freshwater within the karstified carbonate aquifer, representing the main water resource for locals and tourist communities. This study focuses on the evaluation of the seawater intrusion effects on coastal karst aquifers through hydro-chemical data analyses and the realization of hydro-geomorphological maps. Moreover, the scientific activities aim to develop a unique procedure to assess future scenarios in terms of groundwater vulnerability and saline intrusion extension, taking into account climate change effects and rising freshwater demand for human, industrial and agricultural purposes. Using multiple ion plots, the hydrochemical results demonstrate a moderate to somewhat high degree of mixing between fresh and saline water, particularly in samples with higher Na+ and Cl- concentrations. Meanwhile, in the samples that have higher concentrations of HCO- and Mg+2, their salinity can be attributed to mineral exchange. Nevertheless, it may be inferred from the combination of hydrogeological and geomorphological maps that regions with a high degree of karst landform development are also likely to have substantial salinity intrusion. since doline and sinkholes play a fundamental role in terms of increasing the seawater flux into karst aquifers. As a result, the assessment of groundwater vulnerability to salinization will allow us to define the areas highly susceptible to seawater intrusion. Furthermore, taking into account the effects of climate change and the growing demand for groundwater freshwater resources, modeling approaches will be used to estimate the aquifer's quality and quantity over time. Multi-approach studies like this are useful tools for developing further and more detailed research, and might contribute to improving groundwater management plans in the Karst region.

Palude del Capitano (Apulia, Italy): a natural coastal laboratory to monitor biological diversity and dynamics of karst hydrogeology

Onorato M.*[1-2], Di Capua I. [3], Liso I.S.[1], Onorato R.[2], Congedo M.[2], Poto M.[2], Palmisano G.[2], Puglia G.[4], Zini L.[5] & Parise M.[1]

Keywords: karst hydrogeology, coastal sinkhole, biodiversity

Coastal karst is characterized by fast evolution due to the simultaneous action of marine and terrestrial processes. Being a peninsula with mostly low-land topography, Salento (Apulia, S Italy) shows complex hydrogeological features related to the groundwater circulation and its interaction with seawater (Liso & Parise, 2023), including the rising of sulphureous deep water (D'Angeli et al., 2021).

The site of Palude del Capitano, along the Ionian side of Salento, represents a natural coastal laboratory for monitoring the high level of biodiversity and to comprehend the dynamics of karst hydrogeology in coastal settings. This wetland area, consisting of collapse sinkholes (Gutierrez et al., 2014) of different size, is flooded by brackish water and characterized by hypothermal waters (T about 19°C) of deep origin, with constant flow throughout the year. It is therefore important to explore the likely correlations between these mixing waters and the high rate of biodiversity.

The aim of this research is to study and analyze the influence of the dynamic equilibrium among the sulphureous, fresh, and marine waters on both rock dissolution process and biodiversity. To reach this goal, Palude del Capitano will be instrumented to become a natural laboratory. Multiparametric probes will be installed to measure physical water parameters like pH, conductivity, temperature and level; further, flow meters will be placed in correspondence of the main freshwater springs and in the narrow channels connecting the sinkholes to the sea, to assess the spring flow rate and the equilibrium between fresh and marine waters, in function of both tides and sea-storms, as well as the migratory flow of euryhaline species.

Moreover, limestone and calcarenite stone tablets will be positioned in transects within the flooded zone of the main sinkhole to assess the dissolution power of such complex mixing water on different rock types. The rock tablets will be placed at different depth of the lagoon to evaluate the dissolution power of sulphur water on rocks, and at different distance from the sea, in order to evaluate the effect of brackish water fluctuation. The role of scuba divers, operating to contribute to the success of the monitoring through actions of Citizen Science, will be crucial to properly install the instrumentation and during the hydrogeological and biological sampling campaigns.

Keywords: karst aquifer, isotope, hydrogeology.

Karst aquifers are among the most complex water storage and circulation systems. La Spezia karst aquifer is composed of Mesozoic formations with a main limestone component that belongs to the Tuscan nappe. Hydrochemical and structural geology studies carried out in recent years in this area made it possible to reconstruct the hydrogeological flow of the karst system, which consists of separate underground circuits, mainly controlled by tectonic lines. New water sampling was conducted in the time interval February-April 2022, to carry out new chemical and isotope analysis.

Previous research has highlighted fast shallow karst conduits with a high variation in terms of water turbidity among the main springs of the town of La Spezia (Brozzo et al., 2013).

According to similar research in karst aquifer (Ronchetti et al., 2023), knowing the values of the isotopes of hydrogen (δD) and oxygen ($\delta^{18}O$) allows us: to define the origin of the groundwater; to confirm the mixing between fresh groundwater and seawater; to assume the altitude of the groundwater recharge area.

The results of the isotopic analyses have shown that for most of the groundwater samples the δ18O/altitude linear correlation is respected (Tazioli et al., 2019; Deiana et al., 2020). Nonetheless, some samples taken from water springs in alluvial deposits in the town of La Spezia show more negative isotopic values, highlighting a groundwater recharge area at higher altitudes. This implies the existence of deep and buried below alluvial deposits karst conduits, which connect the outflow area with recharge areas at higher altitudes, which are located in the main reliefs at north-west from the La Spezia city. The geometry of these conduits is mainly controlled by the geological structures (faults and folds) and the dissolution degree of the different limestone formations of the area.

Hydrochemistry analyses confirmed the presence of different groundwater flow paths, characterized by different lengths and different water transit times, and by the presence of seawater intrusion phenomena along the seacoast.

Nevertheless, the new results of the research, to be able to exploit the water of this aquifer for drinkable purposes it is necessary to continue the groundwater monitoring and to improve knowledge about the hydrogeological behavior of the deepest karst conduits.

Preliminary insights on hydrogeology of Mount Toc from 3D modeling

Riva A.*, Longanesi G. & Ghirotti M.

Dipartimento di Fisica e Scienze della Terra, Università di Ferrara.

Corresponding author email: alberto.riva@unife.it

Keywords: Vajont landslide, karst hydrogeology, fractured Aquifer.

The Vajont Landslide is one of the major man-triggered disasters of the XX century. A vast and detailed knowledge about the geology, geomorphology, geomechanics and modelling of the landslide, results in more than two hundred publications on these topics. However, groundwater conditions of the south slope of the Vajont Valley are poorly known, even if they are a major conditioning factor for slope stability. The existence of two aquifers in carbonate rocks on the north slope of Mt Toc, was hypothesized by Hendron and Patton (1987), supported only by measured piezometric levels before 1963. In their hydrogeological model the water table in the highly fractured and permeable older landslide mass was influenced by the reservoir; the lower aquifer in the Vajont Limestone (OOV) was fed by both the reservoir and precipitation in the Mt Toc watershed. This model implies that high water pressures may have developed in the slope due to rainfall and snowmelt infiltration.

A detailed review of existing data, coupled with geological/hydrogeological surveys led us to build a 3D geological model of the Mt Toc, to unravel the hydrogeological structure that contributed to the triggering of the Vajont landslide in addition to anthropic factors.

The main aquifer below the 1963 landslide is hosted in the OOV, confined by two aquicludes/aquitards at the top (Fonzaso Fm) and at the bottom (Igne Fm), depending on their degree of fracturing. The topmost portion of Mt Toc, where the OOV outcrops, is characterized by the abundance of karst features, such as *karren* and dolines, unfortunately without accessible caves. This portion of the slope is partially covered by continental carbonate breccias that in the past were misinterpreted as belonging to the OOV: the discovery of these breccias allowed us to better evaluate the vertical throw of the known reverse faults which bound the landslide to the south.

The preliminary 3D geological-hydrogeological model shows that the E-W faults theoretically deflect towards the west most of the groundwater contained in the OOV. This imply that a decreasing of the groundwater inflow and pressures at the top of OOV, suggesting further structural/hydrogeological complexity has to be taken in account.

The 3D hydrogeological model, however, is not completely able to predict the location the few water springs from the karst/fractured carbonates aquifer. A rough hydrological balance indicates an average discharge of about 100 l/s from the main aquifer, but the observed outputs are only a fraction. These discrepancies pose a question regarding the faith of the groundwater which flows into the OOV. A modern hydrogeological survey, never been carried out, may clarify the role played by groundwater in conditioning the slope stability.

Keywords: karst springs, water geochemistry, Albania.

The complex geological and geomorphological features of Albania allowed the formation of highly heterogeneous hydrogeological structures, resulting in different types of groundwaters, in function of aquifer physical characters, discharge and its variability, hydrodynamics, and hydro-chemistry. Karst springs drain huge amounts of water, as at the Blue Eye, Vjroi and Black Eye springs, representing important sources for human purposes, and at the same time a remarkable tourist attraction for the beauty of the surrounding landscapes.

Recent scientific studies have been performed at several Albania springs belonging to the thermal water provinces of Kruja, the PeriAdriatic Depression Basin, and the South Ionian (Eftimi & Frasheri, 2013; Eftimi et al. 2022, 2023). Thermal water reservoirs of Albania are typically contained within carbonate aquifers associated with evaporites and molasses. The aim of this research is mainly addressed to the assessment of water geochemistry composition of some of the main fresh and thermal springs in central and southern Albania, both along the coastline and inland, up to the border with Greece. Thirty-four samples were collected in December 2023 and January 2024, including 16 samples from large flow rate cold springs, and 12 from 3 thermal systems and several rivers. Chemical-physical parameters were collected on-site, alongside with samples for the determination of major ions, water and carbon stable isotopes and, at some sites, for dissolved gases. Cold waters are characterized by temperatures from 10 to 16°C, pH from ~7.3 to ~8.0 and conductivity from 210 to 550 microS/cm, while thermal waters have temperatures ranging from 23 to 55°C, pH from ~6.7 to ~7.2, and conductivity from 1600 to 6300 microS/cm. Cold groundwaters from the main karst aquifers are characterized by a typical Ca(Mg)-HCO3 composition with, in several cases, a slight enrichment in SO_4. Only one sample along the coastline shows evidence of interaction with seawater. The thermal waters, on the other hand, show two different hydro-types, characterized, respectively, by Na-Cl and Ca-SO_4 facies. Most of the cold groundwaters show dissolved carbon and gases from shallow sources, whilst deeper contributions cannot be ruled for the thermal waters. These latter, therefore, will be further investigated by means of ongoing data analyses that will shed light on their processes and fluids sources.

The Bossea Karst Hydrogeology Laboratory

Vigna B.* & Fiorucci A.

Dipartimento di Ingegneria dell'Ambiente, del Territorio e delle Infrastrutture, Politecnico di Torino.

Corresponding author email: adriano.fiorucci@polito.it

Keywords: carbonate aquifers, monitoring, climate change.

In the Bossea Cave (Southern Piedmont, Ligurian Alps) a laboratory has been active since 1982, mainly dedicated to monitoring the waters of the carbonate aquifer. Generally, the springs fed by karst aquifers are monitored but little is known about how the water resource is generated through a network of karst conduits (transmissive function) and the very extensive network of discontinuities characterized by very limited karstification (capacitive function). In Bossea the main watercourse receives an innumerable series of inputs linked to water circulation in the discontinuities affecting the carbonate mass. The monitoring system installed in the cavity (acquisition, every 15 minutes, of the flow rate, electrical conductivity and water temperature values with real-time data transmission) therefore concerns the main collector and 9 secondary water inputs. Through the monitoring data it was therefore possible to understand the functioning of the aquifer in different hydrodynamic conditions and in the different areas of the system. First of all, the importance of discontinuities in the circulation of groundwater is evident: near the surface (up to a distance of over 100 m) pistoning phenomena dominate, highlighted by increases in the values of the discharge, temperature and electrical conductivity of the water following significant infiltration. Deeper in the rock mass these values tend to become more constant over time with little relationship with the surface meteorological situation. The karst collector, fed by the different portions of the carbonate aquifer and partly also by the waters flowing on the impermeable rocks that limit the karst structure, has flow speeds that are strongly conditioned by the hydrodynamic situation. During flood periods the speeds even exceed 2400 m/d while in low water they are less than 600 m/d. The circulation in the discontinuities (always inferred with dye tracers) is completely different with values between 10 and 60 m/d. Very interesting are the monitoring data over time (42 years) heavily influenced by climate changes during which situations of significant periods of drought or flood events occurred. In long low periods the discharge remains at values no lower than 50 L/s supported by the contributions of the circulation in the capacitive network of the system while following exceptional rainfall the discharge reaches values very similar to ordinary floods (1500 L/s) due of the runoff phenomena that occur on the karst surface. The changes in flow in the winter period linked to snow melting processes are very evident: the minimum discharge has gone from 50 L/s in the 1980s to the current 100 L/s due to the increase in temperatures.

A karst area shared between carbonate megabeds and siliciclastic units: the example of Mt. Bernadia (NE Italy)

Zini L.*[1], Calligaris C.[1], Finocchiaro F.[2], Ponton M.[2] & Potleca M.[3]

[1] Dipartimento di Matematica, Informatica e Geoscienze, Università di Trieste. [2] Circolo Speleologico Idrologico Friulano. [3] Direzione centrale difesa dell'ambiente, energia e sviluppo sostenibile - Servizio geologico, Regione Autonoma Friuli Venezia Giulia.

Keywords: karst hydrogeology, dye tracer, geochemistry.

A significant portion (28%) of the entire Friuli Venezia Giulia Region (FVG) (NE Italy) comprises carbonate aquifers, many of which are extensively karstified and exploited for drinking purposes. Ensuring water availability and protection remains a critical priority to meet the rising demand driven by population growth. In pursuit of this goal, according to the FVG Regional Law 15/2016, the Department of Mathematics, Informatics and Geosciences of the University of Trieste and the Geological Survey of the Friuli Venezia Giulia Region started a multi-year project aimed at identifying regional and cross-border karst aquifers and assessing their vulnerability. Among the 130 karst areas recognized, one of the most peculiar area is the one of Mt. Bernadia. Sited in the Julian Prealps, it has a particular hydrogeological and karstic context where several megabeds of calcarenites and carbonatic breccias alternate within marls and siliciclastic sandstones of the Flysch formations (Paleocene – Eocene) lies on the limestones of Cretaceous platform. Megabeds are highly karstified, with important sub-horizontal caves draining groundwaters and impressive caprock sinkholes involving siliciclastic materials. The landscape contrast between the characteristic fluvial landforms and karst features is impressive. In order to improve the knowledge of the Mt. Bernadia aquifer, detailed hydrogeological surveys, electrical conductivity, temperature and water level in continuous monitoring were realized. In adjoin geochemical investigations as well as dye-tracers were scheduled. The experiments were realized thanks also to the contribution of the speleological associations, in particular to Circolo Speleologico e Idrologico Friulano and Gruppo Speleologico San Giusto. Data acquired evidenced how carbonate megabeds experience a mature karst where caves and conduits often develop at the contact between carbonates and siliciclastic layers giving rise to peculiar features: caves develop both thanks to solutional and erosional processes. The presence of several sinkholes also in correspondence of a siliciclastic cover, allow anyway a fast and concentrated infiltration of the waters reaching quickly the karst hydrostructure in the megabeds. Here the groundwaters are guided by the dip of the strata and the main tectonic features. Being in a mature karst system, travel times are quite short and as consequence the vulnerability is high.

Corresponding author email: qlnnnl@unife.it

Keywords: Sardinia, granite extraction waste, recycling

The large amount of granite quarrying waste scattered on the island of Sardinia (Italy), accumulated during a time when this region was a leader in granite extraction, poses challenges from several perspectives: landscape degradation, potential pollution problems and soil impoverishment. In a context where ecological and digital transition needs lead to a continuous growth in demand for raw materials, reconsidering quarry waste materials not as waste, but as potential resources, becomes imperative. Consequently, the identification of possible solutions for their utilisation could not only mitigate the problems arising from the presence of such waste, as previously highlighted, but also provide a contribution in the context of raw material supply.

This study focuses on a granite quarry located in the municipality of Buddusò, in central-northern Sardinia. Over the decades of granite extraction activity, in this quarry, several hundred thousand cubic meters of extraction waste have accumulated in designated landfill areas. The objective of this study is to identify innovative solutions for the utilization of this waste in the context of raw material supply including quartz and feldspars crucial for the ceramic industry, as well as Rare Earth Elements. By unlocking the latent potential of these granite extraction byproducts, we aim to find solutions to give new life to extraction waste by contributing to a paradigm change in the supply of raw materials.

The waste samples were characterized using cutting-edge analytical techniques such as WD-XRF, ICP-MS, SEM-EDS, and observation under a polarized light optical microscope. Subsequently, a processing method was tested on some samples of this material, including crushing, screening, gravity separation, and magnetic separation, in order to obtain a series of concentrates from the initial waste material. The resulting material was then analyzed using the aforementioned analytical techniques to assess their potential areas of utilization.

Exploring critical and strategical raw materials recovery potential from mining waste: findings from some Italian historical mining districts

Baldassarre G.*, Fiorucci A. & Marini P.

Keywords: mine waste, critical raw materials, recovery.

The growing demand for emerging green technologies, crucial for advancing ecological sustainability and digitalization, presents new challenges to European institutions. The European Union (EU) has conducted assessments and compiled a list of critical raw materials (CRMs) and strategic raw materials (SRMs) necessary for producing these technologies. Consequently, recent policy initiatives have been developed to reduce the EU's dependence on external suppliers and promote circularity and sustainable sourcing practices, focusing on increasing internal production of SRMs and CRMs. This includes taking measures to investigate the potential for recovery of CRMs from extractive waste as a priority action (European Commission, 2023).

Significant amounts of valuable minerals were disregarded during previous mining operations and relegated to waste streams, including tailings or waste rock piles. In Italy, mining wastes are distributed in more than 500 sites within the country, according to the official National Inventory of Mining Waste Facilities (ISPRA, 2022). Moreover, this waste could also create sanitary and visual environmental impacts and contain substantial quantities of waste material that may comprehend valuable amounts of raw materials overlooked in past industrial operations.

The overall objective of this work is to implement a data-driven circular economy approach within the extractive industry, emphasizing the reuse and recovery of end-of-process materials, seeking to establish a zero-waste supply chain for raw materials and rehabilitate abandoned and polluted mining areas. A multi-step approach was designed, integrating publicly available information from governmental sources, scientific literature, and field data. Bibliographical research from modern and historic literature was conducted and data were collected to narrow down the selection of potential abandoned mining sites in Italy for detailed investigation (Baldassarre et al., 2024).

The historical mining districts of Traversella (Piedmont) and Libiola (Liguria) were selected for a detailed investigation. Sampling campaigns were realized by collecting mine waste to characterize them in terms of chemical and mineralogical composition using both on-site portable XRF analyses and laboratory analytical techniques, such as Optical Microscopy (OM), X-ray Powder Diffraction (XRPD), Scanning Electron Microscopy (SEM) and Induced Coupled-Plasma Mass Spectroscopy (ICP-MS). Based on the results obtained, some valuable minerals and elements were identified. Overall, this approach can potentially identify an alternative source of raw materials, utilizing mine waste as a potential source of SRMs and CRMs.

Keywords: mine waste, reprocessing, magnetic separation.

Recent European Union policies are aimed at exploring extractive waste and potentially identifying alternative sources of Critical or Strategical Raw Materials. Italy had an active base metals mining industry throughout the 20th century. However, these activities were gradually abandoned starting from the 1970s due to political and economic factors. The Traversella mine district is located about 55km North of Turin, Piedmont, Italy and it is characterized by a polymetallic Fe-Cu-W pyrosomatic "skarn" deposit hosted in the Sesia-Lanzo geological unit. Historically, mining operations can be dated back to the Roman period through the Middle Ages. The modern exploitation of the deposit commenced in the XVIII century producing more than 300,000 metric tons of iron ore in its first century of activity. Due to the implementation of more efficient processing techniques, starting from the XX century Traversella mine also produced scheelite, chalcopyrite and uraninite concentrates. Mining operations ceased in 1971 due to economic reasons (Costa et al., 2019).

The presence of mining waste in the area is documented in the National Registry of Extractive Waste Facilities, particularly in regions proximate to the former processing plant and mine adits (ISPRA, 2022). This study encompasses the characterization and reprocessing trials of waste rock samples sampled from waste sites within the Traversella mining district for assessing the potential recovery of valuable minerals. Laboratory-scale mineral processing trials were conducted to produce mineral concentrates from the waste. Initial chemical and mineralogical characterization involved Optical Microscopy (OM), Scanning Electron Microscopy (SEM), and X-ray Powder Diffraction (XRPD) techniques. The analysis revealed the presence of metallic-bearing minerals in the waste, notably magnetite.

The designed process consisted firstly of a crushing and comminution circuit comprising a jaw crusher and a rod mill. For each stage of the crushing process, sub-samples were obtained to determine the free-grain size using OM and SEM image analyses. Comminution products were divided into two size classes suitable for magnetic separation. The coarser class between 0.250 and 0.125 mm was treated using a dry low-intensity magnetic separator (LIMS), while the finer size class below 0.125mm was treated using a wet high-intensity magnetic separator (WHIMS). Consequently, products with elevated concentrations of Fe and other minor components such as Cu, Mn, and W were obtained.

Towards a Green transition: tools and protocols to help decision makers and companies to decide if and when applying extractive waste exploitation as an alternative to remediation

Dino G.A.*[1], Mancini S.[1], Casale M.[2], Tazzini A.[1], Faraudello A.[3] & Rossi P.[2]

Keywords: decision support tool, extractive waste exploitation, green transition.

Extractive waste (EW) facilities pose serious problems concerning environmental impacts, health safety and slope stability. Their management causes economic and social impacts, which, together with the environmental ones, have to be considered by decision makers and companies to evaluate the best solution for the management of the investigated EW facilities. On the other side, the supply of raw materials (RM), including the critical ones (CRM) is a challenge to face in order to guarantee the EU's high development standards. The huge demand for RM and CRM has therefore prompted Europe to adopt policies to find alternative and integrative sources to exploit.

In the last decades, strong effort has been put to prevent, reduce and minimize the negative environmental impacts from the management of the EW, through the adoption of new management strategies and technologies. The extraction and recovery of RM and CRM from landfills and EW facilities and production cycles, applying respectively landfill mining and circular economy approaches, can offer not only economic but also environmental and social benefits. In order to assess, quickly, whether EW facilities prove to be sufficiently rich to become potentially exploitable, the use of investigation protocols and decision support tools (DST) are here presented.

Tools and protocols help in deciding if an EW facility is worth to be consider as "sustainable exploitable" to improve RM and CRM supply from anthropogenic deposits. In particular, trying to provide, depending on the quality of site-specific data, preliminary or secure assessment of the feasibility of EW exploitation, incorporating the social, environmental and economic factors involved in exploitation processes, a DST for EW has been defined. This tool investigates EW facilities both with quantitative (technical, economic, environmental) and qualitative (social) data. The outputs of the DST are represented by several possible scenarios, useful to decide if and how to approach EW exploitation. The DST uses site-specific information to identify which parameters contribute to make EW viable, the costs and benefits, the social and environmental impacts and the fittest process to mine the EW facility. Thanks to the DST it is possible to study different alternatives for EW exploitation: for example, remediation of the EW facility area; production of filling materials for road construction and infrastructures, SRM for aggregate production in-situ or off-site; exploitation of RM and CRM, etc. It is fundamental to define the type of EW facilities interested by the recovery and to propose different scenarios for EW recovery and associate to each of them the technologies and actions necessary for obtaining specific products.

Protocols for investigation at field and laboratory scales together with DST have been tested and validated using data and processing flow chart of real case studies: one of them will be here presented.

Standardization of innovative construction products as a tool for market up-take

Dolenec S.*[1-2], Pavlin M.[1] & Ducman V.[1]

[1] ZAG-Slovenian National Building and Civil Engineering Institute, Ljubljana.
[2] University of Ljubljana, Faculty o Natural Sciences and Engineering, Department of Geology, Ljubljana.

Keywords: standardization, construction products, secondary raw materials.

To advance the objectives of the European Green Deal and the Circular Economy Action Plan, the use of secondary raw materials in construction is promoted through the development of innovative construction products. However, the introduction of new products in the construction industry requires involvement of the standardization. This often means that relevant standards, such as harmonized standards, need to be identified for the assessment of products under the Construction Products Regulation (CPR). In cases where such standards do not exist, alternative routes, such as European or national assessment procedures, must be considered.

This contribution looks at waste management legislation, the processes for converting waste into products and construction product regulations. The most important aspects of EU legislation on waste (e.g. the Waste Framework Directive and the Landfill Directive) and construction products (in particular the Construction Products Regulation-CPR and REACH) are presented. It also outlines the legal framework for the transformation of residues from waste into products. When waste is classified as such, its use for construction purposes is subject to environmental and health protection requirements laid down in both EU and national waste legislation. However, once ceases to be waste, it is considered a product and falls under product-related legislation. Consequently, the use of waste in construction is regulated under the CPR by harmonized European product standards (hENs) and REACH. In cases where there are no EU-level criteria for waste streams, individual Member States set their own End-of-waste (EoW) criteria. According to EU regulations, CE marking is mandatory for products covered by the CPR if a hEN exists. For novel or innovative products that are not covered by a hEN, manufacturers can obtain the CE marking through the European Technical Assessment and the associated assessment and verification of constancy of performance (AVCP) procedures.

Selected examples from our recent European research projects dealing with the use of various secondary raw materials in construction products and possible EU procedures for the legal market introduction of these products will be presented. These projects envisage the incorporation of construction and demolition waste, steel slag or biomass ash into non-traditional concrete materials. Overall, these examples illustrate the potential benefits of using secondary raw materials in construction products and the need for regulations to support their market introduction, resulting in innovation drive and creation of a more sustainable built environment.

Transforming extractive waste into ceramic innovation: a comprehensive characterization and recycling study

Fantini R.*[1], Bernini M.[1], Conte S.[2], Zanelli C.[2], Dondi M.[2], Gualtieri A.F.[1] & Arletti R.[1]

[1] Dipartimento di Scienze Chimiche e Geologiche, Università di Modena e Reggio Emilia.
[2] Istituto di Scienza, Tecnologia e Sostenibilità per lo Sviluppo dei Materiali Ceramici, CNR, Faenza (RA).

Corresponding author email: riccardo.fantini1@unimore.it

Keywords: extractive waste, raw materials, ceramic industry.

The recycling of extractive waste (EW) holds the promise of transforming landfills into valuable resources akin to "new mines," benefiting quarrying and recycling industries, as well as the environment and society. Thorough characterization of the selected EW are essential to find the most suitable industrial field of application, as the potential for recovery largely depends on the waste's chemical composition, mineral makeup, and physical properties.

This study focused on EW obtained from a company specializing in producing construction aggregates. These aggregates primarily consist of organogenic limestone and calcarenites. The extraction process involves blasting the ore, followed by transportation to two separate dressing plants for crushing, washing, and sieving. The EW originates from two water clarification systems treating effluents from the aggregate washing plant. These systems collectively generate around 120 tons per day (15-20 thousand tons per year) of waste silts, categorized as non-hazardous special waste under Italian regulations. Typically, these silts are used for restoration within the quarry or deposited in excavation voids or landfills for environmental projects beyond the extraction site. Additionally, this waste was previously utilized in concrete production at a local cement plant until its closure in 2009.

In this project, four batches of waste silts (WS) underwent chemical, mineralogical, and rheological characterization. They were then incorporated into different batches for porcelain stoneware tiles. Subsequently, ceramic tile production was replicated at the laboratory scale, and the final ceramic products were thoroughly characterized.

Qualitative and quantitative analyses of mineralogical compositions was performed by combining thermogravimetric analysis (TGA), calcimetry, elemental analysis (EA), and X-ray powder diffraction (XRPD). XRPD data from randomly oriented samples were refined using the Rietveld-RIR method. All waste silts (WS) showed significant amounts of carbonates (70-80 wt.%), predominantly comprising calcite and ankerite. XRPD analysis of oriented specimens revealed the presence of a minor fraction of clay minerals (also confirmed by TGA), including mica (likely glauconite-illite more than muscovite), illite-smectite (IS) mixed-layer clays, and kaolinite.

From a textural perspective, we examined the particle size distribution of the WS using laser diffraction. All samples exhibited a trimodal distribution, with major components around 30 and 5 μm and a minor component below 1 μm. Overall, the four batches demonstrated high homogeneity, indicating readiness for industrial implementation, particularly where large and uniform volumes are necessary.

Corresponding author email: sgraziano@unina.it

Keywords: Indian quartzite, stone waste recycling, cementitious tile adhesives.

Waste deriving from quarrying operations of heritage stones, which are widely used in social and economic contexts despite the possibility of pollution given by tools' wear and tear, retain almost all the mineralogical and compositional characteristics of the original material. This research aimed to test prototypes of tiles' cementitious adhesives made up recycling quartzite waste used as fine and ultra-fine aggregate (UNI EN 8520-1, 2005). Particle size distribution analysis, along with X-ray diffractometry, X-ray fluorescence and Scanning Electron Microscopy were carried out to characterize the waste. Experimental research involved the mix-designing of three dough formulations tested by using different types of tiles with different grip. Fresh doughs were tested for reology and cured for normative requested time after being stuck on a concrete support as reported in standards (UNI EN 12004-2, 2017). Adhesives' technical performances were evaluated by the Pull-Off test allowing us to acquire results for high initial tensile adhesive strength (UNI EN 12004-1, 2017; UNI EN 12004-2, 2017). Experimental results carried out in this research proved the possibility to use huge amounts of waste coming from Indian stone industry in cementitious adhesives' sector without compromising technical performances, proposing itself as an alternative method to landfill disposal for this waste.

The role of secondary prospectivity of mine waste for enhancing critical metals recovery in South Australia

Jackson L.[1], Parbhakar-Fox A.[1], Colombi F.[1] & Baldassarre G.*[2]

[1] WH Bryan Mining Geology Research Centre, Sustainable Minerals Institute SMI, University of Queensland.
[2] Dipartimento di Ingegneria dell'Ambiente, del Territorio e delle Infrastrutture, Politecnico di Torino.

Corresponding author email: gabriele_baldassarre@polito.it

Keywords: critical minerals, tailings, South Australia.

According to its Critical Minerals Strategy of 2022, Australia aims to turn into the "global critical minerals powerhouse" by 2030 by becoming an integral part of the international critical minerals supply chain (DISER, 2022). The Mine Waste Transormation through Characterization (MIWATCH) group is applying a set of integrated geometallurgical tools to assess the secondary prospectivity of mine waste across Australia to find new sources of critical metals.

The primary focus of these studies is to determine critical metal abundances and their modes of occurrence in tailings, stockpiles and waste dumps of operational and/or abandoned mine sites. This is achieved by a preliminary compilation of the relevant available information from public and confidential sources. A targeted mine waste sampling follows and uses a comprehensive set of analyses, including multi-element geochemical analysis (ICP-MS) and targeted mineralogical and geochemical characterization of selected representative samples (MLA; XRD; LA-ICP-MS).

MIWATCH in conjunction with the Geological Survey of South Australia (GSSA) has identified there is potential to explore for critical metals in mine waste materials across the state forming part of this new supply chain. The initial phase of this research focused on the identification of mine waste with potential to host economic accumulations of critical metals in South Australia. For this desktop study a ranking criteria was created using five key inputs based on data available from the Mines and mineral deposits (MinDep) database, accessed via the South Australian Resources Industry Gateway (SARIG). The criteria included, i) mine status; ii) known commodity; iii) associated commodity; iv) discovery year and, v) mine waste feature/s. The ranking was used to identify abandoned/historic mine sites with a high probability of containing critical metals in the mine waste.

The results of the desktop study indicate that South Australian mine waste is fertile in metals including Co, Cu, Ni, REEs and Au (particularly within the Adelaide Rift Complex, Gawler Craton, Nackara Arc, Kanmantoo Group and Willyama Supergroup). The second phase of this research involves integrated characterisation of the chemistry and mineralogy of mine waste from the sites identified in phase one, including Kanmantoo, a copper mine site (currently under manteinance) located southeast of Adelaide.

[3] School of Mining Engineering, Anhui University of Science and Technology, Huainan, China.

Corresponding author email: antonio.tazzini@unito.it

Keywords: mineral waste, technosols, greening and land reclamation.

Mineral wastes coming from demolition activities, including rock and soil from excavations, and extractive industry, represent the first and the second source of waste production at EU level (35.9% and 26.6% respectively). Although some of these waste products can cause environmental and economic problems if not adequately managed and disposed, they represent an alternative resource for civil, building, infrastructure and environmental applications.

This study introduces the state of the art of the research and applications of products arising from mineral waste, with a focus on new potential application of fine fractions for artificial substrate production (namely technosols). The agronomic characteristics of the produced technosols were tested to evaluate their use and the environmental criticalities for land rehabilitation and urban greening. In particular, it is intended to evaluate the different technosol combinations and check for the best yielded results to implement in a large scale mesocosm. A geochemical and agronomical characterization of the produced mixed has been carried out and the results show that total concentrations of trace metals, particularly the potentially toxic metals (e.g., Cd<0.1 mg/kg) of most tested mixes are within permissible limits indicating that the technosols reflect no hazard of metal contamination. The evaluation of the agronomic properties of the soil revealed that the germination rates are higher than expected. Meanwhile, the phytotoxicity rates are relatively low and remained tightly associated to the metal content. All of the results confirmed that, when properly managed and treated the mineral waste fine fraction could be effectively employed for land rehabilitation at large scale.

The application of such materials could largely boost the circular economy by preserving natural soil and recycling the continuous flows of mineral waste, such as extractive waste (in particular residual sludge from dimension stone industry) and construction and demolition waste.

Sustainable and circular management of mineral waste contributes to guarantee raw materials supply, contemporary reducing environmental (including CO_2 production) impacts associated to waste management and landfilling. The potential decrement of environmental impacts and CO_2 production will contribute to enhance the NET-zero greenhouse gas emissions EU strategy.

Sustainability in geo-resource management through shared competence-building projects. The example of GEODES Erasmus Project

Keywords: sustainable development and georesources, geology and mining engineering high education.

Natural resources, and in particular geo-resources, are a precious and irreplaceable asset, which have always been of primarily economic interest, and only secondarily of environmental and social interest. In recent decades, the concept of sustainability and sustainable development has become increasingly concrete and the social and environmental problems associated with human activities in the management and use (exploitation) of natural resources have been recognised.

Sustainable and responsible management of geo-resources requires rethinking and redesigning our production and consumption patterns through an awareness of the natural environment as a common good to be preserved and knowledge of the close link between the natural environment and the socio-economic system.

The training and education of all actors involved in geo-resource management are necessary tools to activate a profound change in human attitudes at the individual and societal level, to develop critical, ethical and conscious thinking, and to acquire the technical skills needed to solve local problems.

Knowledge of existing innovative technologies, impacts and complex environmental, health and socio-economic dynamics is essential to develop awareness of the need to respect and conserve geo-resources and to adopt sustainable policies and techniques that respect the environment and local society.

In this context the Erasmus project GEODES, which is the continuation of the past Erasmus project SUGERE, aims at standardising and implementing training curricula for teaching mining engineering and geosciences in non-EU countries (focus on Angola and Mozambique).

GEODES project brings together 3 European universities, 2 African universities with advanced structures and extensive teaching experience in geosciences, already present in the SUGERE project, and 4 new African institutions from Angola and Mozambique.

The GEODES project fosters new collaborations at an international level focused on sustainable development in the geomining context. The strengthening of geoscientific skills and the exchange of experiences allows us to develop modern strategies for the responsible and sustainable management of natural resources and acquire the ethical values necessary for solving local problems.

It contributes, together with SUGERE, to achieve this objective through a strong network of sharing, exchange and research activities between European and non-European universities.

The culture of sustainability and education for sustainable development are the basis for the development of critical thinking and the right skills to solve local problems. The path towards environmental and social sustainability of the ‘wise’ use of geological resources leads to a ‘rethinking’ of ‘our’ way of producing and consuming in an intergenerational perspective, through an ever deeper understanding of the ethical value of the interrelationships between factors socio-economic and natural systems.

Toward novel strategies for consolidating earther cultural heritage manufacts

Keywords: adobe, climate change, consolidation.

The impacts of climate change are evident worldwide, with rising temperatures, rising sea levels and the increasing frequency of extreme weather events. With international initiatives dating back to the first World Climate Conference in 1979, followed by the creation of the Intergovernmental Panel on Climate Change (IPCC) in 1988 and subsequent global conventions such as the UN Framework Convention on Climate Change (UNFCCC) and the Kyoto Protocol, the world has acknowledged the urgency of addressing this pressing issue (Ford et al., 2016). Although considerable efforts have been made to reduce greenhouse gases emissions, the inevitability of some degree of climate change has prompted the need to focus on adaptation strategies in many aspects of human life.

While the world grapples with the multifaceted challenges of adapting to climate changes, one area that emerges as exceptionally vulnerable is cultural heritage, in particular archeological sites that are typically exposed outdoors and now face an unprecedented threat as climate change disrupts established weather patterns and introduce unpredictability. This problem needs adaptive measures to enhance the resilience of this valuable heritage. In the frame of a PhD project we are addressing possible strategies for consolidating earthen manufacts consisting of adobe bricks, a typology of construction that has been widely used throughout the human history (the oldest structures in earth dating back to 8300 B.C.) and that is still commonly used worldwide. To this purpose, we investigated two strategies including (i) making stronger adobes by adding different reinforcing agents within the starting material and (ii) coating the traditional adobes with potentially erosion resistant materials. The starting bricks for the experiments were prepared from a clayed soil added with straws and ashes, such as to reproduce the original composition of ancient mud bricks (Adorni et al., 2012), and drying the samples at 40°C in a laboratory oven. The used additives include different amounts of nano-idrossiapatite (Capitelli et al., 2020) and a mixture of MgO and MgCl (sorel cement). The latter agents have also been used for the coatings by spraying them to the surface of the adobes. The samples have been subject to artificial weathering in a “rain box” by simulating a wide range of rainy conditions and monitoring the evolution of the sample shape by using both a photogrammetric system and a 3D light scanner. While the project is still ongoing the preliminary results provide the first quantitative data on the response of adobe bricks, treated with the different reinforcing agents, to controlled rain weathering. This information is critical to plan future strategies for the preservation of archeological structures of immense heritage value.

Keywords: CDW, XRF, XRPD.

The European Community (EU) states that each nation by 2020 must recycle ≥ 70 wt.% of CDW (construction and demolition waste) (EU 98/2008/EC), accounting for ~ 40 wt.% of waste in Europe (Eurostat, 2020). The amount of CDW is even more compelling in areas hit by adverse events. Advanced recycling of CDW would help the reconstruction process by reducing downfilling and limiting the exploitation of further raw materials. However, the upcycling recycling of CDW is still a challenge due to the low and heterogeneous physic-mechanical performances of some CDW types (Galderisi et al., 2023). They have to be sorted into homogeneous fractions with defined and constant features. Here, textural, mineralogical, chemical and physical characteristics of highly heterogeneous CDW rubbles produced after the 2016-17 seismic events in Central Italy are investigated. More than 200 cm-sized CDW samples were first visually inspected to determine their mesoscale texture and colour; then, their density was determined (Galderisi et al., 2022). These CDW were grouped into six categories: concretes/mortars, natural stones, tiles, bricks, perforated bricks and roof tiles. 25 representative specimens were analysed with XRPD (X-Ray Powder Diffraction) to identify and quantify crystalline and non-crystalline phases; these XRPD outcomes were corroborated and complemented by XRF (X-Ray Fluorescence) determinations to measure their bulk chemical compositions. Concretes/mortars, natural stones and tiles are whitish to grey coloured with apparent densities > 1900 kg/m3, whereas masonries are coloured with apparent densities usually < 1900 kg/m3. Concretes/mortars and natural stones in this area are rich in calcite (and dolomite) or equivalently in carbonates (CaO- and CO_2-rich) and depleted in silicates; the opposite holds for masonries, while tiles are rich in non-crystalline silicate phases. In parallel, the porosity and water absorption of these CDW categories were quantified; masonries have the largest porosity and water absorption values (≥ 25 % and 15 % respectively), mortars and natural stones the lowest ones (≤ 10 % and 5 %), while concretes plus tile intermediate ones, providing further peculiarities for discriminating these waste. Hence, several mineralogical and chemical aspects correspond to physical features and can be mutually used to identify CDW categories. Only the distinction of ceramic-like CDW categories can be applied to plan effective sorting procedures. Homogeneous, dense, poorly porous and water-absorbing separated CDW can be used to produce RAC (recycled aggregate concretes) with defined and constant performance. By contrast, light, porous and water-absorbing separated CDW can be recycled for downcycling applications or used for unexplored uses considering their chemical attributes. This damaged area of Central Italy could represent a unique opportunity to experiment with innovative selection procedures.

Sonic drilling: evaluation of the best techniques for tailings and mining waste exploration and valorization

Scervini S.*[1], Baldassarre G.[2] & Bellopede R.[2]

Keywords: sonic drilling, waste.

Sonic Drilling is an advanced form of drilling that employs the use of high frequency resonant energy to advance a barrel or casing in underground formations. During drilling, the resonant energy is transferred by the drill head to the drill string at various sonic frequencies. The main advantages are: high performance and high recovery rates in poorly consolidated or fractured material such boulders, sand and heterogeneous material; dry drilling or with low water content; minimization of drilling discard: about 70% less discard compared to traditional drilling; straight holes with minimum deviation; up to 4 times faster compared to traditional drilling; big core diameters.

Most of the current applications are related to exploration drilling, for example: titanum exploration in sands; lithiums exploration in salars; bauxite, kaolin, uranium, REE (Rare Earth elements) in clays. Other relevant applications are related to the characterization of heterogeneous material present in tailing dams, stock and waste pile. Actually this technique is mostly used in Australia, USA, Canada, Brazil ,Cile, and in few European countries (Orberger et al., 2018, 2019; González-Díaz et al., 2022, Santos et al., 2022) and it is innovative for mining dumps exploration.

In addition the main goal of Europe Commision highlighted in recent Critical Raw Material Act is to investigate the potential for recovery of critical raw materials not only from extractive waste in current mining activities but also from historical mining waste sites. For all the above mentioned reasons this technique could be a interesting opportunity of exploration with the objective of circular economy in the mining sector.

The research aim to give an overview of the exploration activities by means sonic drilling of Horizonte Mineiro Serviços Geológicos Ltda, in Brazil in order to select the best technologies to be used for the mining tailing storage facilities and waste rock dumps in Europe.

Sardinia's mining heritage revaluing: a path to sustainable critical raw materials extraction

Sedda L.*, Attardi A., De Giudici G. & Naitza S.

Dipartimento di Scienze Chimiche e Geologiche, Università di Cagliari.

Corresponding author email: lorenzo.sedda@unica.it

Keywords: mining dumps, circular economy, resource revaluation.

Modern societies rely heavily on critical raw materials (CRMs) for advanced technologies. However, Europe currently imports most CRMs, often from regions with unstable geo-political conditions. To address this, the 2024 CRM Act promotes using Europe's own resources, especially recycled materials from old mines and industrial waste. The success of this plan depends on identifying and analyzing these potential sources across Europe. Sardinia, the most important historical mining region of Italy, must be regarded as a primary target in southern Europe. The past mining activities in the region were oriented to base metals (Pb, Zn, Cu, etc.), baryte, and fluorite. In about 150 years of industrial mining, about 70 Mm3 of mining dumps were produced (Regione Autonoma della Sardegna, 2003).

Our project starts from a regional-scale mapping of the historical mining wastes of Sardinia, to obtain a new database aimed at identifying and hierarchizing the deposits of possible economic interest. Data coming from previous databases were verified and implemented through GIS software. Available ore geology, mineralogy, and geochemistry data from the mined bodies (metallogenic and georesources map of Sardinia: Tocco et al., 2008), together with deposits' volumetric size and with data on minerallurgical processes, allowed a first compositional classification and a preliminary hierarchization of the mining wastes. Over 1200 mining dumps in 109 mine sites of Sardinia have been up to now classified. On selected mine sites, CRMs contents in the wastes are verified with field surveys, sampling, and physical, mineralogical, and geochemical characterization of waste materials by XRF, XRD, ICP-MS and SEM-EDS. First studies were performed in the Montevecchio Pb-Zn mine (SW Sardinia). In the tailings still accumulated in the western plant area, up to 600 ppm of LREE were found, together with up to 1.2% Pb, and 2.6% Zn (Sedda et al., 2024). These metals are related to mineralogical phases – monheimite [(Zn,Fe)CO3], synchysite [Ca(Ce/Nd/Y/REE)(CO3)2F], bästnasite [(Ce/Nd/Y/REE)(CO3)F] and xenotime [Y(PO4)] - once discarded with the quartz-carbonate gangue during ore beneficiation. Similar studies are now ongoing in other mine areas of SW Sardinia where significant contents of CRMs and strategic minerals have been found in Santa Lucia (fluorite, LREE, Ni, Co), Seddas Modditzis (Zn, baryte), and San Leone (fluorite, W, Bi, Sn, Mo). Overall, these preliminary data are indicative of a high secondary raw materials potential of the historical districts of Sardinia and are the necessary premise and a first step in a path for their future sustainable recovery. Reusing these materials brings significant advantages beyond just Europe's resource supply. It can restore polluted areas and ecosystems and improve public health. There's even potential to use leftovers from the recycling process to prevent cave-ins in old mines, like sinkholes (Manca et al., 2014), ensuring safety for the people.

Keywords: CRMA, extractive waste, urban mining.

The general objective of the project is to respond to the need expressed by the EC in the art. 27 of the Critical Raw Material Act to re-verify all the potential and availability of critical raw materials from primary (natural) and secondary (anthropogenic: deposits of extractive waste, municipal waste, electronic waste, construction & demolition etc..) deposits, in a context of sustainability and circular economy. To achieve this target, ISPRA has proposed, within the PNNR RePowerEU, the creation of an intelligent knowledge platform on a geographical basis completely dedicated at a national level to the collection, geolocalisation and visualization of all the information available on: 1. Closed or abandoned storage facilities for extractive waste from mining activities and waste deposits from metallurgical plants; mapping and characterization in terms of CRM and SRM contents 2. Storage facilities for extractive waste from quarrying activities, in the case of possible CRM/SRM content, such as in granites and metamorphic rocks 3. Active storage facilities for extractive waste (data provided by managers) 4. Urban Mining, Mapping and characterization of all urban and industrial deposits, potential sources of CRMs/SRMs. The intelligent platform will be implemented by building a geo database that follows the FAIR (Findability, Accessibility, Interoperability, Reusability) principles and a multidimensional document database of all information and unstructured data. The first action for the implementation of the proposal will be the creation of a CTS for the management, coordination, definition of technical actions and dissemination of the entire project. The two-year action will consist of four operational actions, one of which is coordination, one is implementation of the operational platform and two themes as described below Particular attention will be paid to the characterization of the extractive waste deposits of abandoned mining sites and metallurgical plants for the recovery and reuse of critical materials and the mitigation of environmental problems associated with abandoned deposits (acid drainage, diffusion of pollutants by air, contamination in local and vast areas of environmental matrices, possible collapses due to degradation of containment structures, etc.).

EC (2024) - Regulation (EU) 2024/1252 of the European Parliament and of the Council of 11 April 2024 establishing a framework to ensure a secure and sustainable supply of critical raw materials and amending Regulations (EU) No. 168/2013, (EU) 2018/858, (EU) 2018/1724 and (EU) 2019/1020Text with EEA relevance. Alkaline-activation of natural and artificial pozzolans as binders for soil treatment

Vitale E.*

Dipartimento di Scienze della Terra, dell'Ambiente e delle Risorse, Università di Napoli "Federico II".

Corresponding author email: enza.vitale@unina.it

Keywords: alkaline activation, natural and artificial pozzolans, soil treatment.

The development of soil treatment techniques using alkali-activated binders is a relevant issue since the increasing interest into the use of new sustainable binders as an alternative solution for soil improvement in geotechnical engineering applications.

Alkali activated binders are formed by alkaline activation of an aluminosilicate source, containing precursor materials like pyroclastic soils, fly ash, silica fume, steel sludge, which chemically react with an alkaline solution (i.e. sodium hydroxide, sodium silicate) forming a three-dimensional aluminosilicate gel with cementitious properties (Provis & van Deventer 2014). Recycling of waste materials such as by-product from industrial process and/or valorisation of natural alumino-silica sources (i.e. volcanic pyroclastic deposits) to synthesize a new binders favor a closed loop use of materials, which minimizes the generation of waste and reduces the production costs. Alkali activated binders represent a viable sustainable alternative to the use of ordinary binders for soil improvement (Vitale et al. 2017; Coudert et al. 2021; Miraki et al. 2022).

An insight into the mechanical improvement induced by alkali-activated binders based on the activation of two different pozzolanic materials (i.e. volcanic ash and fly ash) on a clayey soil is presented. An experimental multiscale analysis on chemo-physical evolution of the system and its influence on the microstructural features of treated soil is developed highlighting the link between alkaline activation processes and macroscopic evolution of soil properties. Mechanical tests are performed and interpreted taking into account the chemo-physical evolution of alkali activated binders. Effects of binder content and curing time are also considered. Addition of alkali-activated binders increases shear strength of the treated samples since the very short term. A reduction of compressibility and an increase of yield stress of treated samples are also detected, whose extent depends on the curing time and on the binder content. Macroscopic behaviour of treated soil is linked to the experimental evidences at microscale. Mineralogical and fabric changes induced by alkali-activated binders are monitored over time by means of X ray diffraction (XRD), Scanning Electron Microscopy (SEM) and Mercury Intrusion Porosimetry (MIP). Test results show a high reactivity of alkali activated binders as alumino-silicate source promoting precipitation of new mineralogical phase forming chains and networks with cementitious properties, responsible of the mechanical improvement of the treated soil. The efficiency of treatment is also highlighted by comparing the mechanical performance induced by alkali-activated binders with the one promoted by ordinary Portland cement.

Keywords: REEs, characterisation, extractive waste.

Critical raw materials (CRMs) supply is a challenge that EU countries have to face, also thinking about domestic procurement from natural ore deposits and anthropogenic deposits (landfills and extractive waste facilities).

The present research focuses on the possibilities linked to the supply of CRM and the potential for exploiting rare earth elements (REEs), investigating a large number of extractive waste and siliceous rocks in the Piedmont Region (Northern Italy). Indeed, the recovery of REEs from the extractive waste (EW) of siliceous quarries and other siliceous ore deposits can be a valuable way to reduce supply chain risks.

Starting with a review of the literature on mining activities in Piedmont, and continuing with the sampling and geochemical, mineralogical, petrographic and environmental characterization of EW facilities connected to siliceous dimension stones, of kaolinitic gneiss ore deposits and of soils present near the investigated areas, this study shows that the degree of REE enrichment differs depending on the sampling area (soil or EW) and lithology.

The concentration of REE in the EW at some sampling sites fulfils the indicators of industrial grade and industrial recovery: the high cumulative production and potential market values of EW, and the positive recovery effects through proven methodologies indicate a viable prospect of REE recovery from EW. However, REE recovery industrialization faces challenges such as the difficulty of achieving an efficient large-scale recovery due to large regional differences in REE abundance, the mismatch between potential market value and waste annual production, etc. Nonetheless, in the future, quarry EW can be differentially studied and reused based on the enrichment and distribution characteristics of trace elements.

The present paper shows investigation procedures, to determine both CRMs potentialities and environmental issues (on the basis of literature data to select the more promising areas and on sampling and characterization activities on the selected areas), together with procedures to determine waste quantities and tentative economic values of REEs present in the investigated areas. This approach, tested on a large area (Piedmont region), is replicable and applicable to other similar case studies (at EU and non-EU levels), and offers decision makers the possibility to have a general overview of the potential available resources, in order to decide whether and where to concentrate efforts (including economic ones) on a more detailed study to evaluate the exploitable anthropogenic deposits.

CRMs prospecting through comparative ore deposit modelling in SW Sardinia

Attardi A.*, Cocco F., Deidda M.L., Sedda L., Funedda A. & Naitza S.

Dipartimento di Scienze Chimiche e Geologiche, Università di Cagliari.

Corresponding author email: attardi.geo@gmail.com

Keywords: skarn, hydrothermal veins, structural control.

The demand for Critical Raw Materials (CRMs) in the last years brought the need for systematic and large-scale prospecting in fast and efficient ways. Recent studies highlighted the discrete structural control displayed by two types of ore deposits of SW Sardinia: a) mixed sulphides (Cu, Pb, Zn, Fe) skarn deposits with variable contents of W-Sn-Bi, Ni-Co, and F minerals, set along shear zones related to the Variscan Nappe stacking with a low-angle, top-to-the SW transport direction thrusting (Cocco et al., 2022); b) F-Ba (±Pb±Zn) low-temperature hydrothermal veins hosting REEs and subordinate Bi and Ni-Co arsenides-sulfarsenides (Scano et al., 2023) filling high-angle, N-S and E-W striking normal faults with strike-slip components, crosscutting any Variscan structure.

We present two case studies in southwestern Sardinia prospected by comparative modelling: the Rosas Shear Zone (RSZ) and the Santa Lucia-Su Zurfuru (SLZ) areas. In the RSZ, the skarn protoliths are Cambrian limestones sliced within the Ordovician succession by a system of anastomosing NW-SE Variscan thrusts, enhancing the circulation of the mineralizing fluids and the passive structural control on skarn genesis (Cocco et al., 2022). N-S striking F-Ba veins cut the thrusts. In the SLZ, the skarn protoliths and host rocks are analogous to the RSZ: km-sized limestone slices are metasomatised at their peripheries and show a distinct lithological zonation: limestone, marble, and chlorite-skarn. Preliminary field surveys indicate that the limestone slices are cut by later high-angle faults, hosting the F-Ba (Pb-Zn) hydrothermal veins. Decimetre-thick N-S striking veinlets cut across the limestone bodies. The vein system displays a generally good continuity and is distinctly zoned: a) the northern sector is barite-rich, with several generations of fluorite cementing brecciated marble/skarn, rare galena and sphalerite; b) the central zone is constituted by banded fluorite and galena, intercepted by a two kilometres E-W quartz vein that fades into a barite-rich ore at the contact with the limestones; c) the southern part is fluorite-rich and cuts across the skarn ore at depth.

The comparative modelling of RSZ and SLZ helps us to investigate the metallogenic processes that led to skarn and hydrothermal systems emplacements in both areas: a) the RSZ skarn model gave us a key to understanding the general structural setting of SLZ; b) the SLZ hydrothermal veins model suggests some economic potential left in the area and may be used as well as a point of reference for further regional-scale mineral explorations in other related deposits. Globally, skarn and hydrothermal veins are common bearers of CRMs, and the structural-mineralogical comparative modelling we leveraged is an efficient and low-cost way for prospecting and exploring, meeting all the requisites for modern economic needs.

Corresponding author email: ipicaparopo@gmail.com

Keywords: syn-tectonic porphyroblasts, Mississippian plutonism, Variscan orogen.

In SW Iberian Massif, the evolution of the Variscan belt involved a Mississippian intra-orogenic extensional event, related to the gravity-driven collapse of the thickened continental crust (Pereira et al., 2009). It is consensual that after the continental collision between Laurussia and Gondwana (Late Devonian), continental crust thinning was caused by the rise of a thermal front, associated with plutonism and the formation of gneiss domes. The development of these Variscan gneiss domes at lower structural levels was controlled by tectonic movement along extensional shear zones, formed under low-pressure and medium-to-high-temperature metamorphic conditions (Dias da Silva et al., 2023). Simultaneously, syn-tectonic plutons, like the Reguengos de Monsaraz pluton (Ossa-Morena Zone), were emplaced at upper structural levels composed of metasedimentary rocks deformed by ductile shearing under relatively lower temperatures (Carvalhosa & Zbyszewski, 1991). The emplacement of Mississippian quartz-diorite and granodiorite, and a minor amount of gabbro-diorite and granite (Antunes et al., 2010), was responsible for the genesis of aureole of contact metamorphism in the Ordovician metapelites. The host metasedimentary rocks contain a pervasive S2 foliation that transposes an older fabric/compositional layering (S1 foliation parallel to bedding), suggesting regional, early, tight to isoclinal folding. Many of the early structures probably have been transposed by S2 at least locally, by ductile shearing subparallel to the axial planes of the early folds. The intrusion of hot magma produced a peak assemblage including biotite, andalusite, cordierite and sillimanite rimming the Reguengos de Monsaraz pluton. Close to the contact with the pluton, pelitic hornfels show a pervasive foliation (S2) defined by elongated biotite and andalusite porphyroblasts in a fine-grained matrix composed of quartz, biotite, muscovite, and opaque minerals. Poikiloblastic cordierite and prismatic sillimanite are also present. Moving away from the contact, microlithons lying between S2 foliation that contain a crenulated foliation (S1), are recognized in the lower-grade host metasedimentary rocks. In these spotted metapelites contact metamorphic andalusite (chiastolite) porphyroblasts grew over an older foliation (S1) during the formation of younger foliation (S2) and related intrafolial folds. A rotation of the internal S2 foliation as regards the external S2 foliation is observed. This highlights the synchroneity of magma emplacement of the Reguengos de Monsaraz pluton, the development of S2 foliation, and contact metamorphism.

Mountain ranges owe their existence to the interplay between tectonics, isostasy, magmatism, and surface processes. To assess their role in the evolution of the Variscan crust of the candidate site for the Einstein Telescope (ET) in Italy, we report preliminary data constraining the regional geochronological and thermochronological evolution. The study area is situated within the high-topography Variscan crystalline basement of northeastern Sardinia. The ET site has been selected for its seismic stability and isolation from significant active faults and hydrothermal activity. To further substantiate this geological stability, we investigate the timing of relief formation.

In this communication, we report the results of U–Pb dating on zircon and apatite (U–Th)/He ages (AHe), to unravel the thermochronological evolution of the studied crystalline area. Our results provide new preliminary constraints on the magmatic and erosive processes as part of our 4D characterization plan for the region. U–Pb analyses on zircon crystals from five samples provide the first age estimate for the magmatism associated with the Bitti intrusion, dated at 320.9 ± 1.0 million years (Ma). Significantly older ages ranging from 479.3 ± 1.3 Ma to 468.5 ± 1.7 Ma have been determined for orthogneisses of the plateau area. To explore the more recent cooling history of the region, samples spaced across an elevation profile have been analyzed and yield AHe ages, ranging from 68 ± 6 Ma on the Mamone plateau to 36 ± 3 Ma in the Rio Mannu Valley near Bitti village.

These preliminary findings indicate that the Bitti intrusive rocks were emplaced during the middle Carboniferous and testify an early magmatic activity that formed the Corsica-Sardinia Batholith. Furthermore, available cooling ages suggest the removal of ~2 km of rocks from the plateau. A first estimate of the exhumation/erosion rates since Paleocene-Eocene time shows very low values (maximum 0.06 mm/yr) compared to a global average of tectonically active regions that are characterized by values between two and four orders of magnitude higher. The geochronological analysis underscores the long-lasting evolution of the Variscan crust while highlighting the limited impact of recent erosion and tectonic activity on its topography. Further U–Pb dating and thermochronological analyses will provide a better understanding of the magmatic and erosive processes shaping the ET candidate area.

Geology of the Asinara Island (Sardinia, Italy)

Keywords: Asinara Island, Variscan belt, geological map.

The Variscan belt exposed in Sardinia represents an area where it is possible to investigate the inner part of this orogen and a km-scale transpressive shear zone, i.e. the Posada-Asinara shear zone (PASZ), that drove the exhumation of the metamorphic core of the belt (Carosi & Palmeri, 2002). Even though the Asinara island offers very good exposure of main tectonic units building up the Variscan belt of Sardinia, a detailed geological map of the island was lacking, due to a former limitation of access that lasted for many years.

Two juxtaposed complexes have been recognised: the structurally lower Medium Grade Metamorphic Complex (MGMC) and the upper High-Grade Metamorphic Complex (HGMC). The contact in between, i.e. the PASZ, is marked by a km-thick mylonitic zone affecting both complexes. Detailed mapping coupled with multi-scale structural observations allowed the definition of a polyphase evolution consisting of four ductile deformation phases, as recognised in other sectors of the Variscan belt in Sardinia.

The polyphase history recorded in this sector of the Variscan belt in Sardinia emphasises that the Asinara island tectonic evolution started from perpendicular collision (D1 phase) evolving towards an orogen-parallel transpression (D2 phase), continuing with HT/LP metamorphism and magmatic intrusions, then ending with the collapse of the belt. The geological architecture of Asinara island is mainly influenced by the D2 phase linked to the partitioned transpressive activity of the PASZ. The MGMC and the HGMC show strain partitioning in a North-South transect with the development of prevailing folds to the south and non-coaxial deformation with mylonites toward the north. The subsequent granitic intrusions and the prominent HT–LP metamorphism affect this setting, probably related to an HT event during the Permian (Langone et al., 2022).

In conclusion, the new 1:25.000 geological-structural map of the entire Asinara island (Carosi et al,. 2024) is useful to better understand this key sector of the Variscan belt in Sardinia and represents a robust base for other types of investigations.

Keywords: Orthogneiss; 40Ar/39Ar mica dating; Variscan Sardinia

The Sulcis Metamorphic Complex (SMC) is a LP-HT metamorphic core complex exposed in the foreland of the Variscan belt in southern Sardinia. It consists of a biotite- and muscovite-bearing orthogneiss (the Mt. Filau Orthogneiss, MFO) together with a pelitic-psammitic host rock (the Settiballas Schist). The SMC is separated from the overlying very low-grade metamorphic units of the foreland by the west-dipping, top-to-the-west, Tuerredda Shear Zone. The MFO crops out with three different facies, a biotite-rich, a leucocratic coarse-grained, and leucocratic fine-grained facies. Two main deformations can be described in the MFO, namely, a high-temperature D1 and a retrograde D2 phase, associated to development of an S1 and an S2 foliation, respectively. In the fine-grained facies, the LP-HT metamorphic peak, coeval with the main S1 foliation, was recorded under conditions of incipient partial melting (<8% of melt produced) in the sillimanite stability field, at ~680–700°C and ~0.32–0.46 GPa (Cruciani et al., 2022). The retrograde P–T path, coeval with the S2 foliation, occurred in the andalusite stability field, and is testified by the growth of andalusite after fibrolitic sillimanite in the fine-grained leucocratic facies. Syn-S1 muscovites of one sample from the leucocratic coarse-grained facies of the MFO have been analysed using laser step-heating and laser *in situ* techniques. The analysed muscovite is a celadonite-poor white mica, with Si within 3.05 - 3.14 a.p.f.u., XNa values between 0.04 and 0.08 and TiO2 contents < 2 wt.%. Preliminary 40Ar/39Ar radio-isotopic data obtained on these syn-kinematic muscovite yielded ages between 290 – 300 Ma. Preliminary 40Ar/39Ar ages of ~285-290 Ma obtained for the white mica in the SMC give evidence of late Variscan deformation under HT/LP metamorphic conditions at depth below the nappe pile in the foreland zone. Syn-S1 partial melting can be linked to a late Variscan, tectonically driven thermal anomaly associated with isothermal decompression of the middle-lower crust, also accompanied to the upward rise of deep hot crust and, possibly, crustal melts. In this scenario, the Tuerredda Shear Zone acted as a preferential channel for upward advection of deep hot melts in the foreland zone of the Sardinia collisional belt.

Sardinia is a transect of southern Variscan Belt characterized by External (SW), Nappe (SE and Central) and Axial Zone (N). From late Carboniferous to early Permian, dextral mega-shears developed in the southern sectors of the Meso-European crust (South Variscan Shear Zone) promoting westwards transport and >90° clockwise rotation of Sardinia. The metamorphic basement was intruded by many post-collisional coalescent igneous complexes forming the Sardinia-Corsica batholith which grew during two main magmatic peaks at about 305 Ma (Old Magmatic Peak, OMP) and 285 Ma (Young Magmatic Peak, YMP). The contribution of crustal melts increased with time along sheared and post-collisional extensional structures. Reworking of crustal material occurred in response to combined deformations, regional metamorphism and extensive magmatism promote the development of two distinct gold metallogenic events in the Sardinian Variscan Mineral System (SVMS: Naitza et al., 2024).

A former amagmatic metallogenic peak consists of As-Au±Sb±W orogenic-type deposits, aligned to mylonitic belts and cataclastic shear zones of SE Sardinia (Baccu Locci Mylonite Zone; Villasalto thrust. A telescoped zonation of deeper Pb-Zn-Cu-Ag(±As±Au±Sb) and shallower As-Au-Sb-W ores is common. The stages of formation of Au-rich ores have been schematized as: earlier sheeted/stockwork veins with arsenopyrite-quartz±scheelite from hot (300-310°C), CO_2-bearing and low-salinity hydrothermal fluids and late Au-stibnite-scheelite-quartz and Zn-Pb-Cu sulfides from cooler (< 270°C), CO_2-poor and low-salinity fluids. Radiometric dating (Dini et al., 2005, and new determinations on scheelite) constraint the mineralisation within a broad range of 307-260 Ma.

A late metallogenic event produced several Sn-W-Mo-Bi(±As±F) granite-related and Au-Bi-Te-W Reduced Intrusion Related Gold Deposits (RIRGD). In SW and SE Sardinia, these deposits are linked to ilmenite-bearing granites (GS1 suite: Conte et al., 2017) belonging to the YMP. The RIRGD consist of hornfels-hosted sheeted quartz veins with ferberite, Bi-tellurides, Bi-Au alloys, Bi-wolframates and native Bi. Fluid inclusions on quartz indicate temperatures of formation in the range of 430-230°C from vapor- and CO_2-rich fluids; U/Pb dating on ferberite indicates an age of 290 Ma. Overall, the SVMS developed from late Devonian to late Permian, with two peaks of activity around 305 and 290 Ma that produced orogenic-type deposits in the SE and RIRGD in SW Sardinia. Metallogenic peaks overlap with post-collisional shearing, uplift and extension and the production of OMP and YMP magmatism. Thus, the differences in metals budgets and types of Au-bearing mineralisation from southern Sardinia were inherited from pre-Variscan crustal sources with distinct geochemical signatures such as Au-Sb-fertile Ordovician continental arc and Silurian black shales, more common in the SE, and an inferred, Mo(-W-Sn)-enriched Precambrian crystalline basement in the SW of the region.

Mississippian gneiss domes and synorogenic basins: keys to understand the Variscan collisional orogen

Keywords: gneiss domes, synorogenic basins, Variscan belt.

The relationship of gneiss domes and sedimentary basins is of great interest for understanding an orogen. Gneiss domes (GD) are flat-lying tectono-thermal structures, usually related to the fast thinning of continental crust. They are caused by the high thermal influx that invades the upper crust, related to the rapid exhumation of deeper levels. This phenomenon is responsible for the partial melting of the continental crust and lithospheric mantle, and the resulting magmatism.

As a response to this crustal thinning, extensional shear zones develop in depth in conditions of low pressure (LP) but varying from high (HT) to low temperature (LT). Consequently, topography in the hanging-wall of GD reacts forming horst-graben systems and sedimentary basins. In the Iberian Massif (IM) (Variscan orogen), Mississippian GD and sedimentary basins are described as synorogenic. They were formed as a response to the gravity-driven collapse of the thickened crust after the Late Devonian continental collision between Laurussia (upper plate) and Gondwana (lower plate) (Alcock et al., 2015).

In the IM, Mississippian sedimentation was locally synchronous with volcanic activity, linked in time and space to the syn-tectonic plutonism and the development of GD (Pereira et al., 2012, 2020). Tectono-metamorphic evolution of this orogenic extensional event strongly overprinted the earlier tectonic fabrics.

It seems unlikely that these basins were formed in a foreland, backarc, or forearc setting related to the subduction of the Rheic oceanic lithosphere, given that the Laurussia-Gondwana collision occurred earlier. Their tectonic evolution is believed to be controlled by a notable thermal anomaly beneath the orogen, but the tectonic setting remains under discussion. Recently, two models have been proposed (Dias da Silva et al., 2024): Model A) suggests that following the subduction of the Rheic oceanic lithosphere beneath the upper plate (Laurussia) and the ensuing continental collision, the roll-back of the lower plate was responsible for the formation of an orogenic plateau, the lateral flow of partially molten orogenic roots, and peel-back tectonics; in this case, Mississippian synorogenic basins are considered of peel-back type; and Model B) assumes that the ongoing subduction of the Paleotethys oceanic lithosphere (lower plate), following the Devonian continental collision, provides a reasonable explanation for the onset of a magmatic arc in Gondwana (upper plate); As a consequence, Mississippian synorogenic basins are considered of backarc type.

Keywords: structural analysis, Variscan basement, geological modeling.

The Einstein Telescope is a large underground facility designed for gravitational wave detection. One of the candidate sites to host the infrastructure is near the area of the disused Sos Enattos mine (Sardinia). In the framework of the SAR-GRAV and FdS-2021 projects, we performed new geological investigations in the area comprised within the potential vertex (Bitti-Lula-Mamone) limiting the ET triangle, aiming to assess the geological, structural, and hydrogeological conditions. For this purpose, we adopted a multidisciplinary approach involving detailed geological, structural and petrological investigations, and groundwater sampling and analysis (both water chemistry and stable isotopes δD, $\delta^{17}O$ and $\delta^{18}O$). The geological setting of the Sos Enattos area is characterized by metamorphic and magmatic rocks belonging to the Variscan basement. The metamorphic rocks mainly consist of mica-schists, paragneisses and orthogneisses; the magmatic rocks, belonging to the Variscan batholith, are mainly granites and granodiorites, and related dyke complex (Carmignani et al., 2016). Make a comparison with the available published maps, new field data show a more complex geological setting of the study area, characterized by a higher variability of the outcropping lithologies and structures. In particular, a 500 m2 granite intrusion has been detected far from and apparently not in continuity with the other mapped intrusions. Moreover, near to the granite intrusion occur several NE-SW striking aplitic dykes, variable in thickness from a few to tens of meters, never mapped until now. NW-SE striking mafic dyke are also present in the area. The main structural features are the SE-dipping schistosity affecting the metamorphic rocks, and strike-slip faults with a predominantly NE-SW orientation, often paired with dykes. Preliminary petrological data confirm previous works and will be supported by new P-T-t estimates in the near future. Groundwater chemistry varies from Cl-Na compositions to Ca-Mg- bicarbonates in agreement with the lithologies of the area, some samples showed relevant metal concentrations (Al, Fe, Mn). Isotopic composition, close to the South Italian Meteoric Water Line (Giustini et al., 2016) indicates a meteoric origin of water, and does not show evidence fractionation processes.

These preliminary data have been organised in a geodatabase and will be the base to implement a 3D geological model of the area and assess the underground fluid circulation. The new evidence of granite intrusion, dykes and faults suggest that the available geological maps need to be extensively updated to get a 3D geological model as detailed as possible of the area that possibly will host the Einstein Telescope.

The Variscan basement of Sardinia: state of the art and open questions

Funedda A.*

Dipartimento di Scienze Chimiche e Geologiche, Università di Cagliari.

Corresponding author email: afunedda@unica.it

Keywords: tectonics, nappe structures, ore deposits.

The gross structure and evolution of the Variscan basement in Sardinia have been convincingly defined since the 1980s. A Barrovian metamorphic zonation has been recognized, which has allowed the subdivision of the Sardinian basement into three main tectonic zones, separated by regional ductile-brittle shear zones. This tectonic zones show deformation and regional metamorphism increasing from the inner to the external zones (from SW to NE in present -day coordinates), as expected in fold and thrust belt. During the post-collisional stages, an extensional tectonics mainly related to uplift and exhumation occurred and the basement was intruded by a large-scale emplacement of Variscan granitoids.

Nowadays, the main research topics on the Variscan basement of Sardinia concern: a) the pre-Variscan geodynamics, mainly focused on the Ordovician Period; b) the collisional evolution of the nappe stack and tectonic units provenance; c) the kinematics and timing of the late Variscan strike-slip tectonics; d) the mechanism and lithospheric processes leading to the emplacement of the batholiths; e) the metallogenic stages recorded in Sardinia and their relationships with the Variscan orogenic cycle.

The new research on these topics is rising new questions whose answers are essential to better understand not only the structure and evolution of the Variscan Basement in Sardinia, but also the pre-Variscan and the orogenic phases at the scale of the southern Europe Variscan Belt.

The studies on the Ordovician stratigraphic succession and structures of the External and Nappe zones suggest that the Sardinian basement consists of lithospheric blocks that pertained to different geodynamic settings along the northern Gondwana margin. This implies that the Middle Ordovician Sardic and Sarrabese phases are no longer correlatable, and further research is needed to depict the pathway leading to the current structural framework as External and Nappe Variscan zones.

Recent studies suggest a more complex structure of the Nappe stack compared to the previous interpretations. In particular, the occurrence of the Arburese and Bithia Unit directly overthrusting the External Zone, still needs an explanation in the general framework of the belt structure, considering that the Bithia Unit shows a more intense deformation and a higher metamorphic degree than the Arburese Unit, apparently violating the classic ‘nappe rule’.

Studies on the sediment provenance based on detrital zircon will help to shed light on the geological history of the tectonic units now constituting the Nappe structure of the basement, including the role played by the mega-transcurrent faults well known in the European Variscan basement.

Other open questions concern deeper structural levels of the crust, as the batholith emplacement and the related metallogenic processes. It is noteworthy that immediately after the increase in knowledge on the tectonic structuring of the Sardinian Variscan basement, a systematic revision of the metallogenic models in vogue until the 1980s and 1990s began.

Preliminary data from fieldwork in the framework of the CARG Project 546-Guspini (SW Sardinia)

Keywords: Variscan basement, backthrust, ore deposits.

The new geological and structural data collected in the framework of the CARG Project (Geological Map of Italy 1: 50,000) – sheet no. 546-Guspini highlight some differences compared to the existing geological maps of this area and rises new hints on the structural style of this sector of the Variscan basement.

The Variscan basement outcropping in the study area includes the Arburese Thrust, a first-order shear zone that separates the Variscan External Zone of SW Sardinia from the Variscan Nappe Zone, in this area represented by the Arburese Unit, the shallower tectonic unit of the Variscan Nappe stack in Sardinia. A portion of the late Variscan Arbus Pluton, belonging to the Corsica-Sardinia batholith, is also comprises in the area of the sheet.

The stratigraphic succession of the External Zone of the sheet 546-Guspini spans in age from lower Cambrian to Devonian, with a Middle Ordovician stratigraphic gap related to the Sardic Phase, consistently with that known in the rest of the External Zone. However, in the available geological maps, the different formations are not properly distinguished, giving rise to inconsistencies and/or oversimplification of the structural setting of this area.

In particular, we recognized for the first time a thrust affecting the Cambro-Ordovician succession to the SW of the Fluminimaggiore village. The thrust strikes N-S to NE-SW and dips to W-NW. This structure allows to better explain the geometric relationships between the pre-Sardic lower Cambrian limestones and upper Cambrian-Lower Ordovician siliciclastic succession, and the post-Sardic sequence. Up to now, the limestone outcrops were interpreted as normal fault bounded blocks, whereas they are tectonic slices embedded within the Upper Ordovician succession. The sub-horizontal tectonic foliation developed along the tectonic contacts corroborates this interpretation. Furthermore, the new thrust mapped seems contiguous with the Acquaresi backthrust outcropping further to the south.

Another structural characteristic of this area, previously underestimated, is the relevance of several post-Variscan faults that affect the basement, making the reconstructions of the Variscan deformation harder to unravel. These faults strike NW-SE and are sub-vertical, with slickenlines that suggest oblique to strike-slip kinematics. The NW-SE striking faults host F-Ba (Pb-Zn) hydrothermal veins where they cut across the limestone slices.

To the east of the Fluminimaggiore village, new data suggest that the available maps, showing only an indistinct siliciclastic Upper Ordovician succession, can be improved by distinguishing the 5 Upper Ordovician formations defined for the External Zone. An intriguing feature is the main tectonic foliation that dips to the north, inconsistently with usually observed in the other sectors of the External Zone.

The age of the post-Variscan faults and the understanding of the deformation processes leading to the change in the main foliation attitude are the next tasks we will focus on.

Constraining the deformation in transpressive shear zones: insights from the Monte Grighini Shear Zone in Sardinia and implications for the Southern European Variscan belt

Keywords: mylonites, East Variscan Shear Zone, petrochronology.

Dome-shaped structures, characterised by a core of high-grade metamorphic or granitic rocks surrounded by low-grade rocks, are important tectonic features in collisional orogens (Cao et al., 2022). Their origin and setting are still debated, and recent studies have highlighted the importance of strike-slip movement, i.e., transcurrent, transtensional or transpressional tectonics in their formation. Thus, unveiling the evolution of shear zones that drove the dome's exhumation requires a multidisciplinary approach combining structures with petrochronology.

This work presents an updated view of the tectono-metamorphic history of the Monte Grighini shear zone (MGSZ) by integrating field observations, meso- and microstructural data, vorticity analysis, pressure-temperature (*P*-*T*) estimates and in-situ U–(Th)–Pb geochronology of monazite. The study area is characterised by a pure shear-dominated dextral transpressive deformation partitioned into low- and high-strain domains. Geothermobarometry of a sillimanite-bearing mylonitic metapelite indicates that the MGSZ developed under H*T* (~ 625 °C) and L*P* (~ 0.4-0.6 GPa) conditions. In-situ U-(Th)-Pb monazite geochronology reveals that the deformation in the shear zone initiated at ca. 315 Ma. While previous studies have interpreted the MGSZ to have formed at ~ 305-295 Ma in a transtensional regime (Musumeci, 1992; Cruciani et al., 2016), our results indicate that the MGSZ shows similarities with other late-Carboniferous dextral ductile transpressive shear zones both in Sardinia (i.e., the Posada Asinara shear zone) and in the Southern European Variscan belt (Simonetti, 2021).

Due to the MGSZ position within the chain (i.e., hinterland-foreland transition zone or Nappe Zone) and the obtained ages, the MGSZ can be considered as one of the youngest and most external transpressive shear zones active in the network of interconnected shear zones related to the East Variscan Shear Zone framework.

Keywords: microstructural investigations, late Variscan granitoid, CARG Project.

The geological survey of sheet "424 - Asinara Island" of the CARG Project (NW Sardinia), made it possible to investigate the medium- to high-grade metamorphic basement which formed the inner part of the Sardinian Variscan orogen and the related late- to post-collisional intrusive units (e.g., Carosi et al., 2024).

Three intrusive units were recognized i) Castellaccio Intrusive Unit; ii.) Punta Sabina Intrusive Unit; and finally, iii) sheeted dykes complex. The Castellaccio Intrusive Unit consists of inequigranular granodiorite-monzogranite characterised by large laths of K-feldspar, which often define a magmatic foliation. The Punta Sabina Intrusive Unit consists of peraluminous granitoid with stromatic enclaves, and finally, the sheeted dykes complex consists of peraluminous micro-leucogranite and pegmatite from decimetric to plurimetric thickness.

These granitoid rocks are intruded in medium- to high-grade micaschist and paragneiss, and the migmatitic complex. The field observation shows that they crosscut the main regional foliation (S2). The Castellaccio and Punta Sabina intrusive units have recorded tectonic stresses, which affected the granitoid during the cooling of magmatic bodies, exhibiting a range of deformation microstructures from submagmatic to low-temperature subsolidus conditions, but without developing an evident meso/microstructural fabric, as observed in other sectors on Variscan orogen (e.g., Fazio et al., 2020; Fiannacca et al., 2021).

The main observed microstructures are represented by chessboard patterns in quartz and, especially, sub-magmatic fractures in plagioclase, indicating deformation at high-temperature conditions (T >650°C), in the presence of melt. Solid-state high-temperature deformations (T >450 °C) are provided by feldspar bulging, myrmekites, quartz grain boundary migration and subgrain rotation recrystallization. Finally, low-temperature sub-solidus microstructures (T <450°C) consist of quartz bulging, mica kinks, and feldspar twinning and bending.

This complete sequence of deformation, operating from submagmatic to low-temperature subsolidus conditions is recorded in both granitoid intrusions, suggesting a deformation activity during post-collisional exhumation of the Variscan orogen in northwestern Sardinia (e.g., Casini et al., 2015).

Keywords: anisotropy of magnetic susceptibility, CPO, shear zones.

This study, based on a multidisciplinary approach integrating field, microstructural, AMS and CPO data, allowed adding new significant constraints on the architecture of the late Variscan Serre Batholith and the link between batholith construction and activation of regional-scale shear zones. As a first step, a robust field mapping, supported by petrographic investigations, revealed both the relationships and the structural features of the main magmatic units making up the batholith. The field survey allowed also to realise the first geological maps of the magmatic units exposed in the north-eastern Serre Batholith and Capo Vaticano Promontory (CVP), at 1:200,000 and 1.140,000 scale, respectively. In particular, in the CVP, where only the deep-intermediate portion of the batholith crops out, field activity and petrographic studies allowed to separate the promontory in a northern sector characterized by a continuous exposure of the deep-intermediate granitoids, and a southern sector with a more chaotic arrangement due to a stronger tectonic reworking. Deformation microstructures, studied in all the magmatic units from both CVP and Serre Massif, together with kinematic indicators, provide evidence of continuous shear-related deformation, though with varying intensity, during cooling of all the magmatic units making up the batholith, from at least submagmatic conditions. AMS revealed an internal fabric in both deformed and apparently isotropic granitoids from all the magmatic units. In the studied granitoids, AMS is dominantly controlled by paramagnetic phases, with values generally lower than 500 x 10-6 SI for all the granitoid types. The AMS ellipsoid shape is dominantly oblate, implying that flattening component of the strain was important during granitoid emplacement, while minor prolate shapes might provide indication of possible feeder zones. Quartz CPO is consistent with a sub-simple shear regime, which, together with shear indicators, supra- to subsolidus deformation microstructures and AMS data, indicate an important shear zone control over batholith construction. In particular, magnetic data are consistent with emplacement of the earliest and deepest granitoid magmas in a transtensional regime. On the other hand, a transpressional regime with a NW-SE shortening axis operated throughout the main build-up history of the batholith, triggering the nucleation of the Lower Mammola Shear Zone (LMSZ), which accommodated the emplacement of the magmatic units at progressively shallower depth. The last emplaced units remained in direct contact with the waning LMSZ, which concluded at high crustal levels its upward journey through the Calabrian crust.

Far-field interplay between the intra-Ordovician compressional tectonics along the northeastern Gondwana active margin and Gondwana interior: insights from the central Lybia Ordovician succession

Spahić D.[1], Cocco F.*[2] & Tančić P.[1-3]

Keywords: Intra-Arenigian unconformity, Sardic and Sarrabese Phases, Cenerian Orogeny.

The Variscan basement of southern Europe, the Alps, and the Carpathian-Balkans belt hold clues about the pre-Upper Ordovician tectonics along the northeastern Gondwana margin. The folds mapped at the peripheral south European terrane are vital indicators of the compressional northeastern Gondwana event. In addition, intra-Ordovician events affected the remote parts of widespread Cambrian-Lower Ordovician shelfal siliciclastic succession (Sardic and Sarrabese unconformities). In turn to southern Europe, just a few reports explain the middle Ordovician compressional tectonics that affected Saharan's north Gondwanan interior basins. Several hundred-meter-thick conglomerates, often followed by widespread North African ironstone sequences, rest on the angular unconformity, providing evidence of a critical intra-Ordovician erosional event. The constraints on tectonomagmatic imprints show signals of peripheral magmatic activity, characterized by calk-alkaline mafic intrusive and volcanic rocks Middle-Upper Ordovician in age.

The geodynamic setting is interpreted as a convergent margin leading to a late Lower Ordovician folding event (Sardic and Sarrabese phases), uplift and erosion, and the development of a volcanic arc in a peripheral northeastern Gondwana subduction zone. The Ordovician compressional tectonics, characterized by no crustal thickening, is called Cenerian Orogeny.

In this abstract we present data supporting the idea that the Ordovician geodynamics along the northeastern Gondwana margin had a far-field tectonic effect on the Gondwana interior, now detectable in North Africa. A combination of literature review and field mapping provides first-order constraints between the Cambro-Ordovician features of central Libya and peri-Gondwanan Ordovician geodynamics recorded in south-European and Alpine-Carpathian-Balkan basements.

In North Africa, the so-called "intra-Arenigian" angular unconformity separates the Hasawnah (Cambrian-Lower Ordovician) from the Hawaz (Darriwilian) fms. The stratigraphic position of the "intra-Arenigian" unconformity is consistent with the age of the compressive tectonics related to the Sardic and Sarrabese phases. Interferences between the active margin and Gondwana interior are also testified by the change of detrital zircon sources within the transgressive Middle Ordovician Hawaz Fm., suggesting exhumation and erosion of different portions of older basements. Moreover, the lowermost stratigraphic part of the Hawaz Fm. contains K-bentonites, suggesting a relationship with the coeval volcanic arc along the active margin. The long-lasting far-field interplay is further supported by the basalts interbedded within the Melaz Fm. (Upper Katian-Hirnantian), that are consistent with a short-lived back-arc volcanism induced by the accretionary tectonics related to the Cenerian Orogeny.

Polyphase deformations and transposition cycles in the "Median Dacides" tectonic units

Keywords: Cenerian Orogeny, Variscan Orogeny, Alpine Orogeny.

The Carpathian-Balkan fold-and-thrust belt formed during the Alpine Orogeny by reworking a metamorphosed Variscan crust whose protoliths span from the late Proterozoic to the late Paleozoic. The structural style is characterized by a thick-skinned nappe stack emplaced onto the rigid Moesian microcraton.

Up to now, attempts to discern the different tectonic phases are only limited to a distinction between Variscan and Alpine deformation.

In this abstract, we delve into the complex tectonic history of the Carpathian-Balkan fold-and-thrust belt, presenting new data from the central "Median Dacides" (eastern Serbia). The "Median Dacides" comprise two gneiss amphibolite-facies basement units, namely Serbo-Macedonian and Getic/Kučaj, intervening by the Supragetic greenschist-facies basement. The investigated gneiss-bearing units are embedded into Southern Carpathians (Romania) and Carpathian-Balkans (Serbia), where the Serbo-Macedonian Unit strikes across North Macedonia, western Bulgaria, and Inner Hellenides (northern Greece). The main regional structural features result from (i) the Variscan suturing of "Median Dacides" with the Danubian unit or 'Marginal Dacides' (amalgamated to western Moesian microplate) and (ii) the superimposed Alpine deformation. However, employing geological mapping and structural and microstructural analysis, previous deformation phases have been detected in both the Serbo-Macedonian and Getic/Kučaj tectonic units, and a polyphase deformation with several transposition cycles has been defined.

The first deformation event (D1) is marked by a metamorphic imprint and a relict tectonic foliation coupled with the evidence of magmatism dated to the Middle-Upper Ordovician. Moreover, an angular unconformity in the Getic/Kučaj tectonic unit has been mapped and ascribed to an Early-Middle Ordovician uplift. This tectonomagmatic phase has been connected to the Cenerian Orogeny.

The second deformation event (D2) is marked by rare folds characterized by axial plane foliation, NE-SW-striking fold axes, and NW-vergence. HP metamorphism showing amphibolite and eclogite facies is mainly related to the Variscan Orogeny. During the Variscan Orogeny, the features that originated from the Cenerian Orogeny were almost entirely obliterated and transposed.

The third deformation event (D3) is marked by a new fold generation characterized by axial plane foliation and NW-SE-striking axes. Several kinematic indicators, such as δ-type and σ-type porphyroclast, indicate a top-to-east transport direction. The axial plane cleavage acted as a transposition surface of the previous structures. The spatial arrangement of the fold axis coupled with the tectonic exhumation of the late Mesozoic-Paleogene age allows us to ascribe this tectonic phase to the Alpine Orogeny.

The fourth deformation event (D4) is marked by the eastward emplacement of the nappe stack, which led to the current structural configuration of the Carpathian-Balkan fold-and-thrust belt.

Special thanks to the Geological Survey of Serbia for support during field seasons.

Carlin Canyon, a key area for the study of the latest Carboniferous deformation in Nevada (USA)

Keywords: Nevada, unconformity, structural geology.

The debate on the Late Paleozoic deformation identified in Nevada has grown in interest during the last years due to its importance in understanding the geodynamic evolution of the western portion of the North American Plate. One of the key areas for the study of this deformation is the region near Carlin, Nevada, renowned for its gold ores and its historical significance as part of the California Trail used by pioneers in the 19th century. In Carlin Canyon, clear evidence of pre-Pennsylvanian tectonic deformations related to NW-verging fold-and thrust structures has been documented in several papers (Trexler et al., 2004) and recently revised in detail (Beauchamp et al., 2022; Snyder, 2022). Here, the lower member of the Upper Pennsylvanian (Gzhelian) Strathearn Formation unconformably covers the Lower and Middle Pennsylvanian stratigraphic units (Ely Group, including the Tomera and Moleen formations) and the Upper Mississippian Tonka Formation. Paleosoils, followed up-section by fluvial conglomerates, document an impressive angular unconformity, which is well exposed along the Carlin Canyon section and dated to the Gzhelian (Trexler et al., 2004; Beauchamp et al., 2022), and known by geologists since the 19th century. In spite of these clear field relationships, Jansma & Speed (1991) previously interpreted the unconformity as a fault surface, which was defined as an "omissional" fault on the base of young-on-older stratigraphic relationship between the supposed hanging wall and footwall, implying the tectonic erosion of part of the succession. The aim of this contribution is to revise the structural setting of the historical locality at Carlin Canyon, based on structural field analyses carried out at the macro- and mesoscopic scale on folds and faults exposed in the area. Tectonic deformations recorded in the pre-Gzhelian successions of the Ely Group have been compared to those affecting the Strathearn Formation in order to define a relative chronology of the tectonic events. Starting from the paper by Trexler et al. (2004), the pre-Late Pennsylvanian deformations have been analysed in terms of fault and fold analyses, confirming their direct relationships with a NW-SE contractional event (in present coordinates), occurred before the deposition of the Lower Strathearn Member, which unconformably rests on the deformed units of the Carboniferous Ely Group. A subsequent tectonic event is responsible for the folding of the Lower and Upper Strathearn Formation showing NNW-SSE trending tights folds involving the Pennsylvanian unconformity, as also shown in Beauchamp et al. (2022). These structures may belong to the Cretaceous Eastern Nevada W-verging thrust belt directly related to the late Mesozoic Sevier Orogeny. The Permian succession of Carlin Canyon and nearby area has recently attracted considerable interest because a base-Kungurian GSSP candidate has been identified at Rockland section (125 km to the east), and the possibility of Standard Auxiliary Boundary Stratotypes for the base-Sakmarian, base-Artinskian, and base-Kungurian at Carlin Canyon.

Keywords: Mesozoic shallow-water carbonates, basin-bounding faults, Discrete Fracture Network (DFN).

Faults can have a profound influence on the accumulation and migration of fluids in the shallow crust. Due to their conductive, sealing, and/or combined fluid barrier-conduct behaviour, faults impact the subsurface hydrogeology according to the processes associated with their nucleation and growth, the geometry of the interacting fault segments, the strain rates they evolved under, the tectonic environment in which they formed, and their diagenetic history.

In this study, we carried out a structural survey on cliffs several 100's metres high exposing Jurassic–Cretaceous platform carbonates crosscut by WNW-striking, high-angle trans-tensional faults bounding the High Agri Valley Basin. By combining field and digital outcrop structural analysis techniques, we assessed the variation of geometry, distribution, density, and intensity of both fractures and faults according to the host rock lithology and distance from the main basin-bounding faults. Then, we computed their multiscale length and height attributes to obtain input data for Discrete Fracture Network (DFN) modelling and fluid flow simulation. For the DFN modelling, we built multiple stochastic models of fracture networks at bed package (height: 5m), outcrop (height: 50m) and reservoir scales (height: 500m). Our goal is the assessment of variations of both bulk fracture porosity and permeability, as well as the scaling factors for horizontal permeability ellipses. Finally, we carried out a fluid flow simulation of the whole Monte Viggiano area in order to understand the behaviour of the carbonate aquifer at varying boundary conditions.

Field and digital results show a scale dependency of fracture and fault geometry over 3-orders of magnitude for the Cretaceous carbonates, and, in contrast, a scale independent geometry for the Jurassic carbonates. In terms of fluid storage and migration properties, results from the DFN modelling show the profound contribution provided by both strata-bound and non-strata-bound fractures to the computed porosity, and by faults to the computed permeability. Furthermore, most of the DFN models show near isotropic horizontal permeability ellipses, which is consistent with the fractured and faulted carbonates behaving as a porous medium for horizontal fluid flow. We note that fault-parallel dominated flow is exhibited by geocellular volumes representative of the main basin-bounding fault zones. Results of ongoing fluid flow simulation should shed more light on the optimum reservoir development and production strategy to adopt while modelling the migration of fluid through the assessed pathways. Overall, the results of this study will be useful to hydrogeologists for groundwater management and operations, and to other geoscientists and reservoir engineers in understanding shallow reservoir behaviour, identifying production/injection patterns, and optimizing reservoir management strategies.

Building a 3D model of CARG Ragusa Sheet 648 (Hyblean Plateau, SE Sicily, Italy): evaluating/mitigating uncertainty through the integration of structural data at different scales

Anzelmo G.*[1], Forzese M.[2-3], Iacopini D.[1], Carbone S.[2], Catalano S.[2], Montalbano S.[2] & Maniscalco R.[2]

Keywords: 3D geological models, seismic, Hyblean Plateau.

In the frame of CARG Project, a subsurface digital mapping and a 3D geological model of Ragusa Sheet 648 have been performed using both seismic and borehole data.

The CARG Ragusa Sheet 648, 1:50,000 map scale, covers part of the Hyblean Plateau, which is foreland to the Maghrebian thrust belt in SE Sicily. It represents a culmination of the Mesozoic-Cenozoic carbonate sedimentary succession, part of the larger crustal sector known as Pelagian Block, northernmost margin of the African Plate. Since the 1950s, the Hyblean Plateau has been an area of great interest for hydrocarbon exploration due to the first oil field discovered in 1954. Since then, important subsurface research activities have been carried out by several energy companies. For this work, vintage subsurface sections, check shots, and well logs have been made available by ENI S.p.A, plus deep wells and seismic sections from public resources (e.g., ViDEPI database) have been considered. In this work we do show a systematic vectorization of the seismic SEG-Y data through WIGGLE2SEGY script (Sopher, 2018) and then an interpretation of the subsurface data integrated with the structural field maps of the area. The quality and resolution of the SEG-Y vintage seismic lines allow only to infer large scale tectonic structures. Most of the faults recognized on outcrop always have throws that fall below vertical seismic resolution, or often are challenging to identify through the reflection datasets. However, by evaluating/mitigating the uncertainty in the subsurface fault geometry through the integration of structural data at different scales (using some wells), we do propose a first comprehensive 3D subsurface model for the Ragusa sheet, matching outcrop data to seismic scale structures.

Keywords: 3D geological model, Northern Apennines, Salsomaggiore tectonic window.

The increasing availability of software and the improved calculation capabilities of desktop computers allow to approach the 3D geological modelling. The models provide a valuable tool for describing, analizing and showing the geological features of a specific area of variable extents and depth from the surface. The 3D modelling is extremely useful for: 1) collecting, integrating and comparing all the available geological data (geological maps, wells, subsurface geophysical data, etc..); 2) implementing and updating an existing model with new geological data; 3) analyzing quantitatively areal extent, thickness, geometry and volume of geologic units, faults and folds; 4) interactive visualizing, free hand slicing and 360° perspective of the different geological features; 5) foreseeing the most likely prosecution of the geological features in the modelled area where data are less, poor or absent. Therefore, the 3D geological modelling is a strategic tool for researchers, professionals, companies, organizations as well as administrations dedicated to study, plan and manage the territory and its natural resources; but it is also a useful way for disseminating and communicating with non-expert/specialist in geology. In order to test the benefit of the 3D modelling, we built a model of the SE termination of the NW-SE trending Salsomaggiore Terme tectonic window in the Parma province in between the Taro River and the Recchio River. This area has been investigated since long time for hydrocarbon exploration, stratigraphic and structural analysis, morphotectonics studies, geological mapping at different scales (AA. VV., 2005) and unpublished master thesis. All these available data have been integrated and processed by using the software Leapfrog Geo by Seequent.

In order to refine the model, additional field surveys and new geological cross-section were realized and uncertainties arisen by model building were solved providing an anchor for better constraining the 3D model. The new 3D model contributed to confirm the geological evolution of the Salsomaggiore tectonic window since Serravallian to present, as depicted in previous work (Artoni et al., 2004 and references therein), but it unexpectedly provides interesting results by revealing new geological features such as:

- shale diapirs within the Ligurian allochthonous units;
- Serravallian normal faults affecting unlithified sediments and sealed by the overlaying allochthonous units;
- a NE-SW striking transfer fault which is longer than previously mapped and aligned with cold hydrocarbon seepage likely sourced along the buried thrust whose depth has been estimated at around 800 m depth b.s.l.

The 3D modelling provides an easy-to-visualize geology of the area by processing all available, often disomogeneous, geological and territorial data but, in the study case, it has been also a useful tool for re-interpreting and discovering new features of the geology of an area.

Keywords: Northern Apennines, 3D modelling, CARG Project.

Integrating geological maps and outcrops stratigraphic-structural data (i.e., surface dataset) with well data and seismic reflection profiles (i.e., subsurface datasets) is a crucial aspect of creating constrained 3D models of sedimentary basins. The main uncertainty in combining these datasets lies in the different scale of observation of the tectono-stratigraphic elements that are typically found in sedimentary basins. Outcrop- and map-scale surface datasets can be used to reconstruct the three-dimensional architecture of stratigraphic units (e.g., lithofacies, members, formations, groups, and synthems), stratigraphic unconformities, and the main structural elements (e.g., faults and folds). In contrast, subsurface datasets mainly resolve the stratigraphic unconformities and the architecture of geological bodies and tectonic structures at the basin-scale seismic resolution, especially in areas with a flat morphology where no outcrop data are available. Sheet 177 Tortona of the Geological Map of Italy at 1:50,000 scale (CARG Project) represents an excellent example to discuss the best practices for integrating surface and subsurface data, as it includes hilly areas where the tectono-sedimentary assemblage of the Northern Apennines is outcropping, and alluvial plain areas where this assemblage is covered by alluvial sediments of the Po Plain, for which subsurface data are available.

We present preliminary 3D models of selected areas of the Sheet 177 Tortona that are built by integrating geological mapping and outcrop stratigraphic-structural data with the interpretation and correlation of well-logs, borehole data, and some deep hydrocarbon well logs available on the ViDEPI database (www.videpi.com). The tectono-stratigraphic assemblages of the Northern Apennines has been subdivided into the Early Cretaceous – early Eocene External Ligurian Units, which are unconformably covered by the late Eocene-Miocene Epiligurian Units and the Pliocene - Quaternary successions of the Po Plain. Different stratigraphic unconformities, and mappable faults and folds are considered in the 3D model using i) intersecting geological sections to describe the geometries of the main structural and stratigraphic elements, and ii) punctual measurements of the attitude of the geological surfaces. These robust surface constraints allow for down-tracing of main stratigraphic boundaries and tectonic structures for surface-log correlations. The integration of the surface and subsurface datasets helps to visualize the 3D architecture of the complex assemblage that characterizes the Tortona sheet and represents a starting point for implementing the 3D model with deep seismic reflection profiles.

3D reconstruction of regional-scale unconformities in the Po Basin: integrating well data and seismic profiles to improve the understanding of Plio-Pleistocene evolution

Keywords: Po Plain, 3D geomodeling, seismic interpretation.

The tectonic framework of northern Italy is characterized by the complex interaction between the Southern Alps (SA), the Northern Apennines (NA), and their shared foreland basin, the Po Plain (PP). Extensional tectonics dissecting carbonate platforms mainly characterized the Mesozoic evolution of the basin. The structures produced during this phase played an important role in the consequent evolution of the SA since the Late Cretaceous and of the NA since the Lower Miocene. The geometry of the NA and SA fold-and-thrust belt was influenced by inherited structures and consequent basin topography that controlled the evolution of the thrust fronts. In particular, the NA fronts show three different arcs with different amounts of shortening, with the lowest values found in the Monferrato Arc to the west and increasing towards the east with the Emilian Arc and the Ferrara Arc. The particular evolution of each arc controlled the deposition and the architecture of different zones of the Plio-Pleistocene syntectonic successions of the PP (onshore) and northern Adriatic Sea (offshore).

To date, published works on the basin-scale evolution of the Po Basin have primarily focused on the eastern depocenters of the Po-Adriatic Basin (Amadori et al., 2019) This was achieved for specific intervals of the sedimentary infill consisting of siliciclastic units bounded by regional-scale tectono-eustatic unconformities. In a stratigraphic order, these units are defined as Base of Pliocene (PL1), Intra-Zanclean (PL2), and Intra-Piacenzian (PL3) for the Pliocene succession, followed by Early Gelasian (PS1), Early Calabrian (PS2) and Late Pleistocene (PS3) for the Pleistocene succession.

In this work, we present a comprehensive 3D reconstruction of these regional-scale unconformities for the entire Po Basin, using an extensive database of well data and 2D seismic profiles provided by Eni E&P, integrated with previously published studies. Depth conversion was performed using a 3D velocity model based on borehole interval velocities from all over the basin. This allows us to better understand the evolution of the PP by enabling the investigation of relationships between surface development, tectonic activity, and basin-wide changes in sedimentation rate through time. The 3D reconstruction also provides the basis for a better understanding of the degree of interaction between the SA and NA along the basin and its effects on the evolution of the Plio-Pleistocene basin.

Examples of multidisciplinary approach as a strategy to reduce uncertainties in geological models

Bigi S.*

Geological models are used to handle the results of geological processes that create significant heterogeneities at multiple scales below the surface of the earth.

Our observations are always limited for several reasons, including limitation dur to adopted methods, to the observers, to scale, dimension, and time. Uncertainties can also enter at different steps, during acquisition, processing, and model building. These limitations bring to multiple interpretations that can all satisfy the same incomplete dataset. Therefore, the evaluation of uncertainties in geological interpretation and modelling plays an essential role for a wide range of applications, from scientific investigations to geotechnical aspects, hydrogeological investigations, and geo-energy resources exploration.

Reduce uncertainties is very important and there are different approaches, based on different kind of data (surface data, geological sections, geophysical data, borehole data, etc). Statistical methods can be used to quantify and reduce the uncertainty and variability estimating probability distributions and uncertainty propagation.

Geological uncertainties can be considered gaps in the continuity of data observation that can also be fill combining different kind of information from different disciplines. Procedures to provide the evaluation of CO_2 storage capacity can be a good example of the management of uncertainties and of the tools used to improve results and reduce bias.

The volumetric approach is based on the definition of the available volume suitable for storage. As a consequence, the first step is the construction of a "static geological model" which is a geological based model able to provide a volume of reservoir. Here the uncertainties due to the reconstruction of the surfaces is constraint by quality and quantity of data (well logs, seismic lines, surface geology). In fact, 3D models' reconstruction is based on different mathematical algorithm to perform spatial data interpolation. The obtained geological model is than corrected using petrophysical parameters, based on the sedimentological and structural aspects provided by the geological model. Again, multidisciplinary data are needed.

These steps need to be integrated with the application of a statistical evaluation as the Monte Carlo method to reduce bias and to provide a better evaluation of results a statistical evaluation. The fluid flow dynamic approach can than further reduce uncertainties. This latter is, on its turn, based on efficiency factors that integrates geological data and define their dynamic role. An example comes from the role of fractures, where volume availability starts from field data to fluid flow dynamic simulation.

A subsoils model reconstructed integrating geological and geophysical data in the area of the town of Palermo

Keywords: 3D model, geophysical surveys, boreholes.

The plain of Palermo is a strategic area as it hosts the fifth city of Italy as number of inhabitants and several industrial activities and infrastructure arise in this sector. For these reasons, exploiting a dataset composed of both geological and geophysical data, the University of Palermo is implementing the reconstruction of a 3D model of the subsoil of the plain to detail the geologic features of the area and underling hazards that could affect the city. The database used consists of more than 2000 boreholes and active and passive seismic data. The stratigraphic data were initially analyzed due to be homogenized to make them more usable for the definition of a small-scale 3D model. From the analysis of the bores, it was noticed that mainly the subsoil consists of limestones, flysch, clays, calcarenites and alluvial deposits. For each stratigraphic unit the position of the top of each described layer has been computed. In addition, a geophysical survey campaign was carried out to detail the model in areas where there are not many stratigraphic data. The acquisition of data by MASW surveys (Park et al., 1999) had allowed to associate shear waves velocities (Vs) values to the main lithologies outcropping in the subsoil of Palermo. The shear waves velocities computed range vary from 200 - 300 m/s for alluvial deposits to Vs equal or greater than 800 m/s for limestone and flysch. Moreover, several environmental noise recordings have been carried in the city. These data have been analyzed by means of the HVSR technique (Nakamura, 1989). The HVSR curves produced by seismic noise analysis are characterized by the presence of several peaks that have been linked to the main stratigraphic boundaries that characterize the subsoil of the plain. In particular, the peak present at lower frequencies, between 0.8 and 2.5 Hz, has been connected to the stratigraphic contact between the flysch and the overlying Ficarazzi clays. The velocities derived from MASW have allowed to invert the HVSR curves in seismographic models. These models made it possible to calculate the depth of lithological boundaries and integrate the database for the construction of the 3D model. Subsequently using different interpolation algorithms, depending on the number of available data for the top of each recognized lithology and the reciprocal distance between them, the stratigraphic surfaces that make up the 3D subsurface model have been generated. As a result of this, the thicknesses for the most common lithologies in the plain area have been calculated. The achieved model allows to depict the main lithologies that characterize the Palermo subsoil and their spatial distribution, vertical thickness and lateral extension. Furthermore, this model also describes the former morphology of the area, which is nowadays masked by a dense urban settlement. The outcomes of this study will improve the ability to identify areas subject to geological risks such as seismic and hydraulic hazards.

Keywords: geophysical surveys, groundwater bodies, 2D-3D modeling.

The analysis of the geological setting of alluvial plains, located in coastal sectors, currently represents a topic of great importance. Indeed, over time, several urban areas have concentrated in these plains as well as industrial activities and infrastructures. In the north-western Sicily wide alluvial plains are present; in this sector, overlooking the Tyrrhenian Sea and surrounded by the Nebrodi and Peloritani mountains, coastal plains are connected to the hydrographic network that is characterized by gravel bed rivers and streams, better known as "Fiumare". Numerous urban centers and the related industrial areas are located these plains, such as Milazzo and Capo d'Orlando. Many geological hazards have been highlighted in these areas, including seismic and hydraulic hazards. Furthermore, water resources are heavily affected by human activities which often cause groundwater pollution. For these reasons, within a project of the INGV-DAR (Granata et al., 2018), several studies have been conducted to reconstruct 2D and 3D geological and geophysical models of groundwater bodies of three alluvial plains: Caronia, Sant'Agata-Capo D'Orlando and Barcellona-Milazzo. The construction of these models is based on a large database made up of previous and newly acquired geological and geophysical data; several geological data have been derived from field surveys and boreholes, while the geophysical data have been mainly obtained from the Cassa del Mezzogiorno project (CASMEZ, 1978). These previous geophysical data, consisting in vertical electric soundings (VES) and seismic refraction surveys, have been qualitatively analyzed and partly been reanalyzed; in particular, 3D resistivity models have been obtained by interpolating 1D inverse VES models. Moreover, to detail the underground models, new geophysical surveys campaigns were carried out, relating to active and passive seismic acquisitions. The data computed by several multichannel analysis of surface waves surveys (MASW) allowed to describe different S-wave velocity profiles. Furthermore, the VS values have been used to constrain the inversion of the HVSR curves, obtained from seismic noise recordings. Using all the available data the geological models of the three coastal plains were realized. These models describe the depth reached by the alluvial and other deposits constituting the groundwaters bodies and their anomalies in the thickness: the greater volumes described for the Caronia area (Canzoneri et al., 2023) and for the Sant' Agata - Capo D'Orlando and Barcelona P.G. – Milazzo plain (Capizzi et al., 2024) are not closely related to the nowadays morphology and fluvial environment due to some changes in rivers networks net, but are probably related to the recent tectonic movements and differential uplift rates that affected these costal area. Moreover, the realized models allow to identify areas that may be most susceptible to geological hazards.

Geothermal energy is recognised as a sustainable and environmentally friendly solution for power generation and district heating/cooling, offering uninterrupted availability throughout the year and day, with significant development prospects worldwide. However, the exploitation of deep geothermal reservoirs requires thorough a detailed reservoir characterisation.

The InGEO project ("*Innovation in GEOthermal resources and reserves potential assessment for the decarbonisation of power/thermal sectors*") aims to develop an innovative exploration workflow that integrates geological/geophysical data and other direct and indirect information, in order to characterize the reservoir rocks and the overlying sedimentary cover.

To this aim, we chose as a target area the Romagna and Ferrara folds, where a thermal anomaly has been identified and attributed to the thermal convection in deep-seated Mesozoic carbonate units (Pasquale et al., 2013; Pasquale et al., 2014). The Romagna and Ferrara folds represent the outer deformation front of the Northern Apennines thrust and fold belt. They are partly buried under thin (about 200 m) Plio-Pleistocene terrigenous deposits of the Po plain. The Ferrara folds are composed of the Mesozoic carbonate sequence, which has been significantly deformed during the Neogene and Quaternary tectonics, while the Romagna folds are composed of the Tertiary clastic formations overlying the Mesozoic limestones (Montone & Mariucci, 1999).

In this study we present the first results of the analyses of the geological data (e.g., seismic lines, stratigraphic columns, well reports and logs, borehole tests and measurements, gravity anomalies) collected from VIDEPI (https://www.videpi.com/videpi/videpi.asp) and GEOTHOPICA (https://geothopica.igg.cnr.it/index.php/it/) database, in terms of the depth of the main geological units. These results will be compared with those already published in previous studies (Livani et al., 2023), in order to implement a consistent geological model of the study area. The last one will be further supplemented with interpretations from thermophysical experiments on rock samples.

The geological model will contribute to the development of an open-source and web-based GIS tool and will be the main input for calculating the area's geothermal potential, improving business planning for the exploitation of deep geothermal resources in Italy.

Geological 3D modeling is the new geological mapping

D'Ambrogi C.*

Dipartimento per il Servizio Geologico d'Italia, ISPRA.

Corresponding author email: chiara.dambrogi@isprambiente.it

Keywords: 3D geological models, geological maps, CARG Project.

Geological mapping has represented, and largely still is, the most common way to synthesize and communicate the geological history and processes of an area; consequently, geological maps have represented successful and strategic tools not only for geologists. In the last decades, the evolving demands for digital geoscience and the need for up-to-date, high-quality, and public subsurface geoscientific information fixed a new challenge for the geoscientific community.

The Geological Survey Organizations are leading this transition by being able to combine their long-established mapping activities with advanced technologies in the collection, management, integration, and dissemination of the geological data, introducing also the third- and forth-dimension; therefore, documentation of geology is undergoing a transition from static 2D maps to digital 3D reconstructions. The Servizio Geologico d'Italia (SGdI) faced this transition by promoting the systematic production of 3D geological models, now also as part of the CARG Project.

The concurrent realization of the geological map and 3D model of an area allows for a holistic approach, with strong integration of new collected and vintage data, both surface and subsurface, aiming to provide richer, reliable, harmonized, and multi-resolution depictions of the geological architecture and parameters.

The 3D geology paradigm requires i) a clear fit-for-purpose conceptual model, ii) input data from geological field surveys, boreholes, and various geophysical investigations, iii) a well-established harmonization process, iv) a robust, replicable, and iterative modeling workflow. In addition, according to the final use, the geological 3D modeling requires geochronological constraints and physical and geochemical parameters.

The experiences in European (GeoMol, GeoERA, GO-PEG, GSEU) and national 3D geomodeling (RETRACE-3D) projects focusing on the description and analysis of the geological architecture of both shallow and deep subsurface and the cutting-edge technological aspects, allowed to design and refine these steps, emphasizing the need for integration and maximization of different types of available datasets and for finding and testing open-source tools and algorithms for data analysis and modeling. As part of this process, the 3D geological models production in the CARG Project will represent a significant step forward for the national geological community which is asked for a greater effort in reconciling all the available conceptual and physical constraints, and to provide accuracy evaluation.

The production of robust 3D geological models is one part of the challenge, the institutional mandate of the SGdI is also the FAIRness of geological information: through ISO standard metadata and DOI, OGC standard download services, using INSPIRE Geology-based extended data model, and adopting CC-BY open license. The access point of 3D geological models will be the GeoIT-3D viewer https://geo-it3d.isprambiente.it.

Fluid flow history and paragenesis along a syn-rift basin bounding fault: the Helmsdale Fault (NE Scotland)

Keywords: fluid flow, calcite vein, rift basin.

Within syn-rift basinal settings, the juxtaposition of rift-related clastic deposits in the hanging wall of basin-bounding normal faults against a footwall of crystalline basement is a recurrent structural setting where plays for hydrocarbon exploration or carbon storage can be found. Here, fault-controlled fluid flow can significantly influence and change the petrophysical properties of the fault zone and host rocks over time by means of mineralization and cementation, ultimately controlling fluid pathways. Investigating the timing and extent of fluid flow along major faults permits us to better understand the host rock properties and if these can potentially be favourable for subsurface extraction and storage.

Here, we present a detailed investigation of the timing and paragenesis of fluid flow along the well exposed Helmsdale Fault in NE Scotland. The Helmsdale Fault is a major tectonic feature that bounds the western side of the Inner Moray Firth Basin, which developed during rifting in the Late Jurassic. The hanging wall consists of the Late Jurassic (Kimmeridgian-Tithonian) Helmsdale Boulder Beds that are made of alternating debris flow and mudstone/siltone deposits, whereas the footwall is composed of the Helmsdale Granite (Silurian-Devonian). There is ample evidence of paleo-fluid flow along the Helmsdale Fault in the form of calcite cementation and widespread calcite veining in both the hanging wall and in the footwall, locally making up to 5 m thick fault cores of stacked crack-seal veins. U-Pb calcite dating of fossils, veins and cements shows an initial fluid flow event that quickly follows diagenesis in the hanging wall and spans from 147 to 113 Ma, followed by a later reactivation of the fault system between 86-60 Ma. The spatial distribution of the dated calcite veins shows a clear localization over time of fluid flow along the main faults within the footwall.

Carbonate stable isotope analysis, combined with the salinity of the fluid inclusions in the calcite veins, has revealed a marine fluid composition of the calcite vein network over time, irrespective of the structural domain within the fault zone. Furthermore, clumped isotope thermometry shows a gradual temperature increase towards the footwall (35 to 65 °C), but fluid inclusion microthermometry on secondary fluid inclusions also reveals that these fluids could originally have been much hotter (up to c. 80 °C). These data suggest that fluids percolated upwards along the main faults within the Helmsdale Granite. Occurrence of calcite veins derived from meteoric fluids is documented in the youngest dated vein network (60 Ma) and likely related to the later stages of regional uplift.

Our results suggest that the evolution over time of the petrophysical properties of the hanging wall with progressive mineralization and cementation exert a critical control on future fluid pathways as well as localization and style of subsequent fault deformation.

How high-resolution tomographic imaging can provide new information on fault interaction: the case of the 2009 L'Aquila seismic sequence

Fonzetti R.*[1-2], Buttinelli M.[1], Valoroso L.[1], De Gori P.[1] & Chiarabba C.[1]

[1] INGV, Roma. [2] Dipartimento di Scienze, Università di Roma Tre.

Corresponding author email: rossella.fonzetti@uniroma3.it

Keywords: geometric-kinematic fault interaction, L'Aquila 2009 seismic sequence.

The geological and structural complexity of the Central Apennines (Italy) often hinder the identification of which factors control the development of energetic seismic sequences, like those occurred in recent decades.

In this study, we built a new seismotectonic model of the area affected by the Mw 6.1 2009 L'Aquila seismic sequence based on a multidisciplinary approach, combining geological and structural evidence with 3D high-resolution Vp and Vp/Vs velocity models obtained by inverting about 36,000 seismic events to compute Double-Difference seismic tomography.

The tomographic model's high-resolution (2x3x2km cell) has unprecedented details that allow us to isolate velocity anomalies and refer them to geological bodies.

The area is mainly characterized by compressional structures of the Mio-Pliocene belt and pre-existing normal faults, vertically segmented and confined between major thrust sheets. Our results indicate that the complex structural setting due to the compressional stage still controls the evolution of extensional earthquakes. The original lack of continuity of inherited normal faults embedded within different thrust sheets influences the evolution of seismic ruptures during large earthquakes, the dynamic coseismic propagation, and the segment interaction. The chance of long segments to be activated (or reactivated), favored by interaction of vertically juxtaposed segments, relies on their original orientation that is not always favorable with the actual extensional stress field. We infer a consistent geometric and kinematic interaction between a large, mostly NW-SE fault located in the footwall of the Gran Sasso thrust sheet activated by the Mw 6.1 mainshock, and the surface expression of part of the Paganica Fault, even their different orientation, in the area where they are vertically and coincidently continuous.

Regional subsurface 3D model of southern Sicily for potential seismogenic fault characterization and seismic scenarios: the INGV SPIN project

Forzese M.*[1], Lipparini L.[1], Chiacchieri D. [1-2], Cavallaro D. [3], Firetto Carlino M. [3], Scarfì L. [3], Faenza L. [4] & Molinari I.[4]

[1] INGV, Roma 1. [2] Dipartimento di Scienze, Università di Roma Tre. INGV, Osservatorio Etneo. [4] INGV, Bologna.

Keywords: 3D subsurface model, fault kinematics, seismic scenarios.

The monitoring and characterization of potential seismogenic features in the Italian Peninsula have been pivotal goals for the National Institute of Geophysics and Volcanology (INGV) for decades. The development of more advanced tools allowed the investigation of structures which might or actively contribute to the actual and historical seismicity of our territory. In particular, the elaboration of more sophisticated 3D models led to a better understanding of the possible scenarios at different scales – nationally and locally. However, regional scale work relating fault activity, seismic hazard potential, and associated scenarios is a complex task to accomplish.

We here present the ongoing INGV work under the framework of the project "SPIN", which aims at defining seismogenic faults and evaluation of their effective hazard through synthetic scenarios. It tracks down the previous INGV projects to corroborate a solid workflow at different scales. Here, the complex frame of Sicily Island, which is also prone to tsunamis, is introduced. An area of ca. 19'000 km2, both onshore and offshore, covers the three main domains of the Island: Apennine-Maghrebian thrust fold best; Catania-Gela foredeep; Hyblean Plateau foreland. A copious subsurface dataset has been developed in the last 70 years thanks to the interest of Oil and Gas companies and their ongoing productions, in particular in the foreland domain. Thus, this project considers most of the 2D seismic lines and deep wells from exploration surveys, as well as literature geological and structural maps, sections, and reports. The result is a regional 3D model up to ~50 km depth through the integration of available crustal models.

The characterization of the model allows a better constraint of fault activities through time and their associated seismic shaking scenarios. Plus, it represents the starting point for geomechanical modelling.

3D workflows, such as the one here developed and shown, represent a solid practice to lead to a more accurate and realistic characterization of fault activity, contributing to the characterization of local seismicity, thus, risks, at any scale.

A first step toward a 3D geological model of Florence area (CARG Programme, Sheet 275): first approach for the reconstruction of the top substrate surface

Iandelli I.*[1], Marchetti E.[1], Benvenuti M.[1], Coli M.[1] & Maestrelli D.[2]

Keywords: 3D geological models, gravimetry, CARG.

The CARG sheet n°275 "FIRENZE", currently under realization, in addition to the surface map includes for the same area a reconstruction of the top bedrock surface, which for the urban area of Florence will constraint a 3D geological model of the Quaternary infill deposits. The methodology followed for reaching this goal is based on the integration of two main datasets. These include a collection of geognostic surveys (boreholes) for which a stratigraphic description is available (Coli, 2022) and gravimetric data provided by ENI under a confidential agreement with ISPRA for the realization of the CARG sheets (ISPRA,ENI, 2020). For the Florence area the database includes more than 2,000 stratigraphic logs coming from different sources (Regional Tuscan Administration, Florence Municipality, ISPRA L.464/84). Borehole data are managed through a three-dimensional geognostic database, the structure of which is set up for use in the reconstruction of the three-dimensional model. The gravimetric data consist into the Bouger Anomaly provided by ENI that was calculated considering a rock density of 2670 kg/m3 and computed over a regular grid of 500x500 m. To estimate the sediment thickness we first computed reginal Bouger Anomaly considering only measurements performed on bedrock and therefore inferred residual Bouger anomaly for the sedimentary basins (Salimi & Motlagh, 2012). This was inverted to sediment thickness by adjusting the unknown sediment density in order to minimise the difference with real bedrock depth that is available for more than 1250 boreholes distributed over the area of analysis (Moretti, 1942; Coli, 2022). The poster addresses the problems of processing and integrating these two different types of data, i.e., direct and indirect and shows the results obtained with different processing levels, integrated using the software Leapfrog® and the basic geological concepts and regional knowledge.

Seismotectonic characteristics of the 2022/24 Fano seismic sequence (Central Italy)

Invernizzi C.*[1], Costa M.[2], Penza G.[1], Teloni S.[1] & Pierantoni P.P.[1]

[1] Scuola di Scienze e Tecnologie, Sezione Geologia, Università di Camerino. [2] Freelance.

Corresponding author email: chiara.invernizzi@unicam.it

Keywords: transversal faults, strike-slip, active tectonic.

On November 9, 2022 a seismic sequence began offshore of Fano town with a MW= 5.5 mainshock. The affected area falls in the external sector of the central Italy (Marche region) structurally characterized by a series of NW-SE high-angle Plio-Quaternary transpressive flower structures. These latter are generally interrupted by left-lateral transversal fault systems ENE/WSW to NNE-SSW trending (Pierantoni et al., 2019). Compressional structures are mostly sealed by undeformed Quaternary deposits in the off-shore, while the transverse structures are active and seismogenic (Costa et al., 2023).

The sequence developed with rapidly decreasing intensity and number of events until the end of 2023 and beginning of 2024 consisting of more than 900 earthquakes with M>1. The main shock is characterized by a compressive or transpressive focal mechanism with NW-SE, low-angle focal planes.

Several steps can be recognized within this sequence, some with epicenters distribution falling along NW-SE compressive structures and others with a prevalent NE-SW alignments of the epicenters in accordance with transversal structures. Furthermore, strike-slip focal mechanism along subvertical planes consistent with the transversal structures occasionally occurred.

According to current literature, the external sector of the Apennine is characterized exclusively by low-angle, NE-vergent thrusts that developed without interruption for tens of km (Structural Model of Italy, 1989). Maesano et al. (2022), Pezzo et al. (2023) believe that the Fano seismic sequence occurred because of the local activation of NW-SE compressive structures buried below thick undeformed Quaternary marine deposits.

Nevertheless, based on available focal mechanisms and epicenter distribution, a different seismotectonic hypothesis can be suggested. It appears that limited segments of NW-SE trending compressive structures have been activated, and this could be connected to movements along a transversal strike-slip structure in the area, the Metauro-Fano Fault System (MFFS, Pierantoni et al., 2019). This is an active fault system marked by recent seismic sequences (Costa et al., 2023). The largest number of events belonging to the 2022-24 seismic sequence is concentrated in a subtriangular area bounded by the offshore branch (NNE-SSW) of MFFS to the W, and by an approximately NE-SW alignment (probably unknown branch of MFFS) to the E. Since MFFS is an active left-slip structure, the subtriangular area between the two branches is affected by a NE oriented compression. Therefore, segments of the NW-SE structures, located only in this area, were reactivated and produced the shallowest earthquakes, while other earthquakes can be associated to the simultaneous activation of the strike-slip transversal structures. In fact, some scattered events also occur near the Metauro valley and indicate the occasional activation of the onshore branch of MFFS.

Keywords: fault zones, groundwater modelling.

Fault zones affect to groundwater flow, as the fault volume usually undergoes important petrophysical variations and represent a key zone for trapping, channelling and deviating fluid flows. Through a sensitivity analysis within a groundwater model, we aim to quantify the fault effect on fluid flow conditions within the siliciclastic-carbonate Logudoro basin, in northern Sardinia, Italy. The study is focussed specifically on how groundwater flow may be affected by deformation structures in the fault damage zone, fault rocks in the fault core, and the geometrical effect of juxtaposition along the fault plane. Special attention is given to the role of varying deformation structures such as deformation bands in high-porosity sands and open fractures in low-porosity limestones and marlstones. The groundwater model is completed with MODFLOW6, with 3 orthogonal-to the fault sections in 2D steady-state single-phase, subsurface flow models. Parameters included in the models are: i) the lithostratigraphical framework based on surface control points, lithostratigraphies and the resulting 3D geological model; ii) piezometric heads, measured in March 2021 in wells, and spring locations in the study area; iii) the permeability of the different predefined hydrogeological units, acquired through in-situ air-permeability measurements with TinyPerm3 and converted into hydraulic conductivity for modelling purposes. The model is calibrated with PEST against observations from hydraulic heads in proximity to the fault. Expected outcomes are, (i) the quantification of the individual and combined impact of fluid flow affecting components in the fault-zone on groundwater flow circulation across and along the fault zone and, (ii) the quantification of impact on local and regional fluid flow systems. Hence, with this study we enhance the understanding of the role of fault-zones in groundwater models and quantify the effect, especially in mixed siliciclastic-carbonate basins.

A geology-based 3D velocity model of the Amatrice Basin (Central Italy)

Livani M.*[1], Scrocca D.[1], Gaudiosi I.[2], Mancini M.[2], Cavinato G.P.[1], De Franco R.[3], Caielli G.[3], Vignaroli G.[2-4], Romi A.[5] & Moscatelli M.[2]

Keywords: Amatrice Basin, geology-based 3D velocity model, seismic hazard assessment.

The Amatrice area was historically affected by moderate to large earthquakes, which caused extensive damages and many casualties, like the 1639 and the 2016-2017 seismic sequences. For this reason, the area was extensively studied and a large amount of seismological, geological and geophysical data were acquired. However, a detailed 3D geological model of the area subsoil was still missing and, consequently, the local seismic response evaluation of the area could only be based on the geological and geotechnical characteristics of rocks and the available low-resolution and large-scale models.

In this work we present a new methodological approach integrating geological (e.g., maps, cross-sections and core-wells) and geophysical (e.g., down-hole, MASW, refraction, and seismic noise measurements) data applied for reconstructing a detailed 3D geological and geophysical model of the uppermost hundreds of meters of the Amatrice Basin. All the available data were georeferenced and uploaded into 3D geological modeling software where faults and stratigraphic boundaries were digitized, checked, hierarchized, and modelled. The reconstructed 3D geological model was parameterized with the S-wave (Vs) and P-wave (Vp) velocities values, and the resulting 3D geology-based velocity model was verified by comparing the environmental noise (i.e., horizontal-to-vertical spectral ratio analysis, HVSR) recorded at some seismic stations with the seismic responses modelled at some nearby control points.

The proposed model is the first geology-based 3D velocity model of the Amatrice Basin, which may be used for example as input-model for future ground-motion and seismic-wave-propagation simulations aimed at a more precise local seismic response assessment and, consequently, at the development of more realistic seismic hazard scenarios. The methodological approach here presented can also be applied in other areas for reconstructing detailed 3D geological-geophysical models to be applied for the assessment and mitigation of different geological risks.

Early deformations of carbonate platforms driven by differential compaction of the basinal unit: Finite Element Method-based numerical analysis

Manna L.*[1], Menegoni N.[2], Maino M.[1] & Perotti C.[1]

Keywords: carbonate platform, basin, differental compaction.

In this study, we use a 2D linear elastic Finite Element Method-based numerical model to investigate the relationship between the differential compaction of a basinal unit and the early deformation of a prograding and/or aggrading carbonate platform. The numerical simulation aims to examine changes in stratal geometry and the stress field resulting from differential compaction. We compare the numerical results with two case studies: Lastoni di Formin and Nuvolau Mountains (Passo Giau, Italy). Both outcrops are remnants of Triassic carbonate platforms located in the Eastern Dolomites of the Italian Southern Alps. Our model explains the modifications in stratal architecture and the fault and fracture patterns observed on these platforms. A key finding from our simulations is that the slope and slope-to-basin transition regions are likely to experience the majority of brittle deformation. Contrary to findings from previous numerical studies (e.g. Resor & Flodin, 2001; Nolting et al., 2018), our simulations suggest that within the same region, platform-ward dipping faults and major fractures may form, with dip angles decreasing towards the basin. Additionally, the inner platform region may exhibit a tensile regime, potentially leading to the formation of nearly vertical syndepositional and/or syndiagenetic fractures. These were not predicted in previous research papers but are observed in our case studies (Inama et al., 2020; Menegoni et al., 2022b). Lastly, in platforms that predominantly prograde, our simulations indicate a general tilting and thickening of the inner platform strata towards the platform break.

The subsurface geological map of the Torino metropolitan area (Western Po plain): from 3D model to 2D map export

Marcelli I.*[1-2], Irace A.[1] & Fioraso G.[1]

Keywords: subsurface geological map, sedimentary basins, 3D model.

The 1:100,000 subsurface geological map of the Torino area is the cartographic output of a database-assisted 3D geological model, covering an area of about 890 km2, between the western Alps and the Turin Hill reliefs. This sector is of geologic relevance as it develops above one of the most significant structural elements of the northwestern Apennine - Po plain transition, i.e. the Torino Hill thrust Front and associated folds system, whose late Miocene to early Pleistocene tectonic activity strongly influenced the geologic evolution of this region.

In the recent past, the geologic setting of the northeastern partly outcropping part of this fold-thrust complex was mapped in detail, and its oldest (Late Miocene) tectono-stratigraphic evolution was studied in the Turin Hill. Conversely, the general traits of the architecture of its southwestern, buried counterpart and its Plio-Quaternary tectono-stratigraphic evolution were only partly illustrated by a few seismic reflection profiles. Furthermore, lower detail and scale subsurface maps of the subsurface of the central-eastern and northern portions of the study area have been provided. Therefore, a complete geological subsurface representation of the Pliocene-early Middle Pleistocene tectono-stratigraphic assemblage of the area was still lacking.

In this perspective our map is a more detailed document, providing an updated representation, below the Middle Pleistocene regional unconformity, of the stratigraphic and tectonic relationships characterizing the buried Pliocene-Lower Pleistocene sedimentary pile involved Turin Hill thrust-propagation folds system. The map is grounded on over 500 water-well and borehole logs detailed correlations along shallow triangle meshes (average investigation depth of 200 m below ground surface), managed by the GMS (Groundwater Modeling System) software, and constrained by published seismic transects.

The map provides new elements to discuss late Pliocene-early Middle Pleistocene tectono-stratigraphic evolution of the northwestern termination of the Apennine thrust-and-fold belt (Irace et al., submitted). The map and related 3-D model thus represent a new stratigraphic and structural geological base for various thematic research with application purposes such as groundwater, geothermal and mineral resources management and seismic hazard analysis.

In search of a geological signature of slow earthquakes: structural and geochemical characterization of crack-seal veins in metasediments from the Alpine accretionary prism

Meneghini F.*[1], Rielli A.[2], Boschi C.[2], Baneschi I.[2], Amabile F.[1], Perondi F.[1], Marroni M.[1] & Pandolfi L.[1]

[1] Dipartimento di Scienze della Terra, Università di Pisa. [2] Istituto di Geoscienze e Georisorse, CNR, Pisa.

Corresponding author email: francesca.meneghini@unipi.it

Keywords: slow earthquakes, crack-seal veins, subuction.

Metasedimentary rocks exhumed from various depths in subduction accretionary settings are typically infused by systems of mineralized veins, commonly filled by quartz and/or calcite. Their geometric and chronologic relationships with the multiphase deformation history characterizing the host rocks suggest repeated tensile and/or shear hydraulic fracturing at near-lithostatic fluid pressures.

The zones with evidence for high pore-fluid pressures in active subduction plate interfaces are in the same depth ranges where the spectrum of slip behaviors of slow earthquakes (low-frequency earthquakes, tremor, slow slip events) are seismologically or geodetically detected: the transition zones between the locked seismogenic zone and the shallow and deep stably sliding zones. This suggests that hydraulic fracturing of variably lithified sediments during passage along the plate interface and accretion at the prism base, may represent a possible source for slow earthquakes. Unfortunately, the deformation mechanisms responsible for slow earthquake deformation, or their relationships with megathrust earthquakes, are far from being understood, making further studies of fluid-rock interactions of timely importance.

Here we report on a detailed structural and geochemical analysis of crack-seal, composite quartz/calcite vein systems in the trench turbidite deposits, covering the Ligure-Piemontese ocean-derived units ,cropping out in the Internal Ligurian Units (ULI) of Northern Apennines and in the Upper Units (UU) of Alpine Corsica. The two groups of units were structured in the same Late Cretaceous-Early Tertiary Alpine accretionary complex but at different structural levels (200-230 °C and 0.6-0.8 GPa for the studied ULI; 150-200°C and 0.3-0.4 GPa for the studied UU).

The structural analyses show the occurrence of distinct episodes of hydraulic fracturing and mineralization – with Mode I and/or Mode II opening mode - evidence of a complex fluid-rock interaction, accompanied by progressive lithification and diagenesis of the turbidite sequence during subduction, that resulted in a continuous evolution of the rheological properties of the turbiditic multilayer. The vein textures clearly indicate multiple episodes of fracture and sealing associated with cyclic build-up of pore fluid pressure.

Preliminary C and O isotope analyses of the vein sets in the UU and in ULI show quite homogeneous d13C e d18O values for all the different sets of veins, suggesting a common fluid origin for all vein sets, no matter their geometric and chronological relationships with the different deformation steps. Particularly, the d13C e d18O values for either the Corsica or Ligurian samples seem to suggest a fluid origin related to decarbonation of calcareous sediments. Further investigation will be devoted to deeply understand the isotope trend of host rocks, most probably related to the progressive lithification and diagenesis of the turbiditic section moving along the plate interface.

The importance of lithofacies mapping: a case study of Eocene base-of-slope deposits of the Apulia Carbonate Platform (Gargano Promontory, Southern Italy)

Morabito C.* & Morsilli M.

Dipartimento di Fisica e Scienze della Terra, Università di Ferrara.

Corresponding author email: mrbcld@unife.it

Keywords: lithofacies maps, Apulia Carbonate Platform, Eocene.

Despite their significance in the characterisation of reservoirs, lithofacies heterogeneity, geometry and resulting distribution are often neglected. The Apulia Carbonate Platform (ACP) represents one of the most extensive Meso-Cenozoic isolated carbonate domains of the Tethyan Ocean. During the Eocene, the ACP experienced a generalised uplift and subaerial exposure related to regional unconformity, gravitational collapses and the massive deposition of slope and base-of-slope resedimented carbonates. In the north-eastern area of the Gargano Promontory, the Middle to Upper Eocene Peschici Formation consists of breccias and bioclastic turbidites, alternating with micritic limestones and pelagic marlstone, deposited in a slope to base-of-slope setting that, in this area, are related to a point-source supply mechanism (Calciclastic-Submarine-Fans (CSF) type).

The analysis of the facies distribution of these Eocene deposits reveals significant heterogeneities. The differentiation of eight major lithofacies was achieved through a detailed fieldwork mapping at 1:5000 scale. These include calcarenites (fine, coarse) (CAF-CAC), floatstone and rudstone with nummulitids (NF-NR), breccias with different clast contents such as nummulitids (NB), corals (CB), rudists (RB), alveolinid clasts (APG) and pelagic mudstone (PM) rich in planktonic foraminifera. The resulting detailed map, therefore, allows the reconstruction of the areal distribution and lateral relationships and heterogeneity of the lithofacies.

Consequently, the study of the Eocene Peschici Formation serves as an exemplary case study in demonstrating the necessity for an accurate depositional model deduction and reservoir characterization, to be based on a detailed lithofacies map reflecting the various heterogeneities and geometries. Moreover, the importance of this knowledge also lies in its application to aspects of sustainable energy, such as CO_2 and H_2 storage.

Approach and methodologies for the 3D geological modelling of the CARG 121 Brescia 1:50.000 sheet

Norini G.*[1], Caielli G.[1], De Franco R.[1], Rusconi D.[1], Aghib F.[1], Schirolli P.[1-2], Zerboni A.[3], Piccin A.[4], D'Ambrogi C.[5] & the CARG sheet 121 Brescia research group

[1] Istituto di Geologia Ambientale e Geoingegneria, CNR. [2] Museo Civico di Scienze Naturali di Brescia, Comune di Brescia. [3] Dipartimento di Scienze della Terra "A. Desio", Università di Milano. Corresponding author email: gianluca.norini@cnr.it

Keywords: 3D geological modelling, Brescia geological sheet, 3D GIS.

The 121 Brescia sheet of the 1:50,000 geological map of Italy covers an area stretching from the southern Alps to the densely populated and seismically active northern Po plain. This area showcases a complex geological landscape, with faulted and folded Mesozoic and Cenozoic carbonate sedimentary formations in the southern Alps, transitioning to a wide sector of the northern Po plain. The plain is composed of Quaternary marine, fluvial, fluvio-glacial, glacial, and loess deposits, some of which have been affected by recent tectonic activity.

The area of this geological sheet has been site of intense subsurface exploration, mainly for hydrocarbon search, groundwater management and scientific studies, producing complex sets of subsurface geological and geophysical data. Thanks to the effort and support provided by ISPRA – Servizio Geologico d'Italia, Regione Lombardia, ENI S.p.A., A2A Ciclo Idrico S.p.A. and AATO - Ufficio d'Ambito di Brescia, among others, many of these data have been made available for the 3D geological modelling of the area. This dataset includes seismic profiles, hydrocarbon well logs, gravimetric data, water well logs, Airborne ElectroMagnetics (AEM) soundings, and in-depth logs and sample analyses from shallow scientific and commercial cores retrieved from the alluvial plain. These subsurface data have been complemented by large amount of surface data from the new detailed geological field survey, especially for the mountain Southern Alps sector comprised within the geological sheet area.

This multifaceted dataset represented both a challenge and an opportunity for the geological modelling of the 121 Brescia sheet, because of the great difference in format, resolution, quality, depth, and 3D spatial distribution of the available data. For some of the data, new approaches have been developed to account for their quality and/or novelty. For example, old seismic data in raster format, imaging the deeper part of the subsurface, required complex processing for their translation in SEGY format, interpretation, and time-depth conversion. Also, AEM data, acquired for the shallower part of both the Po plain sediments and the mountain sector, required the design and implementation of a new (semi)automatic GIS algorithm for the delineation of geological surfaces to be correlated with the surface and subsurface stratigraphy.

These different surface and subsurface datasets have been processed in specialized software and then imported in a 3D GIS to: (1) provide a combined view of the subsurface geology, and (2) support the interpolation of surfaces and volumes representing geological objects that can be correlated with the known stratigraphy and structure of the area (e.g. CARG surface stratigraphy and GEOMOL project).

Here, the full workflow for the construction of 3D geological model is shown, discussing its main features, obtained results, and potential replicability in similar geological contexts.

Interpretation of subsurface data for the 3D static model of the High Agri intermontane basin: inferences for Quaternary tectonic evolution of the Southern Apennines

Olita F.*[1], Giampaolo V.[2], Rizzo E.[2-3], Giano S.I.[1], Capozzoli L.[2], De Martino G.[2] & Prosser G.[1]

[1] Dipartimento di Scienze, Università della Basilicata, Potenza. [2] Istituto di Metodologie per l'Analisi Ambientale, CNR. [3] Dipartimento di Fisica e Scienze della Terra, Università di Ferrara.

Corresponding author email: fabio.olita@unibas.it

Keywords: 3D static model, geological geophisical tools, Southern Apennines.

The study of intermontane basins located in fold and thrust belts is of fundamental importance for assessing the control exerted by tectonic structures on the geometry of the sedimentary infill, thus providing clues on the tectonic evolution of the area. In this context, the High Agri Valley (HAV) is one of the most important NE-trending intermontane basins of tectonic origin located in the axial sector of Southern Apennines. The Quaternary infill of the valley, occurred during the activity of two main systems of high-angle faults exposed along the two sides of the valley. The study of Quaternary deposits in the HAV was realised by using geophysical and well data, which can be interpreted considering the geological structures exposed in the sides of the valley.

Piling of tectonic units in the Southern Apennines took place during the Miocene, following the collision between the African and Eurasian plates, which led to the formation of an allochthonous wedge migrating in a NE direction above the carbonate rocks of the Apulian foreland (Patacca & Scandone, 2007). This older deformation is testified by regional-scale thrusts and folds, that are exposed in both the sides of the HAV. The younger deformation producing normal and transtensive faults that cross-cut the allochtonous units, piled up during the formation of the fold and thrust belt, were responsible for the consequent opening of the HAV basin during Quaternary.

This study focuses on the detailed reconstruction of the geometry of Quaternary lacustrine and alluvial deposits infills of the HAV, through the construction of a 3D static model of the HAV floor area. The proposed model has been created with the MOVE modelling software and it is based on a dataset of subsurface data including a series of DERTs obtained during a recent acquisition campaign, which integrate the previous DERTs collected by Colella et al. (2004) and by Rizzo & Giampaolo (2019). In addition, shallow wells have been used to calibrate the DERTs. Subsurface data allowed the construction of geological cross-sections, used as a starting point for the 3D modelling.

The construction of a 3D static model of a large area presents a degree of uncertainty due to the type and distribution of data. In particular, the DERTs show limitations in the qualitative resolution due to the scale of acquisition, whereas well data are in some cases not sufficient to calibrate entirely the DERTs. During the development of the model, has also been possible to observe how the scarcity of data in some sectors of the area produced a greater degree of approximation in the interpretation.

The 3D static model allowed us to determine the geometries of the allochthonous sedimentary bodies, with particular attention in the location and distribution of the main depocentral areas. Particular attention was paid to the high-angle faults occurring in the HAV area, which allowed us to recognize how some normal faults were involved in the Quaternary clastic deposition during the last tectonic phases.

Corresponding author email: paolo@pacegeoscience.com

Keywords: 3D Geological Modelling, CARG Project, Central-Southern Apennines.

In this study, we present the results of an integrated subsurface structural-geological characterization and three-dimensional modelling within the 1:50 000 CARG 379-Capracotta geological sheet. The studied area is located at the transition zone between the Central and the Southern Apennines fold-and-thrust belt. This sector of the Apennines is characterized by the complex superposition of different paleogeographic domains that developed during the Mesozoic along the passive southern margin of Adria. Given the structural complexity, different and strongly contrasting interpretations on the origin of the various stacked units and tectonic style (thin-skinned vs wrench tectonics vs combined thin-/thick-skinned) were proposed by many authors over time.

The subsurface dataset includes legacy wells and 2D seismic data from hydrocarbon exploration that were made available for the first time by ENI exclusively for the CARG project as well as public information retrieved from the ViDEPI database and previous studies. The seismic lines of various vintages, provided in the form of scanned copies of the original plots, were digitised and imported along with the digital logs into an industry-standard interpretation and modelling platform. The available geological maps were draped over the digital elevation model in order to constrain the seismic interpretation to the mapped surface geology. The interpretation and 3D modelling regarded the reconstruction of the top of the autochthonous Apulian Platform *s.l.* sequence, some markers within the Molise allochthonous units as well as the main faults.

The Bouguer gravity anomaly data provided by ENI were also modelled through a constrained inversion of the 3D model retrieved after seismic data interpretation. Volumes pertaining to the main geological units were parametrized according to density values derived from well logs. Several inversion procedures with decreasing constraints on the density allowed for each cell were computed. Driven by a distance weighting function, the inversion procedure minimizes the residual between the observed data and the data predicted by an objective function1. Results predict some lateral density variations within the Apulian Platform sequence and within the allochthonous units, respectively in the central and western area of the geological sheet, which are compatible with the sedimentary and tectonic evolution of the area.

The integrated subsurface structural-geological study provided strong insights for a better understanding of some, among of many lively debated, key open topics at the Central-Southern Apennines transition zone such as: i) definition of the tectonic significance of the Sangro-Volturno transverse lineament; ii) relationships between autochthonous and allochthonous units; iii) definition of the deformation and tectonic styles and iv) hydrocarbon exploration potential within the deep autochthonous positive structures.

A proposal for simple accuracy evaluation of geological surfaces based on spatial autocorrelation

Petricca P.*, Castorina G., Congi M.P. & D'Ambrogi C.

Corresponding author email: patrizio.petricca@isprambiente.it

Keywords: 3D geological models, geological maps, accuracy.

A standardized approach for assessing geological surfaces accuracy remains elusive. Recent studies have proposed methods and standards for error analysis in geological or subsurface maps (e.g., Kint et al., 2020 and references therein). However, these methods are still subject to significant bias due to their reliance on data availability and selection criteria. Quality flagging is a common method used to quantify uncertainty within spatial datasets, typically achieved through assessment of metadata fields. This approach may range from simply indicating data presence or absence to more complex methods yielding a comprehensive array of quantitative error ranges (e.g., Bardossy & Fodor, 2001). In the case of few data or datasets without associated uncertainty these methods are not recommended/feasible, and accuracy is not quantifiable.

We propose a more general simplified method already tested in Livani et al. (2023) based solely on the distribution and quantity of input data to generate maps of spatial accuracy. Spatial autocorrelation through the Inverse Distance Weighting (IDW) explores the similarity between nearby observations in geographic space, weighting feature locations and feature values simultaneously. In our analysis, we implemented a method to assess the accuracy/confidence of geological horizon/fault quantifying: i) the data density contributing to evaluating lateral accuracy and depth variability, ii) the accuracy based on data density and spatial autocorrelation, transformed into a probability reflecting confidence in the data at each point within the study area, and iii) the error associated with the depth of geological surfaces due to discrepancies among data from different sources (boreholes, seismic/geologic sections and subsurface maps) where divergent interpretations exist. Consequently, for each point within the study area, we provided values indicating accuracy and estimated error of the depth of the geological surface.

This method, resulting from the geological 3D modelling activities carried out in the GeoSciences IR and MEET Next Generation EU funded projects, will be proposed as a standard for the accuracy evaluation of 3D geological models produced in the framework of the CARG Project.

Keywords: structural diagenesis, carbonate concretions, fluid flow pathways.

The study of selective cementation of high-porosity sandstone bodies is crucial to the understanding of reservoir quality. This has heavy impacts on the efficient exploitation of strategic fossil resources (oil and gas), preservation and management of aquifers and underground storage of anthropogenic CO_2 and H_2. The detailed analysis of selective cementation patterns at the outcrop scale could provide hints to unravel the fluid flow pathways affecting siliciclastic sandstone bodies.

We present the results of a study dealing with the selective cementation affecting fluvio-deltaic, Pliocene age, sandstone to conglomeratic bodies exposed in the Crotone forearc Basin, South Italy. The siliciclastic unit was deposited in a shallow marine setting and reaches a maximum thickness of ~80 m, unconformably overlying the Paleozoic Sila Massif metamorphic basement. The sandstone is almost completely devoid of any primary diagenetic cement thus appearing nearly incohesive. The mild brittle deformation affecting the high porosity sandstone is characterized by sparse deformation bands, small deformation band clusters and a few subsidiary faults. Selective cementation can be traced along the studied outcrops as diagenetic concretions of different shapes and sizes. Concretion types comprise tabular and laterally extensive up to 10's m-wide bodies, elongate blade-shaped objects from 10 cm up to several 10's meter-long, asymmetric drop-shaped concretions and nodular-spherical bodies. The elongation direction of concretions parallels the subtle southeastward dip of bedding surfaces, except in the vicinity of deformation bands and faults, where elongate concretions are vertically oriented. The selective cementation was due to pervasive calcite precipitation, which caused a dramatic porosity loss, leading to a significant increase in sandstone cohesion and stiffness. Tightly cemented bodies enclose deformation bands and host 2-3 sets of joints which abut at the concretion-host rock boundary. Cold cathodoluminescence analysis revealed the extensive presence of yellow-bright calcite cement within concretionary bodies. Calcite cement has granular to poikilitic texture with rare bright-dull zonation rims along coarser crystals. Carbon and Oxygen stable isotopes performed on calcite cement suggest two different cement sources responsible for the selective cementation. The first source can be traced within weaky cemented lens-shaped bodies and along secondary faults and is made of mixed marine-meteoric fluids with contributions from soil percolation. Conversely, the second one can be documented in tightly cemented lens-shaped and nodular to elongate concretions and is given by a mix of marine fluids with contributions from biogenic methane likely related to biological-bacterial activity in a shallow marine setting. The evolution of fluids from meteoric to marine ones can be associated with the sea level rise and marine transgression that occurred after sandstone deposition.

Multidisciplinary approach for 3D geological model reconstruction: the example of Mt. San Calogero (Sciacca, Southwestern Sicily)

Rizzo G.F.*[1-2], Maiorana M.[1] & Gasparo Morticelli M.[1]

Keywords: 3D geological model, Mt. San Calogero, Sicilian chain

The inability to access continuously and directly to subsurface data forces geologists to use a combination of different methods and a multidisciplinary approach to determine in high detail the possible extents of deep geological geometries. We analysed the carbonate relief of Mt. San Calogero (about 390 m a.s.l.), part of the "geological sheet 628 Sciacca" (CARG project). Field collected data were used for a preliminary 3D geological model reconstruction. The results were integrated with the seismo-stratigraphic and structural interpretation of 2D seismic reflection profiles calibrated with stratigraphic wells, covering the offshore sector of the study area. Mt. San Calogero, which belongs to the outer sector of the western Sicilian Fold and Thrust Belt, represents an outcrop of part of the paleogeographic domain known as the " Saccense". The outcropping succession is characterized by thick shallow-water carbonate platform deposits from the Lower Jurassic overlain by condensed pelagic deposits from the Middle-Upper Jurassic to the Eocene, covered by the Oligo-miocenic syntectonic clastic deposits. The new collected data confirmed that Mt. San Calogero represents the outermost deformed portion of the western Sicilian chain composed of a double verging compressional structure delimited by NNE-SSW-trending left-lateral transpressive faults involving deposits of Calabrian age. In the offshore sector the seismic profiles interpretation highlighted the presence of a NE-SW-oriented ramp-anticline, bounded by high-angle deformation with transpressive kinematics. To establish a structural continuity between Mt. San Calogero structural high and the adjacent offshore compressive structure, additional data were integrated. The gravimetric anomaly map of this sector shows positive values of the Bouguer anomalies, with approximately NE-SW direction. In addition, data regarding heat fluxes show that there is a direct connection between the geothermal field of Sciacca, which reaches a temperature of approximately 76°C at a depth of 2600 m b.s.l., and the offshore sector, where thermal anomalies and fluids evidence are documented. In general, the structure thus identified represents the northward prosecution of a compressive/transpressive structural high with an approximately N-S trend, recognized in different literature data (Catalano et al., 2000; Fedorik et al., 2018). This multidisciplinary approach therefore allowed a more correct and continuous correlation between onshore/offshore structures and the definition of the offshore extent of a structure essential for understanding the tectonic evolution of the Sicilian chain.

Keywords: 3D, modelling, Tevere.

Understanding the complex three-dimensional (3D) architecture of Quaternary alluvial deposits beneath modern urbanized alluvial plains is useful for defining the basin evolution and the rock property distribution, and for assessing and mitigating possible geohazards.

This study proposes an integrated methodological approach to reconstruct the complex stratigraphic setting of the Tevere valley in the subsoil of Rome city. We analyzed and elaborated stratigraphic data from 129 boreholes and 24 cone penetration tests. The available data were elaborated applying a kriging geostatistical algorithm in a geological-geophysical modeling software. The model defines the spatial distribution of primary architectural elements within the late Quaternary units of the Tevere River valley, establishing spatio-temporal relationships and evolutionary trends of the alluvial succession.

This modeling approach helps in bridging the gap between the conceptual sedimentary models established for the Holocene Tevere alluvial succession and real-world geological challenges. Moreover, it may serve as a pivotal tool for evaluating and managing subsurface resources and mitigating geohazards in a densely populated area. The methodological approach proposed in this study can improve the 3D representation of sedimentary successions through an efficient and time-saving process.

Preliminary findings from deep 3D electrical resistivity tomography in active faults

Zambrano M.*

Corresponding author email: miller.zambrano@unicam.it

Keywords: deep electrical resistivity tomography, active faults, 3D modelling.

This study presents preliminary outcomes from a deep geoelectrical survey aimed at investigating subsurface resistivity changes associated with active faults in the Central Apennines region. Utilizing a 3D electrical resistivity approach, we conducted comprehensive surveys to overcome limitations posed by traditional arrays and topographical challenges.

We utilised the FullWaver system (Iris instruments), the system consists of 15 wireless dual-channel digital receivers and a 5-kW time-domain induced polarization transmitter (Sapia et al., 2021). Our measurements included induced polarizations, resistivity, and self-potential. The methodological approach mirrored the quadrupole measurement principle (Mazzini et al., 2021; Lajaunie et al., 2019; Carrier et al., 2019), with real-time recording using GPS for data synchronization and combination of transmission and receiver records. The survey design targeted depths of 50 to 200 meters to map the trend of active faults.

Following rigorous quality control processes to ensure data accuracy, we modelled the processed data using ViewLab 3D software, resulting in robust 3D resistivity models. The preliminary results demonstrate the effectiveness of the FullWaver system in deep 3D electrical resistivity tomography for studying active faults. The final 3D volume provides a detailed view of the resistivity distribution, allowing us to relate this variability to the presence of fault ruptures and/or scarps. This research contributes to the analysis of active faults in the region and opens avenues for integration with further geophysical and paleoseismological studies.

Keywords: focal mechanism, earthquake, seismotectonics.

Assessing the quality of fault plane solutions is valuable for numerous activities, including seismotectonic analysis and estimating pore fluid pressures at hypocentral depths. Recently, new techniques have emerged to calculate pore fluid pressures based on focal mechanisms of seismic events and to monitor the temporal variation in the pore pressure field (Terakawa et al., 2014; De Matteis et al., 2024).

In this work, we introduce an updated version of the tool originally developed by Adinolfi et al. (2022), designed to evaluate both the reliability of focal mechanisms and the ability of a seismic network to analyze fault plane solutions and their associated errors. With a specified network configuration, the tool can be utilized to assess the reliability of a focal mechanism solution or to classify the quality of fault plane solutions provided by a seismic bulletin. Additionally, new statistical methods have been developed to more accurately determine the quality of a computed focal mechanism, as well as its associated uncertainties.

The tool is particularly helpful as it enables precise assessments of the reliability of focal mechanism solutions, which is essential when analyzing low-energy earthquakes. Such assessments are crucial for developing seismotectonic models, determining the geometry of seismogenic sources, and understanding regional strain and stress fields.

The geology of Mt. Vettore area in the Sibillini Mountains, Northern Apennines of Italy

Alessandrini M. & Menichetti M.*

Dipartimento di Scienze Pure e Applicate, Università di Urbino "Carlo Bo".

Corresponding author email: marco.menichetti@uniurb.it

Keywords: active faults, thrusts systems, Sibillini Mts.

Mt. Vettore (2476 m asl) is the most prominent relief of the Sibillini Mts. and the Umbria-Marche Apennines mountain chain. The area has been affected by at least three main tectonic phases: I) a Meso-Cenozoic extensional phase responsible for the evolution of the basin, filled with more than 3000 m thick sediments. These marine sediments record the thermal and mechanical subsidence history from the Early Jurassic carbonate platforms to the pelagic realm of the Paleogene. In the Sibillini Mts, the basin was dissected into structural highs and deeper basinal areas by a slope-to-basin transitional domain of varying thicknesses and facies, bounded by Jurassic extensional faults. In the Mt. Vettore area, the Calcare Massiccio Fm (Early Jurassic) crops out along the eastern face, characterised by cyclic sedimentation of carbonate banks, with a few hundred meters local thickness. Lithologically, it consists of white, thick-bedded to massive grainstone and packstone, containing several bioclasts and locally dolomitisation lens. The overlying Corniola Fm (Lower Jurassic) outcrop extensively in well-stratified decimetric to metric beds of dark grey-brownish lime mud wackestone with grey chert nodules. It contains abundant clastic deposits, including slumps and large olistoliths, produced by tectonic activity along the margin of the surrounding carbonate platforms.

II) A compressional phase occurred in the Neogene, forming the Umbria-Marche foreland fold-and-thrust belt. Several asymmetric NE verging rootless anticlines constitute the hanging wall of the Mt. Sibillini thrust system, which runs for more than 60 km with an arcuate shape and a total shortening of many km. In the eastern face of Mt.Vettore, the thrust system has a strike about N-S and transpressional kinematics through NE. Right lateral strike-slip fault systems are associated with the thrust splays. Several detachment levels are located in the Upper Cretaceous and Miocene marls, rooted in the deeper Triassic anhydrites. In the eastern region, outcrops more than 2500 m thick of Upper Miocene to Pliocene terrigenous clastic of the Laga Fm belong to the foreland basin and are involved in the thrusts.

III) Finally, from the Pleistocene onward, the area is involved in an extensional tectonic phase. A set of normal faults striking NW to SE crosscut the compressional structures, which were activated during the 2016 earthquakes of the Amatrice-Norcia sequences. These extensional structures control the evolution of the intramountain basins and their filling of the Pleistocene continental deposits. The field observations of the cross-cutting relationships between the compressional thrust structures and the active extensional faults in the Mt. Vettore area show that the normal faults cut and displace the thrust system.

Quaternary stress and strain patterns in the Italian peninsula from QUIN's data

Keywords: geological stress and strain-field in Italy, intra-Apennine late Pliocene-Quaternary extensional fault system.

Knowledge of the strain and stress field of the Earth's crust is crucial to understanding the structural and seismotectonic contexts. It helps to reconstruct the evolution of geological processes that have affected the Earth's crust and provides information on the orientation and magnitude of tectonic forces controlling seismically active zones. It is also fundamental to constructing predictive models of fault behaviour, thereby improving our evaluation of seismic hazard. Information on tectonic stress can be derived from direct measurements from boreholes, focal mechanisms, or structural-geological data (fault/slip attitude). Information obtained directly from faults provides a long-term view of kinematic and deformation processes. In this study, we exploit the high potential of the QUIN database (Lavecchia et al., 2022, 2024), which collects ~8000 data of Fault Striation Pairs (FSP) distributed over ~800 Structural Sites (SS) and belonging to 74 Fault Systems (FS) along the intra-Apennine late Pliocene-Quaternary extensional belt of Italy. For the strain analysis, we developed a MATLAB code to analyze the kinematic compatibility of the FSP data and to extract the orientation of the strain tensor (P/S1, B/S2, T/S3) axes and the strain ratio R=(S2-S3)/(S1-S3). At the same time, we applied the formal stress inversion to the FSP data using the MSATSI software (Martínez-Garzón et al., 2014) and obtained the stress tensors (σ1, σ2, σ3) and the stress ratio φ=(σ2-σ3)/(σ1-σ3) for the 74 FS. We calculated the horizontal strain/stress (SH) axes using the correction method of Lund & Townend (2007). We compared the data from the latest geodetic velocity models and focal mechanism catalogs with the long-term tectonic trends using QUIN FSPs on a regular grid map. Our results confirm a coherent extensional stress field spanning multiple time scales from the Late Pliocene to the present. The reconstructed geological SHmax directions generally correlate well with observed contemporary stress indicators from earthquake and geodetic data. In general, we reconstruct a multi-wavelength outward arcuate pattern and observe that small-scale SH rotations are detected with increasing resolution of the stress field. The stress field migrates coherently eastwards with time, and generally, temporal stress variations are not observed, except in a few areas corresponding to pre-existing localized W-E to WNW-ESE normal and normal-oblique shear zones. Such discontinuities appear to control regional and local bendings of the strain trajectories. Therefore, we interpret them as tectonic corridors that may act as barriers to along-strike propagation of potentially seismogenic Apennine normal faults. This study demonstrates that a geologically based comprehensive multi-scale strain and stress analysis of active structures over time can significantly enhance and even transform the understanding of local and regional seismotectonics within the broader geodynamic context.

Keywords: structural-geological database, potentially seismogenic faults, Italy.

Extensional tectonics play a crucial role in shaping the morphology and structural characteristics of the Apennine chain in Italy, yet their importance has often been overlooked. Recent advancements in highlighting the significance of Quaternary extensional tectonics have been made possible by developing the QUIN database (QUaternary fault strain INdicators database).

The QUIN database consists of two releases: QUIN 1.0 covering the central-northern Apennines (Lavecchia et al., 2022) and QUIN 2.0 covering the southern Apennines and Calabria (Lavecchia et al., 2024). This database provides the scientific community access to over 8000 georeferenced points related to host fault planes displaying kinematic evidence of prevailing extensional stress.

The QUIN database incorporates data on fault location, attitude, kinematics, and deformation axes, mainly focusing on Fault Striation Pairs (FSPs) along Quaternary faults. Each release includes a comprehensive dataset in .shp and .txt formats and an original .shp file containing fault traces hosting the FSPs.

Key information provided by the QUIN database includes:

- Geographic location and geometric characteristics of fault traces
- Name of fault hosting the structural sites and associated fault system
- Age of the oldest recorded displacement or syn-tectonic deposits
- Evidence of seismogenic or potentially seismogenic activity based on integrated geological and seismological data.

The QUIN database represents a valuable resource due to its extensive coverage across the Italian peninsula, where the regional stress field has remained relatively stable over some millions of years. This stability offers a unique opportunity to analyze long-term structural data, particularly for seismic purposes, extending the investigation timeframe to encompass at least the entire Quaternary period. Such insights are critical for understanding the long-term deformation of the Apennine range, especially in areas that may have exhibited minimal seismic activity in instrumental times but could harbour significant yet unrecognized seismic potential.

The applications of the QUIN database, spanning from northern Tuscany to southern Calabria, are diverse and impactful. Its comprehensive collection of fault traces in a unified database opens avenues for three-dimensional seismotectonics, numerical modeling, forma stress inversion, seismic hazard assessment, and industry and territorial planning applications.

Researchers interested in leveraging the QUIN database for collaborative studies are encouraged to contact us for potential collaboration opportunities.

Probabilistic analysis of slip rates over time of offshore buried thrusts in the Central Adriatic Sea (Italy)

Barrera Acosta D.*[1], De Matteo A.[1-3], Maesano F.[2], Toscani G.[1-3], Seno S.[1-3] & Basili R.[2]

Keywords: seismogenic faults, Adriatic Sea, slip-rates.

Understanding the seismotectonics of buried and potentially active faults represents a demanding challenge and requires robust approaches. Detecting recent-to-ongoing activity of the active buried frontal thrusts of the Apennines is particularly challenging because sedimentation rates easily exceed the very slow tectonic rates and the foredeep deposits of the northern and central Apennines cover the features that better displays the recent activity.

In this work, we quantitatively analyse the Plio-Pleistocene tectonic activity of the major Apennines buried thrusts in the central Adriatic Sea. Then, we calculate the slip rates of those faults combining seismic reflection profiles interpretation, kinematic restorations and balancing.

The northern and central Apennines foredeep is filled by thick Messinian to Quaternary sediments, unconformably lying on a Meso-Cenozoic carbonatic and siliciclastic passive margin succession, which is in turn involved in the East-Northeast propagation of the fold-and-thrust belt (Adriatic Sea). As highlighted by previous studies, the region is experiencing an overall tectonic activity decrease, but local observations on specific structures show evidence of recent tectonic activity.

The frontal thrusts of the Apennines are active nowadays, as demonstrated by the moderate recent (few past centuries) seismic activity recorded in that region. We interpreted, depth converted, and restored two northeast trending regional seismic reflection profiles, roughly orthogonal to the main strike of the buried thrusts. We used the inverse *trishear* approach to determine the slip necessary to restore the residual tectonic deformation (after decompaction) of five (well age-constrained: Zanclean to Middle Pleistocene) deformed stratigraphic horizons. We then calculated and reported the slip rates using probability density functions, considering the uncertainties associated with both horizon ages and the restoration process. At the end, our results show a gradual reduction of slip rates over time, with a main slowdown around 1.5 Ma. The majority of the deep analysed thrust show evidence of ongoing activity, even though they are characterised by much slower activity rates than in the past. A probabilistic analysis of the slip-rates evolution represents an essential tool for taking over epistemic uncertainty on the total seismic moment release in earthquake hazard analyses.

Do faults play hide-and-seek? New hints on the relationship between active deformation and surface faulting in a seismic gap zone of central-southern Apennines – A multidisciplinary approach

Battistelli M.*[1-3], Ferrarini F.[2-3], Carafa M.M.C.[4], Cardinali M.[5], Bucci F.[5], Merryman Boncori J.P.[6] & Brozzetti F.[2-3]

Keywords: Late-Quaternary normal faults, remote-sensing analysis, central-southern Apennines (Italy).

Finding evidence of recent tectonic activity is not a simple task, particularly in areas characterized by low strain rates. The Late-Quaternary activity of normal faults across the Italian belt is constrained by paleoseismology, historical and instrumental seismicity, field geology, stress and geodetic data-, and highlighted by distinctive geomorphic features on the landscape. However, in the sector between the central- and southern Apennines (Abruzzo-Molise border), this evidence is less clear or even missing. Our area of interest is located between two active fault systems (the SW-dipping Aremogna-Cinquemiglia and NE-dipping Isernia-Bojano, Lavecchia et al., 2022). However, across the latter, the structural continuity of the extensional system breaks down suddenly highlighting a "transition zone" marked out, in addition, by the predominance of siliciclastic and marly-limestone lithologies (Bucci et al., 2022) and an evident seismic gap (Rovida et al., 2020). According to Carafa et al. (2020, and reference therein), post-LGM throw-rate estimates (0.7-1.0 mm/yr) of outcropping faults in neighbouring sectors are consistent with geodetic and stress data, remarking that the area is currently undergoing rather fast permanent bulk deformation not strictly associable to known active structures. To investigate this challenging setting and inspect the disconnection between active deformation and (apparent) absence of surface faulting, we used a multidisciplinary approach combining topographic and relief analysis (to detect possible transients in the topography), photointerpretation (to portray continuous lineaments across the landscape to be traced back to tectonics structures) and field survey to support remote data interpretation. This approach allowed us to focus on new potential tectonic lineaments (in the area between Roccaraso and Forlì del Sannio towns) aligned, in continuity, with neighbouring fault systems and consistent with normal-fault kinematics. In addition, other minor fault segments, located in more external positions (east of Vastogirardi village and Mt. Campo-Mt. San Nicola sectors), suggest a further encroachment of the extensional deformation to the East. In contrast with other sectors of the Apennines, normal fault size and their distribution over a ~ 15 km wide area, are likely coherent with a diffusive deformation pattern, possibly led by the peculiar tectono-stratigraphic setting of the sector. Gravitational movements situated on or near the mapped structures further support the hypothesis that, in the specific context, these phenomena can be enhanced by the presence of active faults. InSAR data analysis across the study area will be used to map and analyse the spatial distribution of gravitational movements, and possibly differentiate tectonic versus gravitational (slope-related) signals, thus providing additional information on the seismic hazard of this understudied region.

Keywords: active tectonics, seismogenic sources, Northeast Italy.

The Italian Database of Individual Seismogenic Sources (DISS; DISS Working Group, 2021) describes several individual and composite seismogenic sources in Northeast Italy and neighboring countries, i.e. Veneto and Friuli Venezia Giulia regions and Slovenia, straddling the outer S-verging thrust fronts of the Eastern Southern Alps, and the NW-striking, right-lateral strike slip structures of the Dinaric fault system. In recent years, several new studies have been conducted on the active tectonics of the area that helped better constrain the geometry and kinematics of the active fault systems. We present here an updated seismogenic source model of the area, based on published and unpublished studies and datasets, and original interpretation of new data acquired from field mapping (CARG projects), seismic profile interpretation and subsurface geological models, and terrestrial and space geodesy (InSAR and GPS). The new model includes a reevaluation of the geometry, kinematics, and activity rates of the seismogenic faults in the study area. The results of this study have been used and will be used to reevaluate the seismogenic sources of the DISS database included in the current release and for the next updated versions.

Keywords: seismotectonics, Central Italy, tectonic inversion.

The high seismic hazard area of the central-northern Apennines has experienced multiple seismic sequences in recent decades, including the 1997 Umbria-Marche, 2009 L'Aquila, and 2016-2017 Amatrice-Visso-Norcia, all linked to post-orogenic extension. Following the Amatrice-Visso-Norcia sequence, advancements in subsurface geological data and seismological networks have improved our understanding of shallow crust structural settings and their relation to seismic activity. Recent studies have focused on the role of inherited structures, such as large thrust faults from Apennines orogeny, in compartmentalizing seismic sequences horizontally and vertically. There's also a discussion about how major compressive structures might contribute to seismogenesis by inverting their kinematics within the current extensional regimes. Similar discussions emerged after the 1997 Umbria-Marche seismic sequence, notable for its six main shocks originating on adjacent NW trending normal faults. Our work reviews data from this event, combining seismic reflection profiles, deep boreholes, geological surveys, and passive seismic data. We've developed a new 3D geological and velocity model for the area and computed a revised relocation catalog based on this data. Comparing the geological model with relocated seismicity reveals vertical and horizontal compartmentation of the shallow crust due to thrust action. Seismicity concentrates within specific structural and stratigraphic levels, often on normal faults or reactivated thrusts. Integrating seismological and geological data helps address questions about interference between Quaternary normal faults and Tertiary thrusts, as well as the geometry of faults causing the 1997 seismic sequence. This holistic approach enhances understanding of seismotectonic behavior and improves seismic hazard assessments for the region.

Reprocessed SEG-Y seismic profiles across the continuation in the Apulia offshore of the onshore seismogenic Mattinata Fault (Adriatic Sea, Southern Italy)

Cicala M.*[1], De Giosa F.[1], Piscitelli A.[2] & Festa V.[1]

Keywords: Mattinata Fault, vintage seismic profiles, conversion to SEG-Y.

The Mattinata Fault is one of the most important faults in southern Italy, since it is active and responsible for the most relevant historic seismic events in the northern Apulian Foreland, in Apulia. This fault crops out in southern Gargano Promontory and in map view roughly strikes W-E; its continuation toward the east has been documented by several studies in the adjacent Adriatic Sea area, where it has been named Gondola Line. These studies dealt with the interpretation of both deep and shallow reflection seismic data acquired on the present-day continental platform surrounding Apulia (e.g. Ridente et al., 2008; Argnani et al, 2009). The related seismic data are not freely accessible and, however, can be interpreted in various ways, especially as regards deeper structures associated to the fault. In this respect, it should be noted the recent tendency to interpret halokinetic structures associated to the main faults around the Gargano Promontory area (Festa et al., 2019, and references therein).

The available data possible dealing with the fault on the present-day continental platform are represented only by vintage unmigrated stack seismic profiles, as raster images of poor quality, hence very difficult to interpret. These are parts of the reflection seismic profiles D445, D451 and D452 acquired during the end of the sixties of the last century, and freely available from the ViDEPI database (www.videpi.com/videpi/videpi.asp). Therefore, we wondered: how to improve the quality the existing data, of crucial importance to better constrain the fault in this area?

With the aim to obtain SEG-Y files, namely of increased quality information to be modified and better represented in appropriate software, we have firstly merged the raster images of the related PDF files downloadable as portions of the above seismic profiles. The merged PDF images have been converted into TIFF ones for each seismic profile. By the use of IMAGE2SEGY, a new Matlab program to convert images of seismic profiles to georeferenced SEG-Y formatted files (Farran, 2012), the input files TIFF, together with the corresponding TXT input files (code rows including, for each seismic profile TIFF image, information such as, the trace length in pixels, line number, marine or land position, SEG-Y revision format, SEG-Y numeric format, UTM zone, geographic coordinates, pixel position, delay or time over the datum, time interval of the seismic profile in milliseconds) have been uploaded. Consequently, the output SEG-Y files for each seismic profile have been obtained. Furthermore, a data processing applied to SEG-Y converted dataset in order to remove low frequency noise. In details, a 'boxcar' frequency filter (at 16 Hz low cutoff and 125 Hz high cutoff frequencies) applied basing on poor acquisition data information available by means of DELPH Seismic ® software. Finally, a general improvement of seismic images has been obtained.

Keywords: Montello-Collalto area, seismic monitoring, seismic catalog.

The Montello-Collalto area is located on the outer front of the eastern Southern Alps (Italy), where a fold and thrust belt has formed since the middle Miocene and is still active (Picotti et al., 2022). A medium-high seismic hazard characterizes this area, as a strong earthquake has occurred in the past (the Asolo event of 1695, M6.5), but the causative fault has not yet been identified, even because most of the tectonic structures existing here are buried under recent sediments (e.g. the Montello thrust system). In the study area, seismicity has been monitored by the OGS since 1977 (Bragato et al., 2021) both at the regional scale, and at the local scale, with several temporary surveys carried out for various purposes. A breakthrough in the recording of earthquakes in the Montello-Collalto area is the Collalto seismic network – RSC (Priolo et al., 2015), a local network used to monitor underground gas storage (UGS) located here since 2012 by OGS on behalf of Edison Stoccaggio SpA. The RSC was developed to detect the potential microseismicity induced by the UGS, and after about 12 years, a seismic catalog of more than 3500 events with -0.9. So far, there is no evidence of anthropogenic phenomena, but discriminating between natural and induced earthquakes is still an open challenge, and further analysis needs to be carried out to establish that all the seismicity recorded by the RSC has a natural origin. On the other hand, the spatial pattern of this seismicity has provided insights into the depth geometry of the Montello thrust and its antithetic structure (Peruzza et al., 2022 and references therein), but its seismogenic behavior needs further investigation. These open questions require a multiscale analysis of the seismological data: the local scale for induced seismicity and the regional scale for seismotectonic studies. To this end, we first collected information on all seismic stations operating in the Montello-Collalto area and surroundings since 1977, i.e. location, start and end time, instrumental equipment, and availability of digital data. Then we collected, reviewed, and integrated all the seismic catalogs produced for the area in different periods by different monitoring infrastructures to obtain a unique and as long as possible list of earthquakes to which refer. The next step will be relocating seismicity homogeneously with local velocity models in order to obtain the best picture of seismicity for the study area, which will allow us to analyze its spatio-temporal evolution and understand the local seismogenetic processes.

Keywords: active normal fault, half-graben, geophysical methods.

Understanding the behavior of seismogenic faults from depth to surface is crucial for assessing seismic hazards. This study focuses on investigating the Mt. Morrone normal fault (MF) in the Central Apennines, Italy, to constrain its architecture and the tectonic evolution of the Sulmona basin. As far as the local seismicity is concerned, neither decisive proof of historical earthquakes nor moderate (5.0).

Using a multidisciplinary approach, we integrate geophysical data, geological field analysis, and borehole data to characterize fault structures and basin geometry.

Our findings reveal complex fault geometries and deformation patterns within the half-graben basin, indicating the presence of antithetic faults. Through passive seismic noise measurements and 2D array surveys, we delineate the deep seismo-stratigraphic setting and infer the geometry of faults bounding the basin. Additionally, geological investigations and borehole data provide constraints on sediment thickness and lithology, aiding in the interpretation of seismic velocity profiles.

The results confirm Sulmona basin fault splays forming a half-graben structure elongated NW-SE. Continental deposits reach up to 700 m in the central-southern. Easternmost splays represent master faults, dissecting the Mt. Morrone range, while antithetic structures accommodate eastward downthrow. These findings suggest a complex structural evolution influenced by various fault systems and interference during time. However, complexities such as faulting and velocity inversions pose challenges to this estimation, and fault splays and buried fault systems, influence its geometry and structure.

Overall, our study advances the understanding of fault structures, with implications for seismic risk mitigation and disaster preparedness in tectonically active and populated regions. Despite this is an already-established method and tool, this approach provided new insights and a starting point for future research.

Exploring the significance of fault-earthquake data pairs in unveiling structural and seismotectonic complexities - Case studies across different tectonic regimes in Central Italy

Lavecchia G.*[1-2] & de Nardis R.[1-2]

[1] Dipartimento di Scienze Psicologiche, della Salute e del Territorio, Università "G. d'Annunzio", Chieti.

Keywords: seismotectonics, 3D fault model, Italy.

This study investigates the intricate interplay between fault-earthquake data pairs and their significance in revealing unforeseen structural and seismotectonic complexities. Focusing on central Italy, a region characterized by upper crustal extension and shallow to lower crustal compression, we present three case studies showing relationships between multi-depth fault behaviour, seismic activity, and fluid interaction. Through an integrated analysis involving:

1. Evaluation of the regional tectonic and seismotectonic framework;
2. Detailed examination of outcropping fault geometry, kinematics, and dynamics;
3. Examination of high-quality major earthquakes, microseismicity space-time distribution, and stress pattern features.

We meticulously constrain and reconstruct the 3D fault geometry and earthquake release style of the three case studies, each with distinct depths, kinematics, and earthquake magnitudes. In all three cases, the analysis reveals unexpected geometric complexities, including:

1. Identification of a lower crustal duplex illuminated by background microseismicity within the interconnection area between the Adriatic Basal Thrust (de Nardis et al., 2022) and its major hanging-wall splay;
2. Recognition of an upper crustal extensional system comprising interconnected synthetic and antithetic multi-scale faults, some of which are unexpected, above an east-dipping detachment, as evidenced by the aftershock sequence of the Norcia 2016 earthquake;
3. Discovery of a north-dipping extensional detachment inferred from the distribution of moderate seismic swarms and seismic sequences at middle to lower crust depths in the Sora-Marsicano area (central Apennines).

Furthermore, our results suggest that upper crustal seismicity is closely linked to the configuration of a pre-existing fault system reactivated under the ongoing seismogenic stress field. Conversely, seismicity in the lower crust (>15-20 km) may be influenced by tectonic features, as observed in the ABT duplex, or unrelated to fault discontinuities, as seen in the Sora area. Here, fusiform earthquake volumes observed at the footwall of the north-dipping extensional detachment may be attributed to the upwelling of mantle-derived CO_2 as the result of unloading processes within the footwall rock volume. Our findings underscore the necessity of integrating multidisciplinary approaches to unravel the complexities of fault systems, thereby advancing our comprehension of seismic hazards in tectonically active regions.

Keywords: 3D fault model, seismotectonics, Campania-Lucania-Calabria extensional belt.

Since the pioneering work of Plesch et al. (2007), the development of 3D curvilinear fault modeling, integrating fault surface traces with earthquake data (hypocenters and focal mechanisms), has become a standard practice for reconstructing the geometry and kinematics of active and potentially seismogenic structures.

Numerous such reconstructions have been conducted in Italy across various tectonic settings, from the extensional belt of central Italy (Castaldo et al., 2018; RETRACE-3D Working Group,2021 and many others) to the compressional front in northern Italy (Tibaldi et al., 2023).

This paper presents the first comprehensive high-detail 3D geometric and kinematic reconstruction of the Southern Italy extensional belt, spanning from Campania to Calabria. Our reconstruction, also associated with a formal 3D stress inversion of geological and seismological data, models the extensional belt with an average thickness of 10-15 km from the surface down to a recognized basal detachment along the belt.

The fault surfaces are organized in a systematic hierarchical order, ranging from individual fault segments to master fault alignments, all interconnected across a complex system of synthetic and antithetic structures.

Surface data are extrapolated to depth with varying degrees of approximation, leveraging available geological and seismological information such as fault traces, multi-scale cross-sections, fault/slip data, hypocentral datasets, focal mechanisms, and seismic lines.

The uncertainty of the modeled fault geometry is systematically analyzed, considering two key factors: completeness and geometric variability for each fault element. This systematic analysis enhances our understanding and quantification of uncertainty associated with fault geometry modeling, providing crucial insights for seismic hazard assessment and future research in this field.

Seismological study of transverse faults in a highly segmented extensional front in the Northern Apennines: the case of Sant'Anna Pelago

Lenci S.*[1], Keir D.[1-2], Molli G.[3], Vannucchi P.[1], Del Ventisette C.[1] & Pagli C.[3]

[1] Dipartimento di Scienze della Terra, Università di Firenze. [2] School of Ocean and Earth Science, University of Southampton, Southampton, UK. [3] Dipartimento di Scienze della Terra, Università di Pisa

Corresponding author email: simone.lenci@unifi.it

Keywords: neotectonics, fault segmentation, Northern Apennines.

The Neogene-to-current tectonic evolution of the Northern Apennines has been characterized by slow-rates contraction in the foreland and extension in the internal domain. At chain-scale, the extensional and contractional fronts migrate NE-ward through anticlockwise rotation, while at local scale deformation is accommodated on a multitude of segmented structures. Rotational extension causes an increase in the width of the internal extensional domain south-eastward as the Northern Apennines steps eastward across Italy.

The Sant'Anna Pelago area, located close to the orographic divide between Modena and Lucca, exhibits pronounced instrumental seismicity over the last ~15 years, forming the focus of this study. Here fault geometries tend to be more complex, in terms of segmentation and mutual geometric relationships, compared to the internal domains. Seismicity is expressed through five seismic sequences from 2006. The precise relocation of the seismicity from the INGV catalogue has revealed five major aligned clusters. The 2007, 2010 clusters align, respectively, on minor ~5-10 km-depth, N dipping high angle normal fault, and ~14-18 km-depth SW dipping medium angle normal fault. In 2013 there was a Mw 4.8 mainshock, relocated to ~18 km depth, which was followed by a dense aftershock sequence on an 8 km-long, 10-18 km deep fault dipping 50 degrees towards the SW. This structure aligns with the southern tip of the Fola master fault, surfacing near Pieve Pelago. The subsequent 2018, 2020 clusters align on two discrete, sub-vertical E-W oriented structures, each approximately 3 km long, in the footwall of the 2013 sequence, and at similar depths. Focal mechanisms show almost normal kinematics on all faults. Only the 2013 main shock focal mechanism shows pure strike slip kinematics, with near vertical NW-SE or SW-NE striking nodal planes. For this main shock, neither nodal planes fit with the 3D distribution of aftershocks. Instead, we interpret the mainshock to be linked to the presence of the subsurface NE continuation of a major transverse fault.

The relocation highlights complex geometries and kinematics on this active front. The NW-SE and E-W trending normal faults are compatible with deformation in an accommodation zone between two stepping extensional fronts. The lateral stepping requires accommodation through a component of lateral fault slip, which we interpret to explain the strike-slip mainshock. The results suggest that the Sant'Anna Pelago area could be interpreted as an immature soft-linkage zone where deformation favourably accommodates on transverse faults at depth and variably oriented normal faults at shallow depths. The next stage of the study will be to use field structural analysis to better define the surface architecture of active faults and use stress change analysis to test whether stress transfer controls the time history of the sequences.

3D imaging and modelling of a complex regional fault system: the Scicli Line (Sicily, Italy)

Lipparini L.[1-2], Forzese M.*[1], Chiacchieri D.[1-2], Cavallaro D.[3], Firetto Carlino M.[3], Scarfì L.[3], Molinari I.[4], Maniscalco R.[5] & Catalano S.[5]

Keywords: Scicli Line, 3D crustal model, fault kinematics.

The Italian peninsula is characterized by a complex and somewhat peculiar geodynamic setting which has been driving the attention of scientists for decades. Here, we focus on the Hyblean Plateau, the emerged portion of the Pelagian Block in southeastern Sicily, which pertains to the African foreland. An area densely populated and characterized by high seismicity; the two major historical earthquakes of the area (M≃7, in 1169 and 1693 A.D) and their relationship with the kinematics of tectonic structures in the Hyblean Plateau are still a matter of debate. In particular, the Plateau is cut by a regional a. N-S trending strike-slip fault system known as the Scicli line and several NE-SW, mostly extensional fault lineaments. This overall fault system shows good exposure on outcrop, and influenced deep fluid migration (both groundwater and hydrocarbons), which made it appealing for structural, geological and exploration studies since the ‘50s. However, a high-resolution integrated 3D focused work which links outcropping and subsurface features from onshore to offshore is still missing.

In this study, we combine fieldwork observations and geological mapping with the interpretation of a large dataset of 2D-3D seismic reflection data and deep wells, related to exploration and production activities carried out for more than 70 years by Oil&Gas companies As a result, a comprehensive high-resolution regional 3D crustal model is here presented along a 90x20 km extended volume, connecting the onshore to the offshore. A robust workflow is defined and allows to correlate in detail subsurface and outcropping features.

This work shows new significant insights on the 3D geometry and development, in space and time, of the Scicli Line, considering its relationship with adjacent structural lineaments and fracture systems as well. Moreover, it will support a more accurate and realistic evaluation of potentially active structures and associated seismicity.

This work is framed in the broader effort, called “SPIN Project”, which aims at improving seismic hazard assessment in Italy through advanced tools, analytical, and modelling techniques.

Keywords: transpression, geo-hazard, Ionian Islands.

The area offshore the Ionian Islands (Kefalonia, Lefkada, Zakynthos, and Ithaca), western Greece, exhibits higher seismic activity than any other Mediterranean region, often with high tsunamigenic potential. Here, the Hellenic frontal thrust above the main detachment fault stops against the right-lateral Kefalonia fault, more than 100 km-long, to step back towards the island of Corfu. In recent decades, this area experienced several destructive events, such as the Kefalonia earthquakes (three M6+ events) of 1953 and the more recent Zakynthos earthquake of October 2018.

In order to improve the knowledge on sediment deformation, fault geometry and assessment of hazard associated with the tsunamigenic faults surrounding the islands, we carried out two oceanographic cruises, one in May 2022 and the other in June 2023, collecting several types of geophysical (e.g., bathymetry, seismic data, chirp data, magnetometry) and geological (gravity cores) data with different resolution. The new multichannel seismic data, combined with the high-resolution swath bathymetry, allowed us to define the sediment deformation patterns at the intersection between the Kefalonia strike-slip fault and the thrust fronts of the Hellenic System. In particular, the Kefalonia fault opens toward the south into a fan composed of elongated, sigmoidal positive flower structures. Several seaward-verging anticlines with a strike-slip component, and uplifted blocks have been mapped for the first time off Kefalonia and Zakynthos, filling therefore the knowledge gap of this seismologically "locked" area. Moving farther to southeast offshore Zakynthos, the tectonic regime changes radically with extension prevailing and abundant translational slides, possibly tectonically-triggered, affecting shallow sediments.

This new dataset allowed us to define a transition zone between the strike-slip and compression domain that is much larger and more complex than expected, and the area to the southeast where extension starts to develop. Furthermore, we defined the distribution and lateral continuity of the fault systems affecting shallow sediments whose kinematics could be controlled by the plate boundaries.

Past to recent tectonic activity in the western Ligurian Margin: new insights from geophysical marine data

Keywords: faults, morphotectonics, Ligurian Margin.

In the framework of the cartographic mapping project CARG 245 - Albenga sheet, new bathymetric and geophysical data have been collected in the offshore of Albenga. The integration of newly acquired and available geological and geophysical datasets allowed a detailed reconstruction of the seismo-stratigraphic architecture of the western portion of the Ligurian margin and its morpho-structural setting. The high-resolution seismic reflection data show the presence, in the continental shelf and in the upper slope areas, of the entire Mio-Pliocene sedimentary cover of the Ligurian Margin and allow a detailed reconstruction of the quaternary sequence, including the Late Quaternary and Holocene deposits. These quaternary seismo-stratigraphic sequences are characterized by evident regional unconformities that can be correlated with the age dated depositional units of the Albenga Plio-Quaternary Basin in the emerged areas. The age dating of the quaternary marine and alluvial sediments of the Albenga Basin have been performed in this study through biostratigraphic and magnetic methods. In the onshore and offshore areas, the stratigraphic sequences of the Ligurian Margin are cut by a well-developed system of faults recording a polyphase evolution with multiple tectonic inversions including the reactivation of Mesozoic tectonic structures. The last Pleistocene inversion, characterized by a transition from transtensional to transpressional regime, is consistent with the Plio-quaternary compressive/ transpressive tectonic event described for the Western Ligurian Margin (e.g., Morelli et al., 2022) and can be associated with the widespread present-day seismicity. In addition, we were able to map the morphological expressions of erosional and gravitational mass movements along the continental slope and within a complex system of submarine canyons. These could be considered the surface effects of the recent tectonic activity described above.

Keywords: Campania-Lucania Apennines, seismic section interpretation, extensional quaternary fault.

The Campania-Lucania Apennines have long been a subject of significant scientific interest due to their stratigraphic-structural setting and the hydrocarbon exploration. This portion of the Apennines is also affected by recurrent and intense seismic activity, including some of the strongest historical and instrumental events, such as the "recent" Irpinian earthquake of 1980. The broad scientific literature suggests that much of this seismicity is extensional and is associated with Pleistocene-Holocene normal faults, whose deformation produced NW-SE elongated continental basins.

In the north-eastern sector of the Alburni Mountains, east-dipping normal faults dominate the extensional structural setting; there are clear evidences that they represent the surface expression of a regional synthetic detachment surface. This work aims to understand if the same deformational style can be generalized to the entire internal sector of the Campania-Lucania arc from the Sele plain, to the Mt. Cervati massif, located a few tens of km south-west.

The survey of key-areas provides new data to integrate into a database for the creation of a regional-scale geological-structural map, drawn up by reprocessed seismic data from literature. The area extends onland from the southern flank of the Picentini Mountains to the northwestern border of Mt. Pollino, covering approximately 9000 km2. These data constitute the surface constraint through which four shallow geological cross-sections are drawn; their integration with the logs of some calibration-wells available from literature, enables the interpretation of a grid of 12 seismic lines. The lines are provided by both the Eni and the openly-accessible Videpi database.

Their conversion to depth led to obtain a series of crustal sections that allow us to compare both the contractional and extensional structures across the entire study area.

The geological sections and seismic lines, interpreted down to the top of the Apulian Platform, shed light on the following significant aspects: i) the subsurface geometry of the extensional fault systems, ii) the depth and sense of dip of their detachment surface, iii) the hierarchy between conjugate faults, iv) the relationships occurring at depth between normal faults and the main thrust surfaces, v) the shape of syn-tectonic Quaternary depressions (Auletta basin, Diano Valley and Agri Valley) and the thickness of the sedimentary infill, vi) the role of every single structure in the regional tectonic setting, and vii) the geometry of the pre-extensional state with an estimate of the elongation obtained from the restoration of the main cross-sections.

The results of this work contribute to the building of a comprehensive 3D model of active extensional faults of the southern Apennines, in the context of the MUSE 4D PRIN project.

New analysis of InSAR and seismology for kinematic reconstruction of the 1995 offshore Aigion M6.5 earthquake (Greece)

Keywords: seismology, inversion, rift.

During the transition from early to mature rifting different fault geometries and kinematics may form. In particular it is debated whether low angle normal faulting occurs during early rifting. It is therefore crucial to constrain how faults slip during earthquakes by thoroughly exploring the variability of the fault models derived from geophysical observations.

Here we study the Mw 6.5 Aigion earthquake that occurred in the Gulf of Corinth on June 15, 1995, using InSAR and seismic waveforms. The Gulf of Corinth is a rift in its early stages, currently extending at a rate of 10-15 mm/yr (Bell et al., 2008) in the N-S direction and characterized by normal faults defining a graben. The Gulf of Corinth can generate major destructive earthquakes, such as the magnitude 6.7 in 1981, and is heavily populated. Therefore it is key to understand the mechanisms of faulting in the Gulf of Corinth rift. The 1995 Aigion seismic sequence included a Mw 6.5 earthquake and an aftershock of Mw 5.2. However, the subsurface geometry and position of the fault is highly debated, including whether it dips to the N or S, and the fault dip angle. The majority of the deformation occurred offshore and analysis of the seismicity or geodetic (InSAR and GPS) data alone leads to non-unique fault solutions.

On the contrary joint inversion of different types of geophysical data can give more robust fault models. In this work, we jointly invert InSAR and teleseismic data for the fault model of the Mw 6.5 Aigion earthquake. Preliminary results show the possibility of a low-angle normal fault as a best-fit model. This multidisciplinary methodology could better constrain subsurface definition of faults in the Gulf of Corinth and other regions, both for past and future deformation events.

The India-Eurasia collision zone is one of the most complex and destructive collisional zones globally. The Indian plate converges with the Tibetan Plateau to the north, exhibiting a convergence rate increasing from ~16.5 mm/yr (Kumar et al., 2023) in the west to ~21 mm/yr in the Bhutan region (Dal Zilio et al., 2020). Compression is primarily accommodated by the basal detachment commonly referred to as the Main Himalayan Thrust, whose surface expression is represented by the Main Frontal Thrust. To describe the destructiveness of this zone, historical and instrumental events such as the 1505 Lo Mustang earthquake (Mw 8.2-8.8), the 2015 Gorkha earthquake (Mw 7.8), and the 1714 Bhutan earthquake (Mw 8.1) are remembered. The Tibetan region, on the other hand, is primarily affected by extensional earthquakes that accommodate a west-east directed extension with moderate to high magnitude earthquakes, ranging between Mw 5.5 and Mw 6.8, such as the 2008 Xizang earthquake (Mw 6.7) and the 2008 Damxung earthquake (Mw 6.3) on the Yadung-Gulu rift. Active strike-slip faults are also present, bordering much of the Tibetan plateau and intersecting its central zones (Wang & Barbot, 2023). Notable examples include the Altyn-Tagh fault, the Karakoram fault, and the Gyaring Co fault. Although the region is particularly affected by high rates of seismicity, seismic and geodetic networks are not well-distributed. In such cases, a multidisciplinary approach allows drawing from several data types to obtain a more comprehensive understanding of the seismotectonic setting. We have computed a new velocity field by processing continuous stations throughout the Tibetan-Nepal-Indian territory. Additionally, through Helmert transformations, all pre-existing velocity fields documented in the literature have been merged into a unified large-scale velocity field. This unified velocity field has been utilized to compute a fine strain rate map over the entire study area. A unified catalogue for instrumental seismicity and focal mechanisms, registered in the area since 1980, has also been collected. Such a unified catalogue is the outcome of a meticulous compilation of data sourced from various national and international catalogues aimed at improving the completeness magnitude of the area (approximately Mw 4.0). The same care has been applied to gather historical events preceding 1980, ensuring a comprehensive understanding of the seismic history (Cheng et al., 2017). The deformation pattern can be completely understood by comparing strain rate maps with focal mechanism inversions. This approach allows us to compare stress and strain and to discriminate the contributions of several sources of different kinematics.

Keywords: fold-and-thrust belt, seismicity, Northern Apennines.

The interpretation of a partly unpublished set of nine seismic reflection profiles, calibrated by eight deep boreholes, sheds light on the subsurface stratigraphy and structure of a segment of the active Northern Apennines outer front, in the Northern Adriatic off-shore, between Ancona and Pesaro (Marche region, Italy). On the 9th of November 2022, this area was struck by a Mw 5.5 earthquake, as part of a complex seismic sequence, including six M>4 events, with NW-SE striking thrust fault focal mechanisms. The sequence is coherent with the seismotectonic framework of the outer front of the Northern Apennines fold-and-thrust belt, where geodetic data demonstrate active contraction, with a strain rate of 2-3 mm/yr, accommodated by a set of SW-dipping thrusts, as also testified by the occurrence of instrumental and historical seismicity.

The most important compressional structures of the study area are a pair of én échelon, major anticlines, developed at the hangingwall of SW-dipping thrust ramps. Two deep wells, drilled in the crestal zone of these folds, show that the whole Mesozoic-Paleogene carbonate multilayer, more than 3 km thick, is involved in the anticlines. Geological cross-sections, derived from the interpretation and depth conversion of the seismic profiles, reveal the box-shaped geometry of the anticlines, with a wavelength greater than 7 km. A complex pattern of imbricated thrusts and short-wavelength folds is generated in front of the outer limb of the northern anticline, generating multiple repetitions of the Neogene-Quaternary succession, consisting of a group of marly formations, overlain by sandy and clayey clastic sediments.

The structural style of these buried compressional structures is quite similar to that of the innermost (i.e. westernmost) and older structures exposed at the surface in the mountains of the Umbria-Marche Ridge, sharing a common mechanical stratigraphy and tectonic evolution. The comparison and integration of the observations collected, with different data and techniques, in these two adjacent regions, allow us a complete and detailed description of the buried contractional structures of the study area. This includes the longitudinal continuity of the folds, the length and width of the seismically active thrusts, the slip rate and its variations through time, the depth of the main decollements, the thickness of the seismogenic [layer and the linkage mechanisms of the én-échelon anticlines.

A better comprehension of the geological structures at depth, combined with improved geodetic and seismological data, are essential for a realistic identification of the single seismogenic sources, as well as of their general seismotectonic framework, and ultimately for a correct evaluation of their relevance in terms of seismic hazard.

Exploring historical seismograms: moment tensor inversion of the 1947 Squillace Basin Earthquake (Calabria, South Italy)

Scolaro S.*[1], Batlló J.[2], Orecchio B.[1], Presti D.[1], Stich D.[3] & Totaro C.[1]

Keywords: Analog seismograms, Waveform inversion, Ionian subducting system.

Seismograms from the analog era span over a century of seismic activity, offering invaluable insights, particularly for assessing seismic risk in regions affected by significant historical events and minor seismic activity in recent decades. In this framework, this study explores the 1947, May 11 Squillace Basin earthquake, that is the only M>5.5 event instrumentally recorded in central Calabria (Southern Italy), according to the official catalog (CPTI15, Rovida et al., 2022). The study area is characterized by high seismic risk and a complex geodynamic context driven by northwest-trending Nubia–Eurasia convergence and southeastward Ionian slab rollback. Thus, the 1947 earthquake could provide crucial information to better characterize regional seismotectonic and seismic hazard.

To investigate the 1947 earthquake, fifteen medium- to long-period analog seismograms with relative instrumental parameters were accurately selected. These collected recordings underwent rigorous processing, including vectorization and waveform corrections, to make them suitable for modern analysis techniques. We applied a technique tailored for time-domain moment tensor computation through waveform inversion of analog seismograms (Stich et al., 2005). The moment tensor solution estimated for the 1947 earthquake reveals a strike-slip mechanism with focal depth of 28 km and moment magnitude Mw=5.1.

The inferred hypocentral depth and left-lateral kinematics along a west-northwest–east-southeast-oriented fault align closely with the local seismotectonic framework and are consistent with STEP fault activity in central Calabria (Orecchio et al., 2014; Corradino et al., 2021). This study serves the dual purpose of contributing new data to the ongoing debate on slab edge kinematics and deepening methodological insights concerning the management of historical seismograms.

Keywords: tomography, seismotectonic, fault geometry.

The Outer Thrust System (OTS) segment extending from Pescara to Benevento (Italy) represents a scientific conundrum due to its complex geometry, seismic activity, and deformation style. Traditional seismic analysis methods have been hindered by low seismicity levels, blind thrusting, and inadequate seismic data quality, resulting in an inconsistent seismotectonic model.

This segment of the OTS (Abruzzi Thrust), having an arcuate eastward convex shape, is articulated in two minor arcs, the Abruzzo Citeriore Arc northward and the Frentani Arc southward. The frontal thrust and its splay are buried under Plio-Pleistocene deposits, but they are evident in seismic lines and highlighted as potentially active and seismogenic in recent morphotectonic studies (Ferrarini et al., 2021).

Employing travel time, seismic attenuation, and scattering tomography methods, we improve the characterization of the thrust-related deformation at different depths for the first time in that area.

High anomaly values of attenuation and peak delay are interpreted in the literature as fractured shear zones that trap seismic waves, increasing the scattering effect (King et al., 2022, 2023) and making them lose energy during propagation. Our results show shallow (between 5 and 7 km in depth) and continuous high-attenuation volume located between Campobasso and Benevento, striking N-S for about 80 km: in our interpretation, these features represent the southern prosecution of the Frentani Arc.

At greater depths, in correspondence with the middle-lower crust, travel time tomography reveals a significant Vp inversion recognizable along several cross-sections having different orientations. This result, validated through spike tests, carries out crucial implications for crust-scale geometry and deformation style of the compressive structures and suggests a deep-rooted thrust system.

We have gained insights into the geometry of the Abruzzi Thrust by combining the results obtained from seismic attenuation and travel time tomography. These findings indicate the presence of a crustal doubling zone, which is especially evident in correspondence with the Frentani thrust. The model offers valuable constraints for reconstructing a regional 3D fault model and reveals the geometry and size of this potentially seismogenic structure.

This work emphasizes the importance of tomographic imaging in supporting fault model building to be interpreted from a seismotectonic perspective, particularly in regions with insufficient traditional seismological data and seismic lines. Furthermore, these findings provide a valuable understanding of the structural style of the overall Outer Thrust System, reinforcing a thick-skinned interpretation.

Keywords: 2D model, gravity anomalies, Central Apennines.

Crustal models based on surface geology and seismic lines interpretation can only account for the shallow (within 10 km or less) portion of the crust. Other geophysical investigations, such as receiver functions or tomography, provide information respectively on the depth of the Moho and the velocity distribution within the crust but cannot be interpreted in a unique way. Only an integrated multidisciplinary approach that combines those techniques with other independent data, such as Bouguer anomalies, could validate the results and help with the interpretation. Here we present a 2D gravity model across the Central Apennines, in the area affected by the 2016-17 Amatrice-Visso-Norcia seismic sequence, as a part of the RETRACE-3D project and aimed at completing and verifying the crustal geometries resulting from the 3D geological model. The cross-section was built integrating different data types, such as surface geology, hydrocarbon wells, seismic lines, and results from receiver function analysis. It was then checked against gravity anomalies and the velocity distribution from Local Earthquake Tomography (LET), adding further details, and, finally, against seismicity recorded during the 2016-2017 sequence. The results substantiate the reliability of the geometries proposed in the RETRACE 3D model. Furthermore, the integration of different types of data allowed us to describe in detail the structural setting of the Apennine chain also in the surroundings of the RETRACE study area, where the cross-section length exceeds the 3D model, and to add some new elements at seismogenic depths, that exceed those typical of hydrocarbon exploration. In particular, we were able to investigate the nature of the basement top and its relationship with seismotectonics.

From active faults to seismogenic sources: understanding their geometry, hierarchy, and earthquake potential through a fully multidisciplinary approach

Valensise G.*

INGV, Sezione Roma 1.

Corresponding author email: gianluca.valensise@ingv.it

Keywords: earthquakes, seismotectonics, faults, seismogenic sources.

The modern concept of active faulting has been developed in the aftermath of the great 1891 Nōbi and 1906, San Francisco earthquakes. But up until the late 1970s there was little perception of the importance of the size, geometry, or simply of the existence of faults that are non immediately visible at the surface, and yet participate in the evolution of geology and landscape (let alone, in the generation of earthquakes).

The large earthquakes that occurred around the turn of the 19th-20th century raised awareness that a large earthquake requires a large fault, both in width and in length. But in most countries worldwide, this perception did not clearly develop until the occurrence of a large earthquake.

The 23 November 1980, Ms 6.9, Campania-Basilicata earthquake is the event that modified this trend in Italy. The event caused undisputable surface faulting over a length of about 40 km, disrespecting all the minor faults that had been previously mapped as active or potentially active. Suddenly it became clear that even in the Italian Apennines, fault come in different sizes, entail different hierarchy levels, and may be generated by an extremely youthful tectonic regime. It became also clear that the geologic and geomorphic signal left by the activity of that certainly active and seismogenic fault is almost hopelessly hidden by the cumulative deformation caused by extinct faults and by the associated landforms.

In the following years the Italian active faulting community turned to the two largest earthquakes of the 20th century, namely the 1908 Mw 7.1 Messina Straits and the Mw 7.1 Avezzano-Marsica events, both of which featured early seismometric and geodetic observations. The first turned out to be a blind faulting event generated by a rather shallow dipping normal fault; once again, the deformation it caused did not much resemble the topography of the Messina Straits, and it became clear that it had very little to do with the numerous normal faults mapped on both sides of the Straits. The second caused sizable and relatively clear surface faulting, and deformed the Fucino Plain consistently with its current physiography and subsurface geology, and yet it did not match many of the secondary faults that had been mapped in the area by previous workers.

These three earthquakes were a clear and strong indication that the faults responsabile for a large earthquake are much more difficult to identify than most of us thought prior to 1990s. Almost forty years later, we have learned that we cannot rely on the surface evidence of brittle faulting alone, but we have to match structural evidence with subsurface data, geomorphic data, instrumental data, and in many cases also with earthquake intensity data. Where a large earthquake occurs there must be a large fault, but it may be from hard to impossible to derive its properties that from outcrop data alone; keeping in mind that many Italian earthquakes are generated by blind, hidden or downright inaccessible faults. This awareness comprises the corner stone of Italy's Database of Individual Seismogenic Sources.

Keywords: fault roughness, fault linkage, co-seismic ruptures.

Studies on natural and laboratory slip surfaces demonstrate that roughness evolves with increasing slip and displays a scale-dependency inversely proportional to the fault length regardless of lithology. However, only a few studies have quantified the possible variation of roughness along single slip surfaces and at linkage zone between adjacent fault segments.

In this study we aim at highlighting the influence of fault growth processes (i.e. fault linkage) on fault roughness. We integrated structural analysis, Structure from Motion-Multi-view stereo (SfM-MVS) photogrammetric modeling, and microtextural characterization of fault rocks along two principal slip surfaces associated with the Monte Capo di Serre Fault, which is a high-angle and c. 8 km long seismically active normal fault in the Central Apennines (Italy). The Monte Capo di Serre Fault cuts Triassic dolostones, Lower Jurassic limestones and dolostones, and Quaternary carbonate slope debris. In detail, we focus on the roughness of slip surfaces that interact along their mode III edges forming mesoscale relay ramps with left- and right-steps and containing patches of sheared slopes debris.

Our field and microtextural analyses indicate that the Monte Capo di Serre Fault registered co-seismic ruptures, as indicated by ring cracks, truncated clasts, and fluidized and very fine-grained microlayer observed at the microscale. Undulated m-scale grooves are characterized by periclinal terminations along dip. These features are thought to exert a control on rupture propagation at depth.

Kinematic analysis highlights a dominant pure dip-slip normal kinematics accommodated by the individual slip surfaces. Kinematic variations are documented along m-scale grooves along the linkage zones among right-stepping slip surfaces. The aforementioned data collected along the Monte Capo di Serre Fault are compatible with stress fields characterized by both NW-SE and NE-SW trending shmax. In particular, the result of stress inversion analysis is consistent with a local shmax-shmin permutation in correspondence of linkage zones between the different fault segments. There, marked left-lateral components of slip are assessed for the ca. E-W striking slip surfaces which connects two left-stepping main (i.e., NW-SE striking) fault segments and is characterized by a few m-thick, sheared slope debris deposit. Such a linkage zone can be viewed as a 10 m-scale groove for the Monte Capo di Serre.

Utilizing a combination of smartphone, drone, and single-lens camera, SfM-MVS photogrammetric modeling enabled us to conduct detailed roughness analysis on 1 m2 to 0.4 m2 portions of distinct fault planes.

Field and digital structural analyses indicate that the local dispersion of the kinematic vector along m-scale grooves is invariably associated with the overall (seismic) slip along the main fault surfaces.

Preliminary results of Fourier power spectrum analysis conducted on several portions of single slip surfaces confirm the self-affine behavior of the fault roughness at all scales. In particular, we document that the Hurst's exponent and so the fault roughness scales differently in the slip direction compared to the perpendicular to slip direction and that different exponents are recorded on the different portions of the fault. In summary, the result of our work should find application in seismological studies to constrain the fault roughness properties at very shallow depths during low-velocity upward rupture propagation from deeper seismic slip.

Asymmetric microfracture pattern associated to seismic rupture (Gole Larghe Fault, Italy)

Aldrighetti S.*[1], Di Toro G.[1-2] & Pennacchioni G.[1]

Corresponding author email: silvia.aldrighetti.1@phd.unipd.it

Keywords: pseudotachylytes, microfractures, rupture.

Earthquakes are the result of propagation, (at ~km/s) of a rupture and related fault slip (at ~m/s). Rupture propagation generates a transient high-stress field in the rock volume surrounding the fault. Neglecting the work against gravity, during rupture propagation and subsequent fault slip, the elastic strain energy stored in the wall rocks is converted into fracturing, frictional heat, and elastic waves. Pseudotachylytes are solidified frictional melts found in exhumed faults produced during seismic slip (Sibson, 1975) and thus can be studied, together with the associated microstructures, to better understand earthquake source parameters and mechanics.

The natural pseudotachylyte-bearing fault selected for this study belongs to the east-west-striking, dextral, strike-slip Gole Larghe Fault Zone (Adamello, Italian Alps), exhumed from the base of the brittle crust. Microstructural studies were carried out employing EBSD, FESEM-CL and high resolution mid-angle FESEM-BSE. In particular, FESEM-CL imaging reveals a microfracture network in the wall rocks surrounding the frictional melt invisible to other imaging techniques. The microstructural analysis evidences (i) a high degree of fragmentation of the wall rock adjacent to the pseudotachylyte fault vein (formed along the slip surface), with clast size down to <90 nm in diameter, and (ii) a systematic difference in fracture density and orientation of the microfractures in the two opposite wall rock sides of the fault. In the northern wall rock, the fracture density is low and the microfractures strike preferentially east-west (i.e., sub-parallel to the fault), while in the southern wall rock the fracture density is high and the microfractures are oriented preferentially north-south (i.e. sub-vertical to the fault). Instead, this asymmetric microfracture pattern is absent in the experimental pseudotachylyte, produced by shearing at seismic slip rates the tonalite that hosts natural pseudotachylytes.

The asymmetric pattern can be interpreted as the result of the dynamic stress field surrounding the rupture during its propagation, that cannot be simulated in the experimental setup involving seismic frictional slip along pre-cut fault surfaces. According to numerical models, for the studied fault, with a rupture propagating from west to east, the transient stresses will impose compression in the northern wall rock and tension in the southern one. The orientation of the principal stresses becomes sub-parallel to the fault in the compressional side and orthogonal in the tensional side, as mirrored by the microfracture pattern. Moreover, the analysis of the extremely fine damaged domain and the pseudotachylyte allows the estimate of the energy dissipated in fracturing processes (0.008-1.35 MJ/m2) and frictional heat (32 MJ/m2) (Pittarello et al., 2008). A comparison between the two quantities suggests that frictional heat is likely the major energy sink during rupture propagation.

Keywords: seismic velocities, mechanical properties, fluid-rock interactions.

In seismogenic zones, anomalously high P- to S-waves ratio (Vp/Vs) is often recorded, being related to fluid pressure approaching lithostatic levels. In the last decades, several mechanisms have been proposed to explain high Vp/Vs values, including poroelasticity and anisotropy effects, however the relation between high pore pressure and Vp/Vs evolution remains still unclear.

In this study we conducted a series of hydrostatic and non-hydrostatic deformation experiments to investigate the evolution of Vp/Vs changes during fluid pressure changes on both undeformed and deformed samples. We used Fontainebleau sandstone as starting material and tested it hydrostatically between 4 and 30 MPa of effective pressure, with a pore-fluid factor l (Pf/Pc) up to 0.8. During the fluid pressurization under hydrostatic conditions, Vp/Vs increases up to 1.5%, from ~1.63 to ~1.67. This increase is mostly achieved for l above 0.5 when we recorded a progressive decrease of both Vp and Vs. However, Vs decreases at larger rate with respect to Vp leading to a consequent increase of Vp/Vs ratio. We then applied differential stress at the same boundary conditions. Under the application of differential stress, we observe a larger increase of the Vp/Vs with respect to hydrostatic experiments reaching values ranging from approximately 2 to 2.4. Most of this increase appended during the dilatational dominated deformation up to macroscopic failure in particular when the samples where under near-lithostatic fluid pressurization condition (l = 0.8). In agreement with hydrostatic tests, during deformation tests the Vp/Vs increase is due to a larger decrease of Vs with respect to Vp.

These results suggests that the combination of poroelastic effects and crack-induced anisotropy may play a significant role in generating high Vp/Vs leading to changes in the mechanical properties of deformed rocks. These values are in agreement with those observed in natural cases, at crustal scale especially in shallow depth conditions. Our study, thus, contributes to the understanding of processes governing earthquake mechanics. Moreover, it suggests that the ability to monitor fluid pressure in the Earth's crust by examining changes in the Vp/Vs ratio holds great value for assessing potential seismic hazards and risks associated with fluid-rock interaction.

Origin of mirror-like fault surfaces in bituminous dolostones (Central Apennines, Italy)

Chinello M.*[1], Schito A.[2], Bowden S.A.[3], Tesei T.[1], Spagnuolo E.[4], Aretusini S.[4] & Di Toro G.[1-4]

[1] Dipartimento di Geoscienze, Università di Padova. [2] Departament de Mineralogia, Petrologia i Geologia Aplicada, Universitat de Barcelona. Corresponding author email: miriana.chinello@phd.unipd.it

Keywords: mirror-like surfaces, thermal maturity, fault surfaces.

Mirror-like Surfaces (MSs) are ultra-polished fault surfaces that reflect visible light, thanks to their nanometer-scale surface roughness. They are often found in seismogenic fault zones cutting limestones and dolostones. Both natural and experimentally-produced fault-related MSs have been described in spatial association with ultrafine matrix (grain size <10μm), nanograins (<100nm in size), amorphous carbon, decomposition products of calcite/dolomite, and larger but "truncated" clasts. However, the formation mechanism of MSs is still debated. Experiments show that MSs can develop both under seismic (slip rate ≈1 m/s) and sub-seismic (slip rate ≈0.1-10 μm/s) deformation conditions, involving various physical-chemical processes.

To evaluate whether the MSs formed during the co-seismic (possibly associated with frictional heat pulses) or the inter-seismic (no heat pulses) phases where temperature might serve as a distinguishing factor, we assessed the thermal maturity of "bitumen" using biomarkers. We acquired data for natural and artificial MSs in bituminous dolostones. We collected natural samples from faults located in the Italian Central Apennines (Monte Camicia Thrust Zone, past burial depths up to ~3 km; measured displacement from few mm to few m). We obtained MSs in the laboratory by deforming powdered bituminous dolostones in a rotary shear apparatus (SHIVA, INGV) at sub-seismic (V = 10-4 m/s) and seismic (V = 1-3 m/s) slip rates for 1-2 m of slip, under room temperature and humidity conditions, and 20 MPa of normal stress.

We extracted solid bitumen of pre-oil window thermal maturity from the MSs and from the underlying slip zone of natural and artificial samples and we analysed the bitumen using Gas Chromatography–Mass Spectrometry. We identified Steranes and other biomarkers based on relative retention time and measured peak heights to obtain thermal maturity parameters. By comparing different samples, changes in thermal maturity could be measured across slip zones bounded by the MS and possibly associated with frictional heat pulses during co-seismic slip.

Biomarker thermal maturity parameters are consistent with the immaturity of the host rock. In the experimental MSs produced at seismic slip velocity, where frictional heat pulses reached T~400°C, thermal maturity of bitumen in MSs is slightly higher than that of MS produced at sub-seismic slip rate; higher thermal maturities were measured also in natural MSs respect to the entire slip zone.

Microstructural analysis done previously revealed that these slip zones recorded the main phases of the seismic cycle, from rapid co-seismic slip to post/inter-seismic viscous flow and fault strength recovery. The results presented here (1) confirm this interpretation, (2) show that the frictional heat pulse associated with seismic slip may be recorded by biomarkers thermal maturity of bitumen in the MSs, and (3) some natural MSs are associated with heat anomalies caused by seismic ruptures.

Frictional fault healing under hydrothermal conditions

Di Toro G.*[1-2], Gomila R.[1], Feng W.[1], Salvadori L.[1], Wu W.-H.[1], Guglielmi G.[3], Tesei T.[1], Yao L.[4], Sciarra A.[2], Cantucci B.[2], Grassa F.[5], Piochi M.[6] & Ma S.[4]

Keywords: hydrothermal conditions, fluid-rock interaction, seismic cycle.

Fault healing is the ability of a fault to recover its strength over time after a seismic event and is one of the main factors controlling the seismic cycle. There is ample geophysical and geological evidence that most natural and human-induced seismic sequences are associated with the circulation of fluids (H_2O, CO_2) at depth. However, the investigation of rock friction in the presence of hot and pressurized fluids (hydrothermal conditions, up to 450°C) at slip velocities ranging from plate tectonic (~ nm/s) to seismic (~ m/s) rates and for slip displacements (> 0.2 m) typical of moderate to large magnitude earthquakes has been partly hampered by technical challenges.

Here we discuss the results obtained with a newly-conceived experimental configuration which exploits a rotary shear machine and a dedicated hydrothermal vessel. The combination of the two devices allows us to study fault friction and healing at pore fluid pressures up to 70 MPa, normal stresses up to 100 MPa, slip rates from nm/s to m/s, and nominally infinite displacements in experiments that can last up to several weeks. These experimental conditions reproduce, for example, the liquid, vapor and supercritical states of water in high-enthalpy geothermal systems. Rock samples and fluids are recovered after the experiments, allowing us to conduct microanalytical investigations, probe the deformation processes and document the type of fluid-rock interaction responsible for the measured mechanical data and healing.

Through this approach, we found that the physical state of the water and the degree of alteration of the rock have a profound impact on the friction response. For example, common basement rocks, such as gabbros or granodiorites, (1) in the presence of water in the liquid and supercritical state, have frictional strength that is about half that in the presence of water in the vapor state or, (2) have fault healing that decreases, rather than increases like for their altered equivalents, during long hold times in the presence of hot, pressurized fluids. In addition, the friction is higher and the fault "more unstable" under the same effective stress in the presence of steam and superheated steam rather than under liquid or supercritical conditions. Depending on the pressure-temperature conditions of the fluid, microanalytical investigations on the rock and on the fluids recovered after the experiments evidence the dissolution of silicate-bearing minerals and the neo-formation of clays, zeolites, etc. These newly formed "weak" minerals may contribute to the observed decrease of healing of the experimental faults.

In conclusion, the physical state of water has profound effects on the mechanical response of faults and fractures under hydrothermal conditions, something that has been somewhat overlooked so far. The experimental approach proposed here may provide new insight into the mechanical behavior of faults during the seismic cycle.

Rheology of Triassic evaporites and implications for seismicity of the Apennines: insights from triaxial laboratory experiments

Guglielmi G.*[1], De Paola N.[2], Giorgetti C.[1], Collettini C.[1-3] & Trippetta F.[1]

Keywords: triassic evaporites, distributed seismicity, rheology.

The integration of seismic reflection profiles with precisely located seismicity shows that a large number of earthquakes of the Northern Apennines nucleate within the Triassic Evaporites (TE), a lithology made of dolostones and anhydrites (Miller et al., 2004; Barchi et al., 2021). TE hosts the nucleation of the mainshock of the Colfiorito 1997, Mw 6.0 and Norcia 2016-2017, Mw 6.5 seismic sequences, together with widespread distributed seismicity (Collettini et al., 2022).

To better characterize the rheology of the TE and improve our understanding on the seismicity of the Northern Apennines, we performed triaxial rock deformation experiments on TE borehole samples, exploring the role of textural heterogeneities, confining pressure, and strain rate.

We tested a suite of cylindrical samples with different fabric represented by nearly pure anhydrites, foliated anhydrite/dolostone and mixed-chaotic anhydrite/dolostone at confining pressure of 10 and 20 MPa and strain rates of 2·10-5 and 2·10-4 s-1. We loaded the samples up to failure, then, after a holding time of 1000 seconds, we reloaded the samples to investigate fault reactivation. Some tests have been stopped at earlier stages to constrain the evolution of deformation processes through microstructural analysis.

Upon failure, brittle behavior with associated stress drop is observed for all tested specimens. Samples with high dolostone content show thin experimental fault zones characterized by localized ruptures, which gradually become wider and accompanied by distributed damage across the sample as the anhydrite content increases. Lower confining pressure promoted faster fault slip during failure whereas high strain rate promoted larger stress drops and higher fault slip velocity.

Fault reactivation has been characterized after the holding time, and it occurs via slow slip instabilities mostly detected at 10 MPa of confining pressure, independently of rock fabric.

Our observations suggest that lithology, confining pressure and strain rate exert a major role on the rheology of TE. We observe a spectrum of fault slip behavior, spanning from fast instabilities to slow slip events, that seems to be mostly controlled by the boundary conditions of the experiments, i.e. experiments near the brittle-ductile transition of the TE, rather than the frictional properties of the rocks. This research topic will be further investigated through a more detailed characterization of the mechanical data and ongoing microstructural analysis.

Keywords: fault damage, FEM, stress.

The geometrical heterogeneity in fault rocks is observable from the micro- to meter-scale, at the contact zones between grains or clasts and along the fault-surface topography. Among the other, heterogeneity may be represented as a succession of cracks and structural defects within the rock medium. The presence of voids, cracks and anisotropic fabric are all proven factors that perturb the stress field in rocks subjected to deformation. For example, fault roughness is considered a controlling parameter of the inhomogeneous stress distribution over a critically stressed fault surface (e.g. Candela et al., 2012). The density and geometry of the damage control the location of the high local concentration of stress driving the macroscopic failure of the rock and the aseismic/seismic slip. In this contribution, we show a Finite Element Method-based study to investigate the differential stress response to the variations in the damage configuration of a rock body undergoing elastic deformation. We test how stress distribution and concentration vary in relation to a set of geometries, including: collinear, echelon and Riedel crack patterns, each with changing number, distance and length. Configurations reproducing typical roughness of fault surfaces at different scales, as well as random distribution are also performed. Results indicate that the different geometries have dramatic effects on the stress distribution and orientation, with particular emphasis for the geometry that produce constructive interferences in the stress concentration governing the switch from aseismic to seismic slip. The results are compared with fault zones and surfaces from different geological settings.

Keywords: Alpine Corsica, pseudotachylyte, cockade breccia.

Alpine Corsica formed during the Alpine subduction-collision history followed by Oligocene-Miocene lithospheric extension controlled by the eastward migration of Apenninic subduction. Here we integrate field geological surveys, microstructural analysis and carbonate stable isotope ($\delta^{18}O$–$\delta^{13}C$) geochemistry of fault zone rocks to constrain the evolution of the W-dipping extensional Patrimonio Fault System (PFS). The PFS puts in contact the HP-LT Schistes Lustrés (e.g., impure quartzites, marbles, calcschists, serpentines) and slices of Hercynian granitoids, in the footwall block, with the LP-LT Nebbio units and the syn-extensional Miocene sequences, in the hanging wall block.

We describe a deformation sequence during extensional exhumation of the HP-LT units consisting of D_{1ext} ductile shearing followed by two stages of brittle faulting (D_{2ext} and D_{3ext}). D_{1ext} deformation occurred at greenschist conditions (i.e., 300-400 °C) and produced a meter-thick mylonitic zone, part of the roots of the PFS, and diffuse extensional crenulation cleavages and quartz ± chlorite veins in the footwall units. D_{2ext} faults were seismogenic as attested by (i) altered pseudotachylytes and (ii) cockade-bearing fault-veins observed in the footwall splay faults. Cockade-bearing fault-veins exhibit internal inverse grading, injected the host-rocks, and mutually overprinted dolomite-rich veinlet mesh and mirror-like slip surfaces. Seismic faulting was also accommodated by dolomite-quartz(-chalcedony) crack-seal veins, whose isotopic composition is similar to that of the carbonate-rich units of the Schistes Lustrés. These structural and geochemical observations indicate that ancient seismicity was modulated by pressurized fluids with host-rock-buffered isotopic composition. D_{3ext} corresponds to shallow faulting and consists of (i) gouge-bearing fault strands, cutting Burdigalian-Langhian carbonates, and (ii) meteoric-derived calcite-bearing veins and concretions filling open fractures. We speculate that D_{2ext} Early-Mid Miocene faults represent a fossil analogue of the extensional faults currently active in the Apennines where seismicity is driven by CO_2-rich deep-sourced fluids.

Probing the micromechanics of laboratory faults using ultrasonic waves: insights from borehole samples from Delaware Basin, Texas

Mauro M.*[1], Volpe G.[1], De Solda M.[1], Magnani M.B.[2], Collettini C.[1-3] & Scuderi M.M.[1]

Corresponding author email: michele.mauro@uniroma1.it

Keywords: frictional behavior, induced seismicity, ultrasonic waves testing.

Induced seismicity is an increasingly relevant topic due to its socioeconomic implications and hazard impact. Since 2008, seismicity in the central United States has been associated with hydraulic fracturing and injection operations, which have led to the reactivation of critically stressed faults.

Over the last decade, production and saltwater injection have surged in the Delaware Basin, a prolific petroleum-producing region in western Texas. The basin has experienced an increased number of earthquakes beginning in 2009, suggesting a causal relationship with industry operations. However, whether earthquake clusters are related to hydraulic fracturing or saltwater disposal, and therefore the mechanism of fault reactivation, is still unclear due to seismic station siting challenges.

Faults can slip in a wide spectrum of modes, ranging from stable aseismic creep to unstable dynamic slip with many quasi-dynamic transient phenomena between these two end members.

Frictional laboratory experiments allow the evaluation of experimental fault stability using the Rate and State Friction (RSF) framework. However, reconciling these empirical laws formulated in laboratory with natural cases is still challenging due to a fundamental lack of understanding of the microphysical processes governing friction.

In the laboratory, experimental faults can be probed with ultrasonic waves (UW) to investigate the mechanics and evolution of contacts under applied stress variations.

Here we present preliminary results on the stability of experimental fault gouges derived from borehole samples from the Delaware basin. Samples were selected from formations linked to shallow and deep operations, spanning various locations marked by ongoing seismicity.

The experiments were conducted using the biaxial apparatus BRAVA2 in the Rock Mechanics and Earthquake Physics laboratory at Sapienza University of Rome.

Velocity steps experiments were performed in Double Direct Shear configuration to obtain RSF parameters under different normal stress conditions (20 to 60 MPa). The apparatus is instrumented with a recently developed UW generation and acquisition system.

The system comprises transversal polarized piezoelectric transducers, where a well-characterized pulse and frequency response allow the exploitation of information contained in the entire waveforms. Transmitted amplitude and velocity variation is used to track the changes in gouge elastic properties.

We show that frictional properties of the samples are strongly influenced by phyllosilicate content. Most of the tested lithologies show velocity strengthening behavior and a tendency to velocity weakening with decreasing amount of phyllosilicates. Noteworthy, formations that are not hosting seismicity have 0% of phyllosilicate content and are velocity weakening. To understand this observation and microphysical processes linked to RSF laws, we integrate mechanical and ultrasonic measurements with microstructural analysis.

From fault weakening to re-strengthening, new insights on fluidization in carbonate-hosted normal fault

Keywords: deformation mechanisms, carbonate bearing fault, fluidization processes.

The role of fluids in faults during single seismic cycles is a greatly debated topic. An increasingly literature suggests that fluids might trigger instability favoring slip during nucleation and/or propagation of coseismic fault ruptures, and due to fracturing might affect the long-term structural diagenesis of fault zones. Indeed, both cementation processes and mineralogical alteration could influence the fault behavior.

For this reason, in order to contribute to the better understanding of the fluid-rock interactions during seismic cycles, we present results of a microstructural analysis conducted on samples of a carbonate-hosted, low-angle normal fault exposed in the Val d'Agri area of southern Italy.

The low-angle fault crosscut Mesozoic dolostone, dolomitic limestones and limestones, includes low-to-moderate dip-angle principal slip surface (PSS) and secondary slip surfaces. The PSS are wrapped by a white ultractaclasite containing dark fluidized ultractaclastic layers characterized by injection bands and protrusions inclined toward the sense of shear.

In detail, the polished specimen show presence of two types of fluidized layers: i) proximal to PSS fluidized layers (PFL), and ii) detached fluidized layers (DFL). The PFL are in contact with the PSS, and mainly localize within the hanging wall rocks. Differently the DFL occurs as relicts within the slip zone. Both PFL and DFL might exhibit a locally pervasive foliation within the slip zone.

Microscale investigation revealed that the PFL is made up of multiple sub-layer with varying amount of clasts and calcite matrix. In this regard, the sub-layers in contact with the PSS, which are interpreted as due to more recent fluidization events, are characterized by greater amount of calcite matrix. Locally, the boundary between the PFL and cataclastic rocks is provided by either shear veins or secondary slip surfaces.

At the nanoscale, the calcite matrix of the PFL is characterized by spherules and tubes tens of nm in width. The nanospherules show either as nanoparticles like-foam aggregates, or as patches wrapping rhombohedral crystals. Our preliminary results hence suggest that the fluidization processes were active during the faulting events.

The geometry of the PFL suggests that a sudden release of fluids occurred during the single slip event, which were probably associated to seismic ruptures as shown by the nanoparticles, suggesting that fault ruptures were associated to either shear heating or decarbonation mechanisms. In this framework, we proposed that the aforementioned fluidized layers might represent the fingerprint of past earthquakes.

On the other hand, fluidization processes promote pervasive calcite cementation producing the fault re-strengthening, and consequently rheological contrasts within the evolving fault zones that in turn could favor shear localization.

Shallow earthquakes affecting high-porosity rocks in forearc basin settings: a combined meso-microstructural, mineralogical, and experimental approach

Keywords: fault gouge, coseismic deformation, shallow burial conditions.

The unstable portion of the seismogenic zone is the locus of most of the earthquakes occurring in the Earth's crust and is located between 5 and 35 km of depth. The uppermost part (< 5 km) of the seismogenic zone is typically considered stable crosscutting low cohesion rocks and sediments. Nevertheless, many earthquakes have been documented to nucleate at depths shallower than 5 km in different geodynamic settings and kinematics. Such shallow seismicity could represent an additional threat to be accounted for in seismically active regions.

To shed light on this matter, we present the results of a study dealing with shallow coseismic deformation recorded within the fault core of an extensional fault zone. The studied fault zone is exposed along the Vitravo Creek canyon, in the central part of the Crotone Basin, South Italy and affects high porosity, Pleistocene siliciclastic rocks. The total displacement of the fault reaches ~50 m and due to the high porosity of deformed rocks, deformation is achieved by development of deformation bands and subsidiary faults. The fault damage zone width is ~8 m in the footwall and ~6 m in the hanging wall block. The master slip surface is decorated with a 2-3 cm-thick dark gouge layer. The gouge is continuous and isopachous along the entire outcrop exposure and locally has been injected in the brittle fractures affecting the calcite cemented fault core. Secondary, thinner (~1 mm) gouge layers are located at a few cm of distance from the main one in the hanging wall block. Microstructural and granulometric analyses conducted on the dark gouge allowed to document a severe cataclastic particle size reduction and a gradient in comminution from the footwall toward the hanging wall side. XRD mineralogical analysis performed on the < 2 μm size fraction of the dark gouge, revealed high percentage of illite in the illite-smectite mixed layers, suggesting deformation temperature up to 100-120 °C. XRD analyses conducted on samples collected along the entire fault zone returned estimated deformation temperatures of < 50 °C, which are compatible with the calculated sediment overburden (< 800 m). The anomalous and localized increase in temperature within the dark gouge has been linked with flash heating processes during coseismic deformation under shallow burial conditions. Frictional experiments run on natural sand samples collected along the fault zone allowed to constrain their mechanical behavior at different slip rates (aseismic and coseismic) and under different water contents (dry vs water damped). The multidisciplinary approach combining field survey, microstructural and mineralogical analysis with rock mechanics experiments could be useful to the study of seismic deformation of sediments and high porosity rocks in near surface conditions. The systematic adoption of such approach to several fault zones and fault systems could enhance and improve the earthquake risk and hazard assessment in seismically active regions.

Friction, mineralogy, and microstructures: how complex is the brittle deformation of faults?

Keywords: fault, friction, fabric.

Faults accommodate most of the brittle deformation that occurs in the lithosphere. They are also the loci that generate and propagate seismic to aseismic slip. The rocks deforming inside the core of the faults are the main actors that control the modality of slip and thus their mechanical properties are a key subject of study that is carried out through experimental investigation. The most relevant mechanical property is friction, a parameter that commensurates the resistance to shear motion of the rocks. Nevertheless, friction is not an intrinsic, constant feature of the investigated materials. It is instead modulated by several attributes and external factors. For instance, the rate and state framework describes the sensitivity of friction to the sliding velocity, proving a successful theory to quantify the potential of the onset of seismic slip in natural faults. Several works have also demonstrated that the frictional properties of the same material can dramatically change as function of the fabric (the textural, geometrical attributes of the deforming rock).

It is therefore evident that brittle deformation of rocks cannot be assessed in isolation of the conditions at which the phenomenon is measured. To fully understand the complex bulk behaviour of a deforming rock we must investigate the interaction of several mechanisms that are active from the grain-scale up to the entire fault zone.

In this work we present the collection > 60 friction experiments performed on BRAVA biaxial apparatus (INGV, Italy), presented here by associating the analysis of mechanical data with the analysis of rock microstructures. This joined investigation highlights the mechanisms that control rock friction: cataclasis, crystal plasticity, pressure-solution, grain-boundary sliding, cementation, and indentation. We also show the emergence of complex slip behaviours (experimental fault stability) as function of the coexistence of processes with different timescales and explained by the spatial arrangement of the mineral phases in the fault core.

Our results shed light on the origin of the macroscopic frictional properties of fault rocks, stressing the fact that they are not a characterising property but rather the observable of a complex, dynamic, and highly non-linear system.

Frictional strength, healing behaviour and deformation mechanism of low-grade serpentinites at hydrothermal conditions

Salvadori L.*, Tesei T. & Di Toro G.

Dipartimento di Geoscienze, Università di Padova.

Corresponding author email: leonardo.salvadori@phd.unipd.it

Keywords: serpentinites, experiments, friction.

Serpentinites are "weak" rocks that play a critical role in the nucleation and propagation of slow slip events, tremors and earthquakes due to their unique rheological properties that promote strain localization and are common in many tectonic settings, from mid-ocean ridges, to transform faults and subduction zones.

The studied serpentinites pertain to the exhumed Monte Fico shear zone (Elba Island, Italy) that reached greenschist facies conditions where they were most likely deformed. The shear zone is made of 1-10 dm scale lenses of massive serpentines wrapped by foliated serpentinites and cut by brittle faults. Bulk deformation was accommodated by anastomosing and pervasive S/C foliations. Brittle faults are covered with slickenfibers composed of chrysotile and polygonal serpentine.

To determine the frictional and healing properties of these serpentinite-bearing faults we performed experiments on powders obtained from the lenses and from the slickenfibers with a rotary shear apparatus and a hydrothermal vessel (ROSA-HYDROS). We conducted slide-hold-slide experiments at σ'_n=20 MPa, Pf=6 MPa, Vshear= 10 μm/s and at temperatures from room T to 400°C. Powders from the lenses show an increase of friction coefficient with temperature when water is liquid (from 0.3 to 0.5), and a stronger increase (from 0.6 to 0.89) at higher temperatures (300°C and 400°C) when water is in vapour conditions. Moreover, we observe stick-slip behaviour at 400°C. Instead, powders from the slickenfibers show similar friction coefficient for temperatures up to 200°C (0.23), an increase at 300°C (0.34) with water is still in liquid conditions and a further increase (0.47 to 0.57) when water is in vapour conditions (300°C and 400°C). Contrary to the case for powders from the lenses, in the case of "slickenfibers", at 400°C (vapor conditions) no stick-slip behavior is observed.

The frictional healing properties document how the strength of these heterogeneous brittle-ductile shear zones evolves during the interseismic period. The healing behavior is different between the powders obtained from the lenses with respect to those from the slickenfibers. The "lenses" show a continuous increase toward positive healing with increasing temperature while showing a maximum at 200°C; the "slickenfibers" show negative healing for all temperature but not at 200°C, where a postive healing maximum is observed instead.

Our observations highlight a strong rheological difference between massive lenses and bounding faults (slickenfibers). The difference in friction and healing properties is important during subduction and exhumation as they cause different behaviours in the massive lenses and the bounding faults with increasing/decreasing temperature (and depth).

The study of the seismic cycle in hydrothermal conditions through experiments, analysis and modeling in the SCHOTTA project

Sciarra A.*[1], Di Toro G.[2-1], Cantucci B.[1], Gomila R.[2], Grassa F.[3], Piochi M.[4], Brusca L.[3], Bellomo S.[3] & Ricci T.[1]

[4] INGV, Osservatorio Vesuviano, Napoli.

Corresponding author email: alessandra.sciarra@ingv.it

Keywords: fluid-rock interaction, seismic cycle, hydrothermal conditions.

The nucleation and propagation of earthquakes are often connected with the circulation of fluids at hydrothermal conditions (150°C < T < 450°C and Pf < 25 MPa). Geophysical investigations of buried structures and petrological studies of exposed faults evidence how hydrothermal fluids can drive fault mechanics during the seismic cycle by altering both rock properties and pore pressure, across a complex process of sub-critical crack growth, sealing, and healing. Due to technical difficulties in experiments and the timescale of fluid-rock reactions, direct observations of hot and pressurized fluids in rock deformation upon rupture are not well-known.

In order to address this gap, the SCHOTTA project (*The Seismic Cycle under HydrOThermal conditions: experimenTAl, analytical and modeling studies*), funded by Unione Europea-Next Generation EU - PRIN 2022, aims to combine laboratory rock friction experiments with geochemical and mineralogical analyses of fluids and rocks, performed both before and after experiments. The simulation of fluid-rock interaction over time using geochemical models that are properly calibrated with analytical, petrographic, and chemical data is planned, with the constraint being on thermodynamic and kinetic datasets to extrapolate experimental observations to natural faults. The challenge of calibrating models under extreme conditions is necessary as the most commonly used geochemical software is limited to water sub-critical conditions (T < 300°C, Pf < 8.6 MPa).

Through this innovative multidisciplinary study, we will build our ability to identify the primary factors that contribute to the seismic behavior of natural faults in hydrothermal conditions and the relationship between fluid-rock interaction and rock deformation. Our final goal is to assess the outcomes of natural and induced seismicity that develops in geothermal and volcanic environments.

The structural geology of fault healing: a preliminary view

Keywords: earthquakes, friction, fault.

Fault rocks recover strength after being ruptured during an earthquake or another slip event, thus this mechanism controls the recurrence of the seismic cycle. This recovery is commonly known as "fault healing" and is caused by many physical processes that include cementation, compaction, asperity growth etc. In nature, fault healing is generally ascribed to cementation, demonstrated by the transition from incohesive to cohesive fault rocks (e.g., from gouges to cataclasites). However, the mechanics of healing is mostly studied through laboratory studies or inferred from geodetic measurements. This approach is yet unsatisfactory since healing phenomena occur in all rock types and at large scales that laboratory experiments can only partially capture.

Here, we propose a field-based perspective of fault healing that goes beyond the simplistic view of incohesive vs. cohesive fault rocks. We take advantage of outstanding exposures of some Italian faults to propose other indicators of healing, for example: re-worked cataclasites, adhesion phenomena (sidewall ripouts and fault surface patches), and geometrical complexity of the slip surfaces themselves. We also address the complexity due to the juxtaposition of rocks with different strength and composition along major faults, and the role of minor faults.

We compare these observations with frictional healing experiments carried out on both fault gouges and cohesive (=completely healed) slip surfaces. We propose that fault surface "patches" of more cohesive fault rocks bounded by anastomosing slip zones are the result of complex cycles of gouge formation and healing, which modulate the interplay of cohesion, adhesion and localization along the fault surface. These individual structural features can be the target of specific laboratory investigation, which is currently underway.

Microstructural record of seismic brittle failure at intermediate-depth conditions

Toffol G.*[1], Pennacchioni G.[1], Scambelluri M.[2] & Morales L.F.G.[3]

Corresponding author email: giovanni.toffol@unipd.it

Keywords: pseudotachylyte, earthquake, microstructure.

Exhumed pseudotachylytes (quenched coseismic frictional melts) and their wall-rocks are a tool to study earthquake mechanics at hypocentre depth. In particular, pseudotachylytes produced at eclogite-facies conditions in subducted oceanic rocks provide clues to investigate the elusive mechanics of intermediate-depth earthquakes (Toffol et al., 2022).

We study pseudotachylytes hosted in the oceanic gabbros and peridotites of Moncuni (Lanzo Massif, W Alps). These pseudotachylytes were produced at ca. 70 km of depth during subduction and have been interpreted as the result of brittle failure under high differential stress of the dry and metastable rocks of the oceanic lithosphere (Pennacchioni et al., 2020).

We have characterized the pervasive damage surrounding pseudotachylytes within olivine-bearing gabbros. Brittle deformation comprises aseismic (cataclasite bands and foliated cataclasites) and coseismic (pulverized domains with shattering in-situ) features associated with the pseudotachylyte veins. Since their formation the pristine brittle features, including pseudotachylyte glass, escaped alteration and deformation overprint during the exhumation path thanks to fluid-absent conditions.

The pseudotachylyte fault veins are thin (a mm in thickness at most) and internally heterogeneous, with alternating clast-rich and melt-rich layers. Pseudotachylytes are bound by cataclastic bands showing an S-C fabric, with strain progressively localized toward a foliated ultracataclastic core sharply in contact with the overprinting pseudotachylyte. Rare clasts of ultracataclasite and pseudotachylyte are embedded in the foliated cataclasite.

Wall-rock olivine grains are deformed by low-temperature plasticity (LTP) recorded by deformation lamellae, undulatory extinction and associated microfracturing. These deformation features are also present in olivine clasts within the cataclasites suggesting a temporal sequence of (i) crystal plastic deformation at increasing stress conditions, and (ii) shattering and pulverization during seismic rupture propagation. Pulverized olivine fragments are made of healed aggregates of small (50 nm in size) olivine clasts that locally preserve amorphous domains and nano-twins.

We interpret LTP in olivine and the progressive evolution of the S-C fabric to represent the precursory stages of stress localization predating the abrupt propagation of the seismic rupture, responsible for the instantaneous high stress pulse recorded by the shattered wall-rock minerals. The presence of pseudotachylyte clasts and of olivine clasts with evidence of LTP embedded in the cataclasites suggest cyclicity of seismic failure and aseismic creep, potentially explaining the pervasive damage of the wall rocks.

Keywords: Iranian Plateau, low-temperature thermochronology, thermo-kinematic models.

The Iranian Plateau represents a NW-SE striking, elevated morphotectonic feature within the upper plate of the Arabia-Eurasia collision zone. The southern margin of the plateau includes the High Zagros Mountains while the northern margin comprises of the Urumieh-Dokhtar Magmatic Zone and the western Alborz-Talesh Mountains. The plateau interior is characterized by low-topographic relief with several, mostly internally drained, intermontane sedimentary basins. The backbones of these basins are represented by the Sanandaj-Sirjan Zone. Plateau uplift began after ~17 Ma as evidenced by the presence of Lower Miocene shallow-water marine sediments of the Qom Formation within the plateau interior.

Here we present low-temperature thermochronologic data (apatite fission-track and (U-Th-Sm)/He data, denoted as AFT and AHe, respectively), from the northern plateau and its interior to extract information regarding fault slip rates and timing of fault activity along three structural transects across the northern plateau sectors. To achieve this, we employ a numerical thermo-kinematic modeling approach utilizing the Pecube software (Braun, 2003) with its new graphical user interface PecubeGUI(Bernard et al., 2023).

The modeling process involves incorporating field observations, such as back- and fore-limb dip angles, to define the characteristics of the faults, including their typical flat-ramp geometries. A forward model is performed to check if the observed data can be reproduced within a reasonable fit. Then and inverse model is performed in which a prior model space is sampled to find the parameters that yield smallest misfit between observed and predicted data.

Combining our findings with regional structural, stratigraphic, and existing thermochronology data, we discern that after a period of mild post-late Eocene contractional deformation, significant collisional deformation commenced in the early Miocene (~20 Ma) along the plate suture to the southern edge of the plateau and in the middle Miocene (~16-15 Ma) in the Talesh Mountains along the northern plateau boundary. Around 12-10 Ma, deformation intensified in the plateau interior without a discernible pattern of fault propagation. This thrusting activity contributed to the topographic growth of several mountain ranges, with wavelengths spanning approximately 50-60 km, alongside the compartmentalization of the plateau and the development of intermontane basins. Within these basins, filling processes inhibited intrabasinal deformation and faulting along the major range-bounding faults, resulting in the characteristic smoothed, low-relief landscape typical of an orogenic plateau.

The importance of regional-scale shear zones in paleogeographic reconstructions: the case study of the Variscan belt in the Mediterranean area

Keywords: East-Variscan Shear Zone, Variscan Belt, paleogeographic reconstructions.

Paleogeographic reconstruction and recognition of the tectono-metamorphic evolution of ancient orogenic belt is often complex. The combination of an adequate amountof paleomagnetic, metamorphic, structural and geochronological data is necessary. Fundamental data derive from the study of regional-scale shear zones by combining detailed field work with structural analysis, microstructural analysis and petrochronology. The Southern European Variscan Belt in the Mediterranean area was partially overprinted by the Alpine cycle and correlations are mainly based on lithological similarities. Little attention has been paid to the compatibility of structures in the dispersed fragments. A main debate is the connection among the Corsica-Sardinia Block (CSB), the Maures-TanneronMassif (MTM) and the future Alpine External Crystalline Massifs (ECM) and if these sectors were all affected by a network of shear zones of regional extent, known as the East Variscan Shear Zone (EVSZ). We present a multidisciplinary study of shear zones cropping out in the CSB (the Posada-Asinara shear zone; Carosi et al., 2020), in the MTM (the Cavalaire Fault; Simonettiet al., 2020a) and in the ECM (the Ferriere-Mollières and the Emosson-Berard shear zones; Simonetti et al., 2018, 2020b). Kinematic and finite strain analysis allowed to recognize a transpressional deformation, with a major component of pure shear and a variable component of simple shear, coupled with general flattening deformation. Syn-kinematic paragenesis, microstructures and quartz c-axis fabrics revealed that shear deformation, in all the studied sectors, occurred under decreasing temperature starting from amphibolite-facies up to greenschist-facies. A systematic petrochronological study (U-Th-Pb on monazite collected in the sheared rocks) was conducted in order to constrain the timing of deformation. We obtained ages ranging between ~340 Ma and ~320 Ma. Ages of ~340-330 Ma can be interpreted as the beginning of the activity of the EVSZ along its older branches while ages of ~320 Ma, obtained in all the shear zones, demonstrate that they were all active in the same time span. The multidisciplinary approach revealed a similar kinematics and tectono-metamorphic evolution of the studied shear zones and contribute to better constrain the extensionand timing the EVSZ strengthening the paleogeographic reconstructions of the Southern Variscan belt during Late Carboniferous time. This have important implications on the evolution of the Mediterranean area after the Late Paleozoic. Furthermore this case study demonstrates how paleogeographic reconstructions could benefit from datasets obtained from large-scale structures that can be directly investigated.

Corresponding author email: michele.zucali@unimi.it

Keywords: migmatite, lower crust, partial melting.

The lower continental crust represents a lithospheric portion where partial melting, occurring under different deformation regimes, contribute to the internal differentiation of the whole continental crust. Despite significant research on lower crustal sections (e.g., Ivrea-Verbano Zone in the Southern Western Alps; IVZ), a comprehensive model of migmatization that combines relations between lithological associations, pressure (*P*) – temperature (*T*) conditions and timing with the structural evolution is often missing. In this work we analyse the Valpelline Series (VP; Dent-Blanche Nappe, Western Alps) as a benchmark to unveil processes and structures occurring in the Permian lower continental crust. Our approach integrates detailed lithological characterization and multiscale structural analysis with quantitative results (i.e., combining 3D outcrop-model analysis and quantitative microstructural analysis through Electron Backscattered Diffraction and X-ray Micro-CT), thermodynamic modelling, geochemistry and geochronology (U-Pb, Ar/Ar). The VP consists of Permian migmatitic metapelite with different mineral assemblages (i.e., garnet-, cordierite- and orthopyroxene-bearing), migmatitic amphibolite, and marble, intruded by aplite and pegmatite (Caso et al., 2024a). Three deformation stages have been recognized: the D1 is preserved as an S1 foliation in metabasite lenses and locally within metapelites; the regional foliation S2 developed during the D2 phase is related to melt production and is locally transposed during the D3 into an S3 foliation, which is sillimanite-rich and wraps around garnet, cordierite and orthopyroxene (Caso et al., 2024a, 2024b). Contrasting *P–T* conditions related to the D2 stage are detected: (i) 850-900°C and 0.80-0.95 GPa in orthopyroxene-bearing migmatites and migmatitic amphibolites; (ii) 700-770 °C and 0.4-0.6 GPa in cordierite-bearing migmatites. This *P–T* discrepancy is associated with different U-Pb ages consistently older in orthopyroxene-bearing leucosomes (293 ± 2 Ma) than in cordierite-bearing ones (285 ± 2 Ma) and late pegmatites (277 ± 2 Ma). As a final consideration, despite showing many affinities with the well known IVZ, our results highlight few differences between VP and IVZ: (i) the absence of a mafic complex in the VP and related contact metamorphism; (ii) the lack in the VP of evidence of transition from the white mica up to the orthopyroxene-bearing metapelites; iii) migmatites are associated only with biotite and sillimanite, plus the occurrence of cordierite or orthopyroxene, showing difference in ages of migmatization and in the *P-T* conditions.

Evidence of strain partitioning and localization in carpholite-bearing hybrid veins: a case study from the Piedmont Zone, Western Italian Alps

Casoli L.* & Giuntoli F.

Dipartimento di Scienze Biologiche, Geologiche ed Ambientali, Università di Bologna.

Corresponding author email: luciano.casoli2@unibo.it

Keywords: shear zones, brittle-ductile deformation, crack-and-seal veins.

Strain partitioning and localization of deformation have a direct impact on subduction zone dynamics. Localization of ductile deformation may occur along brittle precursors, such as veins. In the Western Alps, the Piedmont Zone high pressure (HP) metasediments display preserved lawsonite and carpholite-bearing veins formed at 30–60 km of depth (Herviou et al., 2023). Similar veins have been recently considered to be a possible fossil record of deep episodic tremor and slow slip events (ETS; Giuntoli & Viola, 2022).

We studied the Lago Nero Unit of the Piedmont Zone deformed at blueschist facies conditions (BS, ~350°C and ~1.7 GPa; Agard, 2021 and references therein). We performed detailed fieldwork, microstructural and petrological analysis on carpholite-bearing HP veins hosted in mylonitic marbles. The host rock marble is massive and shows a mylonitic foliation associated with a S-C-C' fabric marked by elongated and recrystallized carbonate grains and fine-grained aggregates of quartz. We distinguished two sets of quartz + carbonate + carpholite HP veins: i) hybrid veins oriented parallel to the main foliation and ii) dilatant veins slightly inclined in respect to the foliation. In both cases, fibres are oriented parallel to the measured lineation in the host rock. Both veins display crack-and-seal textures. Later iii) quartz + carbonate dilatant veins cut all the previous structural elements and are oriented at high angle with respect to the foliation. The two first sets of veins can be considered contemporaneous, as the second set joins into the first one. Furthermore, the mylonitic foliation is broadly coeval with these two carpholite-bearing HP veins. Considering the presence of carpholite, veins developed at a minimum pressure of 0.8 GPa.

Hybrid veins parallel to the host rock foliation are intensely deformed in carbonate ultramylonitic bands wrapping around relics carbonate ribbons. Quartz and carpholite rich portions of the veins are fractured and boudinated. Therefore, crack seal veins display partitioning into brittle/ductile domains and act as zones where deformation is preferentially localized. Strain could initially localize at the interface between vein and host-rock and quartz-carpholite rich and carbonate rich bands.

Conclusion, the Piedmont Zone HP metasediments display broadly coeval cyclic brittle and ductile deformation, likely related to fluctuation of pore-fluid pressure that reached sub-lithostatic values at low differential stress conditions. These structures can provide insights in the complex deformation mechanisms occurring during deep ETS (Fagereng et al., 2011).

Thermal history solutions obtained from integrated fission-track and (U-Th-Sm)/He analyses of plutonic and metamorphic rock units ranging in age from the Precambrian to the Oligocene indicate consistently that the NW Iranian Plateau has largely escaped significant Neogene dip-slip deformation. Integration of structural, stratigraphic and thermochronologic data shows that cooling/exhumation related to the mid-Miocene hard collision of Arabia along the southwestern Eurasian continental margin focused along the Bitlis-Zagros collisional front and the south Caspian (Alborz) backstop (Ballato et al., 2013; Cavazza et al., 2018) whereas the bulk of NW Iran was affected by pervasive strike-slip deformation with limited local exhumation along transpressional domains and properly oriented inherited structures. The thermochronometric evolution of the NW Iranian Plateau mimics the one of eastern Anatolia, where collisional deformation focused along the Bitlis segment of the collisional front and in the eastern Pontides, located at the rheological transition between the continental lithosphere of eastern Turkey and the quasi-oceanic lithosphere of the eastern Black Sea. Both the Anatolian and Iranian orogenic plateaus were thus by-passed by far-field collisional stresses which focused instead on (i) major rheological contrasts such as the south Caspian and Black Sea backstops or (ii) inherited and easily inverted hinterland structures such as the Adjara-Trialeti, Greater Caucasus, and Talysh backarc basins (e.g. Gusmeo et al., 2021; Cavazza et al., 2024).

Evolution of active margins? A link with the tectonic reactivation in foreland area

Cicala M.*, De Giosa F., Lisco S., Moretti M. & Festa V.

Keywords: Monte Giove, Apulian Foreland, fault reactivation.

The so-called Monte Giove submerged relief/structural high (Adriatic Sea, offshore the Apulia), represents an interesting example of tectonic reactivation in the Apulian Foreland related to the Apennines evolution (Festa et al., 2019; Cicala et al., 2023).

To detect the faults that control the slopes of Monte Giove, the Adriatic Sea offshore from Polignano a Mare–Monopoli towns was examined up to ~30 km from the coastal line, where several reflection seismic profiles, from ViDEPI Project (www.videpi.com/videpi/videpi.asp), were interpreted. Moreover, the cliff between the above towns was surveyed geologically in detail, to seek structural evidence for a possible onshore continuation, in the Murge area, of the submarine relief.

The geometry of the northern and southern margins of the Monte Giove are controlled by faults. The northern structure is an NNE- to N-dipping fault, striking from north of Polignano a Mare to the east, in the Adriatic Sea. This fault is sub-vertical and characterized by post-Lower Pleistocene dextral oblique-slip kinematics. Syn-sedimentary tectonics during the Oligo-Miocene, Pliocene and Quaternary are shown by the increase in thickness of the related seismostratigraphic units in the hanging wall of the fault. It shows clues to Cretaceous activity, represented by ductile deformation structures under diagenetic conditions within the outcropping limestones of the "Calcare di Bari" Fm. involved in faulting.

As regards the southern margin of the submerged relief, two main high-angle faults, active during the Quaternary, have been recognized forming a graben-like structure, that corresponds to the Upper Cretaceous Rosaria Mare intra-platform basin: the northern one is a E-W to NW-SE striking and S-dipping fault; the southern one is a NW-SE striking and NNE-dipping fault. Both faults mostly show dip-slip movement (even though a right transtensional kinematic cannot be excluded), and gave rise to a Quaternary negative flower structure: the S-dipping fault (showing vertical offset of the base of the Quaternary unit up to 200 m) and the NNE-dipping one (showing slightly lower offset) represent the main and the subsidiary fault, respectively.

The faults bordering Monte Giove represent the offshore lateral continuation to the east, in the Adriatic Sea, of the Northern Deformation Zone within the Murge area, active since the late Cretaceous. The faults of the Northern Deformation Zone and those bordering Monte Giove may have been reactivated during post-Lower Pleistocene time with normal dip-slip and dextral oblique-slip kinematics along NE-dipping and N-dipping/E-W striking sub-vertical planes, respectively. The reactivation of these faults may be related to the continental lithospheric gentle buckling of the Apulian Foreland occuring due to halting of the roll-back of the subducting lithosphere, which was accompanied by arching/uplift since the Middle Pleistocene.

Reconciling the onset of Tethyan rifting in the Ivrea Verbano Zone (European Southern Alps)

Corvò S.[1-2], Montemagni C.[3-4], Zanchetta S.*[4] & Langone A.[1-2]

[1] Dipartimento di Scienze della Terra e dell'Ambiente, Università di Pavia. [2] Istituto di Geoscienze e Georisorse, C.N.R., Pavia. [3] Dipartimento di Scienze della Terra, Università di Firenze.

Keywords: Ivrea-Verbano Zone, monazite, Alpine Tethys rifting.

Extensional faults, both in the ductile and brittle realm, play a significant role throughout the evolution of a crustal rift. Constraining the age of faulting, and how and when deformation shifts from the lower to the upper crustal domains, is crucial for the reconstruction of the rifting related processes. The rifting of the Alpine Tethys began in the Early Jurassic due to the propagation of the Central Atlantic rifting, marking the onset of Pangea break-up.

We report on the Premosello Shear Zone (PSZ) in the Ivrea-Verbano Zone (European Southern Alps), a top-to-the-W extensional shear zone consisting in alternated layers of extremely sheared felsic and mafic granulites transformed into mylonites and ultramylonites in which mm-to-dm size garnet and stretched mm-size pyroxene porphyroclasts are the peculiar textural features. Clear cross cutting relationships suggest a progressive development of mylonites, ultramylonites and, finally, pseudotachylyte veins which cross cut the previous fabric.

The studied samples were selected as representative of different textural features for U-Th-Pb monazite dating and pseudotachylites for $^{40}Ar/^{39}Ar$ dating.

Laser ablation-inductively coupled plasma-mass spectrometry U-Th-Pb monazite dating yields concordant ages with a spread from 215 to 188 Ma where $^{40}Ar/^{39}Ar$ on pseudotachylyte yields age of 199 Ma. The new U-Th-Pb and 40Ar/39Ar radiometric ages here presented provide the first quantitative temporal constraints on the onset of the Jurassic extensional regime along the PSZ in the Ivrea Verbano Zone, suggesting that the PSZ was active across the Middle-Late Trias to Early Jurassic.

Our data reveal the propagation of extensional structures from the lower toward upper crust, with crustal extension that finally led to the opening of the Alpine Tethys, as also testified by geochronological data on faults that bordered the Jurassic basins developed in the present-day Southalpine Domain. The bottom-to-top propagation of the deformation is testified by the deformation age of monazite in the lower crust and subsequently by the age of pseudotachylyte in the relatively shallower crust. The pseudotachylyte, with an age of 199 Ma, represents the connection between the shearing along shear zones in the lower crust and along faults in the upper crust, covering a time span from 215-188 (i.e., high temperature shearing in the lower crust from this study) to 192-169 Ma (i.e., low temperature faulting in the upper crust).

This chrono-structural model has significant implications on the role of major extensional faults in focusing deformation involving progressively the lower and the upper crust during the Tethyan rift evolution.

Petrological constraints and geodynamic significance of a Triassic lamprophyre dyke crosscutting the Palaeozoic basement of NE Sardinia, Italy

Keywords: lamprophyre, geochemistry, Sardinia.

A Triassic lamprophyre dyke crosscutting the Palaeozoic basement of northeastern Sardinia, in the south-eastern sector of the Posada-Asinara Shear Zone, is investigated with the aim to decipher the magma source, genesis and P-T conditions of crystallization and emplacement. The lamprophyre dyke shows a porphyritic texture with centimeter-sized amphibole, biotite, ulvöspinel and apatite phenocrystals. The lamprophyre also contains feldspar cluster and xenolithic nodules. The groundmass mainly consists of brownish amphibole, ± biotite, ulvöspinel microcrystals, apatite needles, and feldspar clusters. Biotite phenocrysts (XMg: 0.54-0.60) are not zoned and have high TiO2 contents (~7 wt.%). The centimetric amphiboles are characterized by a wide Fe-rich/Mg-poor core, surrounded by a rim with increasing Mg and decreasing Fe. The rim is followed by an outer rim in which decreasing Mg and Ti and increasing Fe is observed. Small amphiboles in the groundmass match the compositional trend observed for the rim and outer rim of the above mentioned crystals. The core of the amphibole reflects the deepest crystallization conditions, whereas the surrounding rims and amphiboles from the groundmass point to slightly higher temperature and lower pressure. The whole-rock samples, which are Si-undersaturated, resemble the composition of alkaline lamprophyres. The incompatible trace element patterns show weak positive anomalies for Ba, Nb, K and P and negative ones for Th and Ta, whereas the chondrite-normalized REE pattern reflects a constant fractionation from light REEs to heavy REEs with no Eu anomaly. The radiogenic isotope composition clusters between the E-DMM and BSE mantle components at 220 Ma. The REE fractionation pattern (Lan/Ybn) suggests a derivation from a garnet-lherzolite mantle where the residual garnet tends to fractionate HREE whereas the more incompatible LREE are concentrated in the melt. Comparison with other European lamprophyres and palaeogeographic reconstruction suggest that the Sardinia lamprophyre, located along the eastern branch of the fault system that led to the opening of the Alpine Tethys, belongs to the wide Triassic, “rifting-related” magmatism which records the Pangea break-up.

Geology and petrology of the Northern Dora-Maira Massif in the Tredici Laghi - Conca Cialancia area (Germanasca - Pellice Valleys, Western Alps)

Keywords: Western Alps, geological mapping, Dora-Maira Massif.

While numerous studies have been done in the southern Dora-Maira Massif, and recent syntheses have provided an updated view of its metamorphic (Bonnet et al., 2022) and structural (Michard et al., 2022) history, the northern Dora-Maira Massif has been little studied. Recent investigations in the northern-western part of the massif (Manzotti et al., 2022; Nosenzo et al., 2024) have shed new light on the structural architecture and metamorphism of the various tectonic units, with the discovery of a new UHP tectonic unit (Manzotti et al., 2022). Despite these efforts, many open questions regarding its structural architecture and tectono-metamorphic evolution remain. In this contribution, we present preliminary data from an area comprised between the Tredici Laghi and Conca Cialancia natural park (Germanasca - Pellice Valleys), a mountainous region with an elevation comprised between 2000-2800m asl. This previously poorly explored area consists of a polycyclic basement (made up of micaschist, orthogneiss, paragneiss, marble and metabasite) associated with metaintrusive rocks and a monocyclic cover. With the aid of a new structural map and geological cross-sections, realized in the framework of the CARG mapping project (Sheet 172 –"Pinerolo"), the structural setting of the area has been reconstructed. Microtectonics studies and preliminary P-T-t data, derived from ongoing petrological and geochronological studies, will be integrated to tentatively provide a state-of-the-art picture of the tectono-metamorphic evolution of the studied area. Structures referable to at least four deformation phases have been recognized. The S1 foliation, rarely preserved in microlithons, developed at peak P-T conditions and is associated to the syn-kinematic recrystallization of phengite, paragonite, chloritoid, garnet and rutile. A subsequent S2 foliation (the main foliation in the field, defined by phengite, paragonite, chloritoid, garnet, albite, epidote, and ilmenite) developed associated to E-W trending folds. Subsequently, a D3 event, associated to the development of a local S3 foliation, parallel to the axial planes of generally open folds, deformed all the previous structures. S3 foliation is associated with metamorphic re-equilibration and growth of greenschist facies assemblages. Several examples of superimposed D2 and D3 folds are documented at various scales. Final doming of the Dora-Maira nappe stack (D4), is associated to the displacement of the Adria mantle indentor.

Keywords: Western Alps, Dora-Maira,structural evolution.

The Dora-Maira Massif plays a key role in understanding the geodynamics that shaped the Alpine belt. Extensive studies have been already conducted mostly in the southern portion (e.g., Chopin et al., 1991; Bonnet et al., 2022). Recent investigations by Manzotti et al. (2022) and Nosenzo et al. (2024) have renewed the interest in the northern portion of the Dora-Maira Massif. These authors provided new structural and metamorphic data on the area, particularly with the discovery of a new important ultra-high-pressure unit (the Chasteiran Unit). Despite these important contributions, many open questions persist at the scale of the whole massif. In this contribution, we present new data obtained within the framework of CARG mapping project (Foglio 172-Pinerolo). Our aim is to improve the geological knowledge about the structural and metamorphic architecture in the Val Pellice and Val Chisone area. We present a geological map with related geological cross-sections, at the scale 1:10.000, covering the region between Colle Lazzarà and Colle Vaccera. In addition, we performed microtectonic and petrographic studies to reconstruct the area's structural and metamorphic evolution. Within this relatively unexplored terrain, three distinct tectono-metamorphic units crop out, that from bottom to top are: the Pinerolo-Sanfront Unit, the Chasteiran Unit, and the poly-cyclic basement unit of the Dora-Maira Massif. Particular attention has been paid to mapping the tectonic contact between the Chasteiran unit, sandwiched between the other two tectono-metamorphic units. The contact has been mapped, further south, up to Colle Vaccera. At least four deformation phases have been recognized: the D1 phase associated with the development of an S1 foliation at the peak metamorphic condition, preserved only within the microlithons of the S2 foliation. A second deformation phase, associated with the development of the main foliation (S2), axial plane of metric to pluridecametric tight to isoclinal folds with an E-W trends developed during the nappe stack. The main foliation is deformed by structures subsequently attributable to a later D3 deformation phase, which develop an axial plane foliation associated with the thermal re-equilibration. Finally, a D4 deformational phase is recognized in association with the doming of the Dora-Maira Massif.

Keywords: brittle-structural-facies, radiometric dating, permeability.

Fault zones are dynamic structural features commonly embedding a complex patchwork of diverse, non-coeval brittle structural facies (BSFs; *sensu* Tartaglia et al., 2020). The present-day tight juxtaposition of BSFs may represent the end-result of protracted, cumulative and complex histories, characterized by multiple episodes of deformation localization and fluid inflow, possibly also causing a range of different slip behaviors. Thus, (micro)structural, mineralogical, thermal, petrophysical and mechanical data need to be integrated over the lifespan of the studied fault system to unravel intricate tectonic histories and understand fluid flow patterns and seismotectonic styles in the brittle crust.

In this perspective, by means of a multitechnique and multiscalar approach that builds upon the examination and characterization of BSFs, we studied the Carboneras Fault (CF), a c. 140 km-long, active, crustal-scale fault zone in the Betic Cordillera, which is inferred to have accommodated c. 40 km of cumulative offset since the Miocene along its main NE-SW strike. We integrated high-resolution field structural analysis, in-situ air-permeability measurements of BSFs and microstructural characterization and K-Ar geochronology of fault gouge samples with previously presented data (including 8 K-Ar ages, mineral assemblage and maximum temperature of synkinematic clay minerals of fault gouges) to unravel the long-term spatiotemporal and thermal evolution of the CF.

The CF has accommodated progressive deformation over a > 20 Myr time span (from 24.72 ± 0.53 Ma to 0.48 ± 0.77 Ma) through repeated episodes of deformation localization and fluid inflow, interaction with inherited structural discontinuities, selective fault (de)activation and formation of a stark fault rock and permeability heterogeneity (up to 3 orders of magnitude) at progressively colder (from ≥ 275 down to 70°C) and presumably shallower structural levels.

These findings are currently being used to aid well-informed numerical modelling to gain new insights into the mechanisms of growth and exhumation of major fault zones as well as into the understanding of their 3D hydro-mechanical behavior.

Tartaglia G. et al. (2020) - "Brittle structural facies" analysis: A diagnostic method to unravel and date multiple slip events of long-lived faults. Earth Planet. Sci. Lett., 545, 116420, https://doi.org/10.1016/j.epsl.2020.116420.

The heritage of Tethyan oceanic transform faults within Alpine orogens: The Shkoder-Peja transverse zone (SPTZ) of Northern Albania

Feriozzi F.*[1], Siravo G.[2] & Speranza F.[2]

[1] Dipartimento di Scienze, Università di Roma Tre. [2] Istituto Nazionale di Geofisica e Vulcanologia.

Corresponding author email: fabio.feriozzi@uniroma3.it

Keywords: tectonic inheritance, Shkoder-Peja transverse zone, Dinarides-Hellenides boundary.

The Shkoder-Peja transverse zone (SPTZ) of Northern Albania marks the boundary between the Dinarides and the Albano-Hellenides chains and corresponds to a ~100 km SW-ward shift of the ophiolitic nappe front. Over the last sixty years, it has been variably interpreted as an inherited paleogeographic feature, a dextral strike-slip fault, the hinge of the clockwise (CW) rotating Albano-Hellenides system, and a Miocene-to-recent normal fault. Here we report on the paleomagnetism of 27 Triassic-Cretaceous sites from the Krasta-Cukali and the High Karst domain, both within and north of the SPTZ. Two sites yielded only a pre-tilting magnetization, 15 sites were found to be remagnetized after mid-Eocene-lower Miocene tilt, while 8 sites showed both pre- and post-tilt magnetizations. Both pre- and post-tilt paleomagnetic directions yielded a 60-70° clockwise (CW) rotation with respect to Adria/Africa, except 9 sites from the Koman zone at the ophiolitic nappe boundary showing a smaller 38°±15° CW rotation. Thus, the well-known regional CW rotation of the Albano-Hellenides extends northward in the southern Dinarides, and the SPTZ is not a rotation boundary as previously assumed. The ~70° CW rotation is consistent with available data from the nearby ophiolitic nappe complex, and is assumed to represent the sum of a 30° lower Miocene rotation during thrusting of the Kasta-Cukali over Kruja nappe plus the 40° Miocene-Pleistocene rotation well documented in the external zones of Albania. We suggest that the SPTZ is the heritage of a mid-Triassic transform fault of the Maliac Tethyan ocean, later overprinted by the lower Cretaceous obduction of the Vardar ocean, replacing Maliac since the middle-Jurassic.

Textural footprint of orogenic processes: convergence, collision and reequilibration

Gómez-Barreiro J.*

Departamento de Geología, Universidad de Salamanca, Spain.

Corresponding author email: jugb@usal.es

Keywords: texture, orogen.

From the closure of an ocean to the gravitational collapse, the orogenic architecture is the result of a complex interaction of mass and energy, which have been recorded at both the macro and microscopic scale. While texture and microstructure represent the local expression of large-scale processes, their investigation in context provides critical evidence to understand the geodynamic evolution of an orogen and to shed light on new questions. Examples from different orogenic contexts are discussed.

Long-lived activity of a regional thrust-system in a pre-collisional setting: the Orobic Thrust (Southern Alps, N Italy)

Montemagni C.*[1-2], Rocca M.[2], Zanchi A.[2], Favaro S.[2], Viola G.[3], Aldega L.[4] & Zanchetta S.[2]

[1] Dipartimento di Scienze della Terra, Università di Firenze. [2] Dipartimento di Scienze dell'Ambiente e della Terra, Università di Milano-Bicocca. [3] Dipartimento di Scienze Biologiche, Geologiche ed Ambientali, Università di Bologna. [4] Dipartimento di Scienze della Terra, Sapienza Università di Roma.

Corresponding author email: chiara.montemagni@unifi.it

Keywords: Orobic Thrust, pseudotachylyte, cataclasites.

The Orobic Thrust is a regional-scale fault zone, more than 80 km in length, representing the largest structure of the European Alps retro-belt. Along the thrust plane the Variscan basement is thrusted southward over the Upper Carboniferous to Lower Triassic volcano-sedimentary cover of the Southalpine Domain. The 250-300 meters thick fault zone is continuously exposed in several areas, allowing the detailed reconstruction of the fault architecture. A narrow (20-25 m) protomylonitic band marks the top of fault zone suggesting temperature of at least 300°C in the early stage of fault activity. Temperature in excess of 200°C are also supported by analysis of the thermal maturity of clay minerals (<2 μm size fraction) in terrigenous rocks in the footwall of the thrust plane. Different fault rock types decorate the thrust fault zone: cataclasites, foliated cataclasites, pseudotachylyte bearing cataclastic bands and incoherent fault gouges. Apart from fault gouges occurring along discrete plane that appear to be undeformed, all the other fault rocks display mutual crosscutting relationships, testifying for multiple switching between seismic slip and aseismic creep during the fault history. ^{40}Ar-^{39}Ar ages obtained from pseudotachylytes span from 83 to 64 Ma, whereas illite (<0.1 μm size fraction), separated from the gouge along a non-deformed fault plane with a reverse kinematic at the core of the Orobic Thrust fault zone, provided a K-Ar age of 53 Ma. Pseudotachylyte age distribution shows older ages of ca. 80 Ma occurring both at the top and the bottom of the fault zone, with a superposed pattern that display instead a bottom forward younging direction of ages between 76 and 64 Ma.

The geochronological dataset highlights how regional-scale fault systems may benefit of long-lived activity. Due to their relative rheological weakness with respect to host rocks, they can experience multiple re-activations, recording also the change of ambient conditions and regional stress.

The Orobic Thrust was active from the Late Cretaceous to the Early Eocene, as testified by the age of fault gouges associated to reverse faults that mark the last stage of activity. The age pattern testifies for a long-lived (about 30 Myrs) thrust system in the present-day Southalpine Domain, developed in the upper plate of the ongoing Alpine Tethys subduction as a pre-collisional fold-and-thrust belt.

Shearing at the top of the Adula nappe: syn-collisional exhumation of the San Bernardino eclogites

Montemagni C.[1-2], Monti R.[1], Malaspina N.[1] & Zanchetta S.*[1]

[1] Dipartimento di Scienze dell'Ambiente e della Terra, Università di Milano Bicocca.

Corresponding author email: stefano.zanchetta@unimib.it

Keywords: eclogite,exhumation, shear zone.

In the Central Alps, the Adula nappe exposes (U)HP mafic and ultramafic rocks, providing insights into the subduction history of the distal European margin during the final stages of Europe-Adria collision. The Adula nappe is sandwiched between non-eclogitic Sub-Penninic nappes derived from the distal European margin, below, and non-eclogitic Middle Penninic nappes (Tambò and Suretta) consisting of pre-Permian basement and Mesozoic covers of the Briançonnais terrane that stands above. The upper tectonic contact of the Adula nappe consists of a complex shear zone, the Misox zone, along which lenses of non-metamorphic sheared Mesozoic sediments and volcanics also occur.

It is commonly accepted that these three units were thrusted over each other during extensive mylonitic shearing directed towards the north.

The actual structural frame and the metamorphic gap existing between the (U)HP Adula unit and the eclogite-free Tambò-Suretta nappe complex requires instead a normal sense shear zone that at certain time, during the tectonic evolution of the Central Alps, was able to accommodate the exhumation of the Adula nappe. We documented the occurrence of this shear zone between the top of the Adula nappe and the bottom of the Misox zone in the San Bernardino pass area (Switzerland). The shear zone is mainly developed within Adula nappe orthogneisses with eclosed lenses of paragneisses and megnesite-bearing eclogites at the top of the shear zone. Eclogites invariably show a mylonitic texture with the mylonitic foliation that always display rotation at variable angles with respect to the shear zone-related foliation.

The P-T equilibrium conditions of eclogite have been constrained at c. 2.0-2.1 GPa and 520-645°C, that are considered coeval with the mylonitic texture on the base of microstructures. $^{40}Ar/^{39}Ar$ age of phengite in eclogites resulted in 37-39 Ma.

The $^{40}Ar/^{39}Ar$ age distribution across the mylonitic orthogneiss of the shear zone supports a younging direction from the bottom to the top (eclogite-bearing zone) of the shear zone itself, from c. 37 to 29 Ma, that is considered to be coherent with a top-to-E normal shearing that begun just after the HP metamorphism.

Keywords: low angle normal fault, paleopiezometry, Himalaya.

The South Tibetan Detachment System (STDS) is one of the most spectacular example of low-angle normal fault on earth getting in contact the lower high-grade metamorphic rocks of the Greater Himalayan Sequence with the upper very-low grade to non metamorphic rocks of the Tethyan Himalayan Sequence. It covers a primary role in the exhumation of the metamorphic core of the belt and for a long time it has been considered coeval with the lower Main Central Thrust, characterized by an opposite kinematic.

Its architecture is quite complex and it has been previously described as made by a lower ductile shear zone and by an upper brittle fault in the Everest area where it is spectacularly exposed.

Detailed investigation along several sectors of the belt highlight that the upper brittle fault did not developed.

Detailed meso and microstructural analyses, on oriented thin sections, provide new data for the development and tectonic evolution of the South Tibetan Detachment System in these areas.

Microstructural analyses combined with crystallographic preferred orientation, paleopiezometric and vorticity analyses highlighted a complex multistage tectonic evolution (Nania et al., 2024).

Two different stages of non-coaxial deformation have been recognized during which the STDS experienced deformation from lower to upper structural levels with a decreasing temperature.

The first stage, at deeper structural levels, occurred at low differential stress values (<15MPa) while the second one is characterized by higher differential stress (>100 MPa).

Cooling, accompanied by increasing of differential stress, has been interpreted as a progressive exhumation of the STDS during which strain hardening occurred so that ductile shearing persisted at shallower structural levels without localizing the upper brittle fault.

In addition geochronological investigation (Carosi et al., 2013; Iaccarino et al., 2017; Montemagni et al., 2018) pointed out that along several study sections it is not coeval with the lower Main Central Thrust opening new scenarios on the exhumation processes of the belt.

Heterogeneous rock response to deformation in subduction-related continental shear zones: a possible record of episodic tremors and slow slip events from the Saih Hatat window, Oman

Petroccia A.*[1], Giuntoli F.[1], Viola G.[1] & Callegari I.[2]

Keywords: hybrid veins, mylonites, crack-seal microstructures.

Episodic tremor and slow slip events (ETS) are persistent, low-frequency seismic signals associated with slip larger than the average plate motion. They have been documented worldwide in several active and fossil subduction settings (Behr & Bürgmann, 2021). Heterogeneous deformation style and hybrid veins in shear zones are at times interpreted as relicts of ETS preserved in exhumed oceanic terranes. Noteworthy, only a few reports are, instead, available from continental settings (e.g., Giuntoli & Viola, 2021). Here, we document structures possibly related to fossil ETS in the continental framework of the Oman obduction orogen.

We study the Hulw Shear Zone (HSZ), also referred to in the literature as the "upper plate–lower plate discontinuity", which separates two units recording comparable blueschist facies conditions in the Saih Hatat Window (NE Oman; Agard et al., 2010). The HSZ is made up of 60-100 m thick high-strain zones with an overall block-in-matrix fabric and a top-to-the N/NE sense of shear. Field observations reveal that the lower unit of the HSZ is mainly composed of weak metapelite enclosing brownish dolostone lenses. This metapelite is affected by a pervasive mylonitic foliation marked by white mica and pyrophyllite. Brownish dolostone is massive and intensely fractured with no clear preferential orientation. Similarly, the upper unit of the HSZ is composed of foliated/massive mylonitic marble that embeds boudinated and brecciated layers and lenses of grey dolostone. Mode I veins occur in the more viscous rock types (e.g., massive marble) oriented at a high angle to the mylonitic foliation. In contrast, dilational shear veins are more common in weaker rocks (e.g., metapelite) and are subparallel to the mylonitic foliation. Those veins commonly contain crack-and-seal textures within calcite, quartz, and minor white mica infills. K-white mica barometry and forward thermodynamic modelling indicate that the HSZ localised and sheared in the pyrophyllite stability field during retrogression. Nevertheless, in agreement with previous thermo-barometric estimates (e.g., Yamato et al., 2007), we found higher pressure relicts pointing close to blueschist facies conditions.

In conclusion, the HSZ displays evidence of a heterogeneous deformation style with block-in-matrix fabrics and evidence supporting cyclically repeating localised brittle failure and more diffuse ductile deformation developed at minimum high-pressure greenschist facies conditions. These structures may be a fossil geological record of ETS in the Oman continental subduction framework.

Keywords: tectonic mixing, subduction mélange, eclogite facies.

At the boundary between the Piemonte Zone (PZ) metaophiolites and the Austroalpine continental crust a tectonic mélange of thin slivers of calcschists, quartzites, metabasites, serpentinites and fine-grained gneisses (metapelites and metagranitoids) occurs all along the western margin of the central and southern Sesia-Lanzo Zone (SLZ), from Santanel klippe to Lanzo Massif (Spalla et al., 1983; Battiston et al., 1984). All the rocks belonging to SLZ and PZ together underwent four episodes of deformation, giving rise to a complex regional tectonostratigraphy. The metamorphic mineral assemblages marking successive foliations, detected from the central to the southern part of the SLZ western margin, indicate that various metamorphic conditions dominate in different portions of this tectonic mixing. In the southern sector of this "mixing zone" parageneses indicate that rocks experienced an early eclogite facies imprint, followed by re-equilibration under blueschist facies conditions, and that they were finally widely retrogressed under greenschist facies, during the last two deformational stages. The origin of this rock assemblage architecture could be the result of transposition in the mantle wedge, otherwise it may represent the reworked primary series of an extensionally-thinned continental margin. The tectonic picture along the boundary between the PZ and the southern SLZ indicates that during the Alpine convergence slices of oceanic lithosphere, recording different thermal and structural imprints during burial and exhumation paths, are mixed with rocks of Adria continental margin (Assanelli et al., 2020). Similar kinds of tectonic mélange of continental and oceanic crustal slices, with variably serpentinized peridotites, are expected to be generated in an hydrated mantle wedge during ablative subduction as it results by 2D numerical simulations of ocean/continent subduction systems (Roda et al., 2020).

Keywords: Southern Alps, Late Cretaceous, U-Pb carbonate dating.

The central Southern Alps (cSA) represent the south-verging retro-belt of the Alpine chain, forming since the initial stages of Alpine orogeny. In the northern region, the Variscan basement was thrust onto the Permian-Triassic sedimentary cover along the Orobic Thrust during the Late Cretaceous, evidenced by the ages of pseudotachylytes (Zanchetta et al., 2011). Additional evidence of pre-Eocene Alpine compression is inferred from indirect cross-cut relationships between Eocene magmatic dikes trending E-W and thrust planes.

The absence of absolute ages can be attributed to the limited availability of dating techniques, until the last decade with the emergence of *in-situ* U-Pb dating on carbonates. Within the scope of the FAST PRIN project, this study aims to provide new evidence supporting the Late Cretaceous involvement of the central Southern Alps as a part of a doubly-vergent pre-collisional belt, as proposed by Zanchetta et al. (2012).

The examined carbonate-bearing structures in the central and southern regions of the cSA consist of growth fibers, veins, and calc-mylonites sampled along regional thrust planes deforming the Lower to Upper Triassic carbonate succession. The absolute ages obtained indicate a Late Cretaceous tectonic activity, superimposing with the Orobic Thrust. Sampling also targeted the Paleogene units within the exposed frontal part of the belt, yielding younger ages. Microstructural analyses were conducted on all samples using optical and cathodoluminescence microscopy. Furthermore, carbonate phases were characterized using O-C stable-isotope analysis, while paleotemperatures of fluids were inferred through microthermometry of fluid inclusions and X-ray diffraction analysis of sediments' clay-size fraction.

These findings confirm the involvement of the central Southern Alps in a Late Cretaceous pre-collisional belt and provide insights into paleo-fluid circulation during Alpine compression.

Evolution of a rift-related mid-crustal shear zone: the case study of the Forno-Rosarolo shear zone (Ivrea-Verbano Zone, Southern Alps)

Keywords: Forno-Rosarolo shear zone, Ivrea-Verbano Zone, Tethyan rifting.

Studies of rifted margins have benefited from an increasing quantity of high-quality data from several disciplines but the direct investigation of rift-related structures at the mesoscale is not so common and often the structures related to rifting processes lack of a complete characterisation.

The Ivrea-Verbano Zone (IVZ), in the Italian Southern Alps, represents a complete section of middle to lower continental crust, which records both the Variscan and subsequent Alpine Tethys rift-related tectonics (Beltrando et al., 2015; Simonetti et al., 2023).

One of the most important structures is the Forno-Rosarolo shear zone (Siegesmund et al., 2008). It is a NE-SW-oriented, subvertical shear zone made of metapelites, amphibolites, calc-silicates and granulites involved in anastomosed proto- to ultra-mylonite layers enveloping weakly deformed lenses (Simonetti et al., 2023). Mylonites formation postdate Variscan metamorphism and deformation and predate Jurassic brittle fracturing and faulting, locally associated with pseudotachylites.

In present day orientation, the kinematic indicators point to a sinistral sense of shear. Removing the Alpine tilt at high angle of the IVZ, this kinematic points to a former extensional shear zone. Investigations on the mylonitic flow kinematic reveal a non-coaxial deformation characterized by dominant pure shear (between 70% and 50%) and minor simple shear. Metamorphic conditions of the wall rocks vary from the upper amphibolite (SE, footwall) to the granulite facies (NW, hanging wall). Within the mylonites, PT estimate from mineral assemblage points to amphibolite facies conditions during deformation (~650°C and ~5.5 kbar).

Such kinematic data and metamorphic conditions allow to constrain the development of the Forno-Rosarolo shear zone mylonitic deformation, together with other similar structures of the IVZ, during the intermediate phase of the Tethyan rift (Beltrando et al., 2015; Simonetti et al., 2023) known as "thinning mode" (Manatschal et al., 2007). This stage was characterized by general shear conditions (pure shear between 70% and 50%) suggesting a phase of transition from a symmetric to an asymmetric configuration of rift.

Orogenic wedge formation during obduction: insights, implications and new perspectives from the Oman Mountains

Viola G.*[1], Zuccari C.[1], Giuntoli F.[1], Degl'Innocenti S.[1], Sanguettoli T.[1], Callegari I.[2] & Vignaroli G.[1]

Keywords: obduction, orogenic wedge, blueschist metamorphism.

Obduction is an uncommon plate tectonics process at convergent margins causing overthrusting of dense oceanic rocks on top of light continental units. Despite many conceptual models addressing both its initiation and the mechanisms allowing for the significant horizontal displacements of large rafts of oceanic lithosphere, obduction is only partially understood and remains quite an enigmatic process. Uncertainty remains on the triggering tectonic setting and the emplacement modes under mechanically unfavourable frameworks, with recent contributions stressing the role of far-field boundary conditions, such as the impact of bursts of "plate acceleration". Additionally, no research efforts have analysed the processes governing orogenic wedge formation in association with obduction and ophiolite emplacement, when complex orogenic architectures form during the imbrication of highly mobile and deformable slivers of continental crust underneath advancing, and possibly several kilometre-thick, ophiolitic successions.

The northeastern Oman Mountains allow studying one such orogenic wedge in the Jabal Akhdar Dome (JAD), a tectonic domain of Arabian Plate affinity that is now exhumed to the surface from beneath the allochthonous and far-travelled Semail Ophiolite. At odds with the general view, recent studies have shown that parts of the Arabian Plate therefrom experienced a complete cycle of subduction-exhumation concurrently with the Semail Ophiolite obduction in the Late Cretaceous, thus recording high pressure-low temperature (HP-LT) blueschist facies conditions of $\geq$ 0.9 GPa (based on aragonite in carbonates) and $\simeq$ 350 °C (Zuccari et al., 2023). On-going investigations confirm HP-LT conditions elsewhere in the JAD. Preservation of this metamorphic signature in the framework of the relatively undeformed external portion of the Arabian Plate calls for a re-evaluation (i) of the regional picture framing HP-LT metamorphism formation in the absence of obvious links with long-lived subduction or a major continental collision and (ii) of the mechanisms capable to exhume the HP-LT rocks and accrete them beneath the Semail ophiolitic sequence.

Preliminary structural, stratigraphic and metamorphic investigations within the JAD suggest a twofold history sequentially encompassing: 1) Cenomanian top-to-the NE imbrication and accretion under HP-LT conditions in the subduction channel of a SW-dipping Arabian Plate-directed subduction zone nucleating on transitional passive margin crust; 2) top-to-the SW lower-grade shearing during SW-ward thrusting and imbrication of the Hawasina nappes and the obduction of the Semail Ophiolite. This was triggered by an embryonic NE-ward intraoceanic subduction close to the Semail spreading centre, which set in motion the ophiolite thrust that, through >400 km of SW-ward transport, overrode the by-then failed subduction zone of 1). Finally, the current NE-ward Makran subduction zone initiated in the Paleogene.

The Sesia-Lanzo Zone in the Western Alps Subduction Complex: Alpine evolution and pre-Alpine remnants

Zucali M.*, Spalla M.I., Roda M., Zanoni D. & Piloni C.B.

Dipartimento di Scienze della Terra "A. Desio", Università degli Studi di Milano.

Corresponding author email: michele.zucali@unimi.it

Keywords: Sesia-Lanzo Zone, Alpine subduction, eclogitization.

The Sesia-Lanzo Zone (SLZ) is probably the known largest worldwide subducted fragment of continental crust. It beautifully preserves the eclogite facies mineral associations and structures at all scales of observations.

It is well-known to show km-scale intrusive volumes, commonly of Permian age, that spectacularly preserve their igneous features but now replaced by metamorphic eclogite-facies minerals (e.g., Monte Mucrone and Lago della Vecchia). The almost complete eclogitization of the country rocks surrounding these Permian intrusive only locally preserve structures and mineral phases from the Permian high temperature granulite-migmatite stages, associated with an extensional tectonic regime. These pre-Alpine remnants are small, scattered and poorly preserved throughout the SLZ. We used a combination of structural analysis and minero-chemical investigations to discriminate between low- and high- strain domains inferring the Degree of Fabric Evolution and Degree of Metamorphic transformation ratios. This approach allows a more effective identification and mapping of remnants. The quantitative description has been performed combining micro-tomography associated with EMPA XR-mapping, geochemistry, geochronology and neutron texture analysis and comparing the results with numerical modelling outputs. The SLZ is part of the Western Alps Subduction Complex together with the Piemontese Zone and to the Rocca Canavese Thrust Sheet. These domains exhibit complex tectono-metamorphic histories of coupling and decoupling from extensional tectonics to burial and exhumation and show specific traces of tectonic erosion processes and the developed of tectonic mélanges. This area of the Alps provides an ideal setting for testing the reliability of continental crust subduction-related processes, as suggested by numerical modelling or crustal geology.

Fault architecture, age and deformation localisation history of the Mykonos Detachment, Cyclades, Greece

Keywords: Aegean detachment system, K-Ar dating, fault architecture.

During the evolution of back-arc extensional systems, crustal-scale extensional detachments accommodate and aid the exhumation of even deeply subducted crustal slivers, promoting the formation of metamorphic core complexes. Such an evolution is often accompanied by the development of thick mylonitic shear zones that accommodate deformation at mid-to-deep crustal conditions. At the same time brittle fault zones form and slip at shallower crustal levels by cumulating important horizontal and vertical displacements over several million years, potentially through repeated and multiple slip events. An in-depth analysis of fault zone architecture, possibly coupled with the absolute dating of strain and deformation localisation, is therefore crucial for deciphering the long-lasting evolution of back-arc basins in active margins.

In order to provide new insights into those dynamic systems, we analysed brittle structures related to the propagation and evolution of the brittle Mykonos Detachment (MD), which is thought to have facilitated the emplacement of the Mykonos granite, which emplaced and finally exhumed at ~14 and ~9 Ma, respectively. The MD potentially accompanied this exhumation, after the former activation of the (ductile) Livada Detachment (LD), which favoured the beginning of granite unroofing. However, the age of the MD remains only loosely and indirectly constrained, and no absolute ages exist on the activation of the brittle MD, nor a detailed description of the internal architecture of the fault zone.

We carried out a detailed study coupling a Brittle Structural Facies (*sensu* Tartaglia et al. 2020) – based structural analysis with K-Ar dating on syn-kinematic illite from fault gouges that compose the MD fault core in the northern part of Mykonos Island. These gouges rest on and are cut by the MD principal slip surface (PSS), which represents the youngest analysed BSF. Four dated gouges yielded four different K-Ar ages, spanning from 9.3±0.4 Ma to 7.1±0.2 Ma. The results suggest that the evolution of the MD outlasted the exhumation of the granite (which ended by ~9Ma).

These new chronological data and the characterisation of the architecture of the MD fault zone, consistently with existing thermochronological data that indicate a rapid cooling of the granite from ~14 to ~ 10 Ma, stress the role of the MD during the unroofing of the granite, which, in this perspective, exhumed mostly assisted by the ductile LD, which acted before the MD. The latter acted instead only at a later stage, once the granite had exhumed to very shallow crustal levels and cooled to ~40°C, ~ 2Ma before the latest Late Miocene activation of the MD, as shown by our preliminary age constraints.

The 3ka Búrfellshraun lava flow field, Northeastern Iceland: lava dynamics and surface morphology

Brum da Silveira D.*[1], Thordarson T.[2], Höskuldsson Á.[1], Moreland W.[1] & Jónsdóttir I.[1]

[1] Institute of Earth Sciences, University of Iceland, Reykjavík, Iceland.
[2] Faculty of Earth Sciences, University of Iceland, Reykjavík, Iceland.

Keywords: lava dynamics, platy-ridged surface morphology, Búrfellshraun.

The 3ka Búrfellshraun eruption is part of Iceland's North Volcanic Zone and has gained attention due to its platy-ridged surface morphology and as a terrestrial analogue to Martian flood lavas (Keszthelyi et al., 2004; 2006). Through comprehensive satellite mapping, geochemical analysis and studying syn-emplacement processes and surface features. This study provides insights into its eruptive history, lava dynamics and the formation of its platy-ridged surface morphology. Our results challenge the previous interpretations put forth by Haack et al. (2006) that the platy-ridged surface morphology in Búrfellshraun is a result of a major breakout event. The preservation of pahoehoe at the leading flow front and along the margins of the Búrfellshraun lava flow field contradicts the inference of a turbulent drainage from the core of the flow field: rather these evidence are suggestive of a slower, more nuanced formation process typical for pahoehoe. We propose that the formation of this surface morphology shares similarities with the processes that shape sea ice, and that this process is more widespread than previously recognized. In sea ice formation plates and pancakes, resembling a honeycomb or a polygonal pattern, emerge due to the interplay of temperature gradients and a wavy-motion behaviour. Similarly, we suggest that it may be a result of the interplay between lava temperature differentials and cooling mechanisms, as well as due to a wavy-motion behaviour of the liquid lava, probably generated by a pulsating activity of the vent. The ponding of lava within the graben where the Búrfellshraun eruptive fissure is situated played a role in setting up the right condition for the wavy-motion behaviour. Furthermore, field mapping along with image analyses of aerial photographs has revealed a striking absence of clear borders within the platy-ridged surface morphology. Notably, two distinct lava channels originating from different eruptive fissures are observed, yet no contact is observed in between these channels. This strongly suggests that the Búrfellshraun eruption was not a singular event, but rather a series of eruptions interspersed with brief cessation periods. This phenomenon is reminiscent of other Icelandic volcanic eruptions, such as the 1975-1984 Krafla Fires and the recent 2021, 2022 and 2023 Fagradalsfjall eruptions, where successive eruptions overlapped and obliterated contact between different lava flows. These new insights into the platy-ridged lava have implications for our understanding of the emplacement histories of Martian flood lavas.

Keywords: vulcano- and chemostratigraphy, Sulcis, SW Sardinia.

For more than 125 years the Sulcis region has been known as the site of outcropping of a complex sequence of volcanic (mainly pyroclastic) units, including an orogenic suite more complete in the north and central part of Sardinia, and several postorogenic peralkaline units restricted to the SW of Sardinia. This communication refers mainly to the middle and upper part (post-andesitic) of the volcanic succession. The great number of pyroclastic units and macroscopic similarity of some of them has traditionally created conflict in the identification and mapping of these units. Also, the correlation of the units in between the islands of San Pietro and Santo Antioco, and the Sulcis mainland was a permanent matter of discussion. Assorgia et al. (1990) provided the first formal definition of the volcanic sequence supported by 59 whole-rock analysis conducted at Universitat de Barcelona (UB). Successively this situation begin to change with the work of CarboSulcis SpA geologists and several university teams leading to the Sulcis mainland map (Assorgia et al., 1992). Additionally the pyroclastic comenditic units of the upper part of the succession were analyzed with modern methods (Assorgia et al., 1994). Over the last three decades most of the research by the Italian side has focused on CARG mapping. Independently, our group at UB conducted research including 3 Ms Thesis and 2 PhD thesis, leading to the production of a huge amount (718 whole rock, major and trace elements) of field, petrographical and geochemical data. This geochemical dataset is three times larger than the rest of available data, which has allowed us a better definition of the volcanic units and the improvement of their cartography.

Gisbert & Gimeno (2017) provided new geochemical criteria and a protocol for delimitation of pyroclastic units. This work updates that paper, by incorporation new data and significantly modifying the volcano- and chemostratigraphic succession. Particularly noteworthy are the revisions in the upper part of the succession, the San Pietro island sector and in the northwestern part of Santo Antioco island. This includes two new units at San Pietro island (Trachyandesite and Acquedotto units), the accurate placement by chronostratigraphy of the Punta dei Cannoni unit, identification of Pantellerite terms in the formerly named Comenditic unit (and mapping of up to 15 subunits in the Lower and Upper Comendite units). Furthermore, the formerly named Serra di Paringianu unit is redefined as Calasetta unit (as in fact initially was named, because of the locality-type of better expression). Lastly, a new Post-Calasetta unit is here identified for the first time.

This presentation aims to explain these key findings, as a preliminary step to the divulgation of new thematic maps for each of the three sites: the San Pietro and Santo Antioco islands, and the Sulcis mainland.

Understanding the mechanisms governing magma ascent prior to eruption is crucial for hazard assessment and risk mitigation strategies. Traditional methods of assessing magma ascent times have relied on geophysical monitoring and petrological analysis of erupted materials although such techniques often lack the spatial and temporal resolutions required to precisely assess magma ascent times.

In this regard, crystals are a precious resource since they act as recorders of magmatic processes, accumulate distinct chemical and textural layers as they grow in response to changes in temperature, pressure, and composition along the ascent path.

In this study, we propose a combined methodology to infer magma ascent times by analyzing the size and complexity of the crystal zoning features through advanced techniques such as Laser Ablation-ICPMS, SEM imaging and validating them within a finite-element modelling of the magma flow within the conduit feeding system.

To do this, we select the well-studied Pomici di Avellino (PdA) eruption of Somma-Vesuvius (Italy) occurred approximately 3.9 thousand years ago, as described by Sulpizio et al. (2010) for which the conduit geometry has been indirectly derived (Massaro et al., 2018). We focused on the magmatic Plinian phase (EU2-EU3) considering different crystal size classes (from 125 mic to 2 mm). Preliminary results show interesting correlations between chemical elements for different crystal size populations.

Keywords: Marsili volcano, magma differentiation, crystal mush.

Located in the Tyrrhenian Sea, the Marsili seamount is a submarine volcano that formed within a back-arc setting. Aiming to define the complexity of its trans-crustal plumbing system, we investigated the compositional and textural variability of crystal cargoes found within basaltic to andesitic lavas collected from three different sectors of the volcano (northern, axial, and lateral). Lavas erupted from the northern sector are only basalts and generally more primitive in character compared to lavas erupted from the lateral and axial sectors, the latter dominantly basalts and basaltic andesites with a broader variability in terms of mineral assemblage and chemistry. Crystal-poor andesitic magmas were only erupted at the summit axial sector of the volcano. The large abundance of glomerocrysts of different mineralogy and composition is a peculiar feature of samples from all these sectors, providing evidence of a laterally extended and petrologically heterogeneous crystal mush. Thermobarometric calculations performed on clinopyroxene coupled to mass-balance and thermodynamic modeling collectively support the petrographic evidence of a polybaric plumbing system, where relatively less differentiated basaltic magmas reside at depth (300-450 MPa, 1040-1080°C) and either feed eruptions at the northern sector or evolve to form andesitic magmas stored at shallow depth (< 250 MPa, 920-980°C) in the axial sector. Furthermore, basaltic and basaltic andesitic magmas erupted from the lateral sector testify to intermediate storage conditions (200-400 MPa, 980-1060°C). The variable content of incompatible (TAl and Ti) and REE in clinopyroxene contained in lavas from the three sectors relates to different undercooling conditions, with magmas erupted from the northern sector recording higher undercooling compared to those erupted from the lateral and axial sectors. The emerging scenario is that basaltic magmas erupted from the northern sector experienced a more rapid ascent (also testified by the occurrence of high-Fo olivine and dendritic clinopyroxene in the groundmass) compared to magmas erupted at the lateral and axial sectors, otherwise experiencing prolonged time within the crust.

The 1538 eruption at Campi Flegrei resurgent caldera: implications for unrest evolution and eruption hazard

Keywords: caldera unrest, volcanic seismicity, Campi Flegrei.

The recent unrests in the Campi Flegrei caldera which began several decades ago, pose a high risk, in a densely populated area, due to the occurrence of large uplift, very shallow earthquakes of intermediate magnitude and possible evolution towards eruption. Given the high population density it is crucial, especially for civil defense purposes, to consider realistic scenarios for the evolution of these phenomena, particularly seismicity and potential eruptions. The eruption of 1538, the sole historical eruption in the area, provides a valuable basis for understanding how unrest episodes in this caldera, in particular seismicity, may evolve towards eruption. In this paper, we provide a new, reliable historical reconstruction and analysis of the precursory phenomena for the 1538 eruption, in the light of recent volcanological observations and results obtained in the last decades. We can then build a coherent picture of the mechanism and possible evolution of the present unrest, both in terms of expected seismicity, ground uplift and eruption. Our work points out two main alternative scenarios, providing a robust guideline for civil protection measures, and facilitating the development of effective emergency plans in this highly risky area.

Skarn formation associated with alkaline magma chambers: comparison of Somma-Vesuvius, Colli Albani and Merapi volcanic systems

Knuever M.*, Mele D. & Sulpizio R.

Dipartimento di Scienze della Terra e Geoambientali, Università di Bari "Aldo Moro".

Corresponding author email: marco.knuever@uniba.it

Keywords: skarn, Vesuvius, magma.

Skarn formation is common process when shallow magma chambers are emplaced in the carbonate basement. The thermo-metamorphic reaction of the magma with the surrounding carbonate-bearing host-rocks results in the formation of exoskarns, endoskarns, cumulates, exsolved fluids and differentiated melts. This process is well documented through mineralogical and geochemical studies of ejected skarns and cumulates and through fluid and melt inclusion studies of these samples. We compared the results of several studies on skarns associated with shallow alkaline magma chambers from three distinct volcanic settings: i) Somma-Vesuvius, ii) Colli Albani (both Italy) and iii) Merapi (Indonesia).

Our results indicate that the major mineral phases are very similar and do not reflect the changes in magma composition between the three systems. Instead, host-rock composition (Ca-rich limestone or dolomite) and the availability of a melt to assimilate the host rock define the major mineral composition. In already silica-undersaturated systems (here: Somma-Vesuvius and Colli Albani) the formation of Skarns drive the magma to an even higher degree of silica-undersaturation and enrichment of Ca and Mg in the melt. In parental magma s with higher SiO_2-contents (here: Merapi) skarn formation does not affect the major element magma composition and might only be recognized by isotope systematics like $\delta^{18}O$ and Sr-ratio. The accessory mineral assemblage crystallizes from the magmatic brines during magma cooling in which incompatible elements are enriched. Here it depends on the dominating volatile phase which minerals crystallize.

Plagioclase dissolution and reaction in a hydrous basaltic melt: a proxy for deciphering time scales of mixing events at Stromboli volcano (Italy)

Masotta M.*[1-2], Colle F.[3], Costa S.[4] & Landi P.[4]

[1] Dipartimento di Scienze della Terra, Università di Pisa. [2] Centro per l'Integrazione della Strumentazione CISUP, Università di Pisa. [3] Dipartimento di Scienze Chimiche, della Vita e della Sostenibilità Ambientale, Università di Parma. [4] INGV, Pisa.

Keywords: plagioclase, dissolution, reaction.

Plagioclase is a widespread mineral component in basaltic magmas across all geodynamic settings. The physico-chemical (P-T-Xi) conditions of a magma primarily determine the stability field of plagioclase in silicate magmas and the composition of the An-Ab solid solution. For this reason, plagioclase is commonly used to decipher pre-eruptive conditions, whilst the diversity of textures and chemical zoning patterns of plagioclase phenocrysts can provide clues on the magmatic processes in active volcanoes. Several experimental works have constrained the stability and composition of plagioclase in hydrous basaltic systems, but only a limited number investigated the behaviour of plagioclase crystals under disequilibrium conditions. Here we present the results of time series experiments designed to constrain the time scale of plagioclase dissolution and reaction in a hydrous basaltic magma from Stromboli volcano (Italy). Experiments were performed at 1150°C and 150 MPa, under both anhydrous and hydrous conditions (H_2O = 2-3 wt.%) and with time varying from 30 to 240 minutes, using natural crystals separated and selected from basaltic mingled-pumices erupted during major explosions and paroxysms. The experimental strategy is based on the comparison of textural and chemical features of plagioclase phenocrysts before and after the dissolution-reaction experiment. Plagioclase dissolution is observed only at hydrous conditions and in phenocrysts characterized by a homogeneous (low-An) outer rim, whereas phenocrysts characterized by pre-existing (high-An) reaction rims show no evidence of reaction with the melt. The formation of the An-rich reaction rim testifies to a rapid chemical re-equilibration of the plagioclase with the hydrous silicate melt at the crystal interface. These reaction rims are very similar in terms of both texture and composition, to resorption bands occurring as concentric layers in natural phenocrysts. The width of crystal dissolution and the thickness of the reaction rim increase with the duration of the experiments following an exponential law. A linear regression derived from the experimental data permits to quantify the time scale of dissolution-reaction processes, simply by measuring the thickness of the reaction bands of natural plagioclase phenocrysts. Specifically, in the case of Stromboli volcano, reaction bands are attributable to the periodic interaction between a deeper volatile-rich magma (lp-magma) with a degassed magma residing at shallow depths (hp-magma). By employing this methodology, it is possible to identify characteristic time scales for mixing events occurring during the normal activity and preceding the more energetic explosions.

New evidence of syn-eruptive magma-carbonate interaction: the case study of the Pomici di Avellino eruption at Somma-Vesuvius (Italy)

Keywords: Pomici di Avellino eruption, magma-carbonate interaction, carbonate assimilation.

Calithics are commonly found within the products of some explosive eruptions of Somma-Vesuvius, but their short-term contribution to the eruption dynamics has never been evaluated. The pumice fragments from the final phase of the Plinian fallout event of the Pomici di Avellino eruption contain abundant calcareous xenoliths. Previous works on that eruption, as resulting from numerical simulations, suggested that the release of CO_2 from the entrapment of carbonates may have prolonged the magmatic phase of the eruption by maintaining sufficient driving pressure in the feeding dyke.

The texture and thermo-metamorphic reactions of carbonate xenolith-bearing pumice fragments of the Pomici di Avellino eruption are analysed through petrography, scanning electron microscope images, energy dispersive spectrometer, and micro-computed X-ray tomography to deduce the behaviour of short-term carbonate-magma interaction and its contribution to the eruption dynamics.

Results show that calcareous xenoliths experienced short-term magma-carbonate interaction, which took place in three steps: i) ingestion, i.e., the physic-mechanical process of carbonate xenoliths entrainment, ii) decarbonation, related to high-temperature decomposition reaction, and iii) digestion or dissolution of the incorporated calcareous xenoliths into the melt with diffusion of Ca and Mg. The CO_2 released during the syn-eruptive decarbonation process thus provided extra volatiles to the rising magma, which may have maintained magma buoyancy longer than expected if only magmatic volatiles were involved in the eruption.

H_2O-CO_2 fluid infiltration and the Campi Flegrei unrest: from hydrothermal drying to shallow magma rejuvenation

Moretti R.*

Dipartimento di Ingegneria, Università della Campania "L. Vanvitelli", Aversa (CE).

Corresponding author email: roberto.moretti@unicampania.it

Keywords: H_2O-CO_2 fluids, magma rejuvenation, thermodynamics.

In the last two decades consensus has developed that the current unrest at Campi Flegrei caldera (CFc) involves or is even triggered by the arrival of magmatic gases. Different but reconcilable geochemical scenarios have sparked debates about the state of magma(s) releasing fluids, particularly the depth of the degassing magma(s). In a series of papers since 2013 (see references in Moretti et al., 2018; 2020) and based on data until 2016, coauthors and I have shown that such fluids were released by a ~8 km deep magma, whereas a shallow one at ~4 km has contributed through the 1982-84 unrest until year 2000, when it exhausted its volatiles. The volatile exhaustion of the shallow magma was related to its crystallization. In this scenario, the subsequent evolution until 2016 (based on data available at the time of publications) was mainly due to the infiltration of the deepest gases and their interaction with the hydrothermal system. It was also proposed that the progressive heating of the Solfatara hydrothermal system by CO_2-rich magmatic fluids was the main driver of the CFc unrest, essentially triggered by the thermoelastic response of the hydrothermal reservoir (Moretti et al., 2018). Several studies have recognized the role played by the double magmatic degassing reservoir. It is a fact that the chemistry of gases discharged at Solfatara fumaroles since decades bear a depth-varying magmatic signature which through time has differently modulated the hydrothermal interaction (e.g., Caliro et al. 2014; Buono et al. 2022). With reference to the recent unrest dynamics felt by population, the main in question has become whether the shallow reservoir at ~4 km is active or not which of course means whether it can be mobilized or not via a magmatic eruption. By using the data available from the current literature, in this contribution I show that gas ratios point to the drying of the bottom part of the hydrothermal system operated by a magmatic gas with H_2O:CO_2 proportions of about 70:30. However, whether this fluid is directly released from the 8 km deep magma or not, becomes secondary. Energy budgets coupled to phase equilibria show in fact that the heating process promoted by the deep fluid ascent may lead to the remelting of the shallow magmatic rock. The (re) forming magma will then buffer the fluxing volatile components, hence the H_2O:CO_2 gas composition released upward. How this process should affect the other gas ratios is then discussed.

In conclusion, we cannot discard the possibility that a shallow magma batch is rejuvenating or has already rejuvenated. Only the infiltration of a CO_2-rich fluid is required to reactivate a "ghost" magma at shallow depths. This process would occur in absence of clear geophysical evidence for magma migration and ascent from the 8 km deep caldera reservoir. This should be seriously considered for volcanic hazard assessment. Finally, I also speculate how such a process may have produced the 1538 CE eruption.

Keywords: strain rate, crystallisation, magma dynamics.

Crystallization processes occurring in trans-crustal magmatic systems strongly influence magma rheology, conduit dynamics, and eruptive style. The presence of deformation fields within magma storage regions and plumbing systems can impact crystal nucleation and growth processes. Here we present novel experiments designed to investigate the effect of strain rates on crystal texture and zoning patterns, crystal nucleation and growth rate, mineral phase proportions, and the chemical composition of the residual glass. The experiments were carried out at controlled pressure and temperature conditions on natural trachybasalts from Mt. Etna. Mineral zoning was forced by oscillating temperature (1170-1130°C) at a constant strain rate ($1s^{-1}$) using a concentric cylinder viscometer. Major element single spot analyses and elemental maps were collected with an electron probe microanalyzer (EPMA) at the University of Geneva. The data were analysed using custom-built unsupervised and supervised machine learning algorithms (e.g., Hierarchical Clustering and Random Forest). We quantify the impact of strain rate on nucleation, growth, and mineral phase proportions through electron backscattered diffraction (EBSD) scans conducted at the University of Vienna. The EBSD analysis provide the strength of crystallographic preferred orientations (CPO), with plagioclase CPO used as a proxy for the degree of deformation experienced by the crystals in different regions of the experiments. The experimental results show that a small increase in strain rate can lead to a large increase in nucleation rate and thus in crystal number density. This process has a direct influence on the growth competition between different mineral phases, controlling their growth rates, the final proportion of mineral phases, and the composition of the residual melt. These results highlight the need to take deformation processes into account when linking textures and chemistry of volcanic products to pre-eruptive magmatic processes and emplacement dynamics.

Solid-state synthesis of calcosilicates mimics pyroclastic rheomorphic rhyolitic- xenolith interaction in the Monte Ulmus peralkaline unit (SW Sardinia, Italy)

Novembre D.*[1], Carrazana A.[2-3] & Gimeno D.[2]

[1] Dipartimento di Ingegneria e Geologia, Università "G. D'Annunzio" di Chieti-Pescara. [2] Departament de Mineralogia, Petrologia i Geologia Aplicada, Facultat de Ciències de la Terra, Universitat de Barcelona, Spain.

Keywords: calcosilicates, solid-state synthesis, powder X-ray analysis.

The Upper and Middle part of the volcanic Miocene succession in Sulcis region is mainly built up by pyroclastic units rhyolitic in composition. Most of these units are of ignimbritic type and some of them present a syndepositional rheomorphic basal vithophyre (Gisbert & Gimeno, 2017). Basal vithophyres correspond to high temperature flows (i.e. of boiling-over type, see i.e. Gimeno et al., 2003) and are more ubiquitous in the postorogenic peralkaline upper part of the succession. An example of this is the pyroclastic Monte Ulmus comenditic unit; this unit marks a sharp compositional change within the peralkaline part of the volcanic succession. The lower part of this unit contains abundant xenoliths that can be related (taking into account our current knowledge of the tridimensional geologic framework at Sulcis region) to the host rock into the upper part of a shallow magmatic chamber. Previous petrographic, mineralogical (XRD) and isotopic study (Carrazana et al., 2018) has shown that calk-silicate xenoliths came from the Lower Cambrian carbonatic platform of Iglesiente-Sulcis. At that stratigraphic level other constituents (mainly clay-rich and siliciclastic material from Precambrian and Lower Cambrian) are also present, but are not considered here. Different solid-state synthesis experiments were prepared in order to determine the conditions and reaction times of the calcosilicate pyrometamorphic paragenesis found in the more reactable protoliths of a presumed starting carbonatic composition. A stoichiometric Monte Ulmus-like typical composition was created from natural and synthetic reactants (limestone, Tripoli, hematite, 700°C calcined metakaolin, Na_2CO_3, and KCl).

The tests were carried out in a solid state and different runs at 400-550-650-700-750-850°C and atmospheric pressure, with relative proportions between the theoretical magma and carbonate rocks (1:1 to 1:05). The reaction times were from 12 to 504 hours. In the paragenesis found at 400 and 550°C, the amorphous silica has just crystallized (cristobalite and quartz or exclusively quartz if it is a lower content of limestone). The runs at 650°C show the beginning of the vesuvianite formation. At 700°C wollastonite, vesuvianite and diopside were formed. Runs at 750°C show the gradual replacement of quartz by tridymite. Finally, run at 850°C shows the persistence of quartz-wollastonite with minor proportions of amorphous phases. All these experiments are in good agreement with published data and are compatible with short reaction times and natural paragenesis. The expected range of temperature in peralkaline rhyolitic rocks fits well with the absence of diopside and wollastonite in the paragenesis and experimental data (Novembre et al., 2018), while it has been described i.e.in carbonate xenoliths present in basaltic lavas and plugs. These data provide new criteria for successive synthesis experiments looking for minor present phases in xenoliths (i.e. grossular garnet).

Keywords: alkali feldspar, dissolution kinetics, trachyte.

Mineral dissolution is an important process in magmatic systems, as it can affect the remobilization of cold reservoirs, magma transport dynamics, and magma ascent rates. Investigating the dissolution kinetics of minerals is important to constrain the timescales of the crystal-liquid interaction and mineral resorption rates at magmatic conditions.

Previous studies have investigated mineral dissolution in silicate melts focusing on clinopyroxene (Neave & Maclennan, 2020; Bonechi et al., 2021) olivine (Donaldson, 1985; Chen & Zhang, 2008), plagioclase (Donaldson, 1985) and quartz (Donaldson, 1985). However, dissolution of alkali feldspar has not been investigated. For this reason, we performed melting experiments to investigate alkali feldspar dissolution in trachytic melts at high pressure and high temperature conditions.

Our experimental results are relevant for magma transport dynamics and magma ascent rates in trachytic magmatic systems.

Keywords: lava fountains, volcanology, carbon dioxide.

Etna's activity over the last ten years has been characterized by intense explosive activity with numerous lava fountains.

In order to test new monitoring parameters for monitoring volcanic activity at Mt. Etna, a geochemical station for the measurement of soil CO_2 concentrations was first installed in 2019 for one month into a vent formed in 2002 along the North-East rift, at altitude of 2450 m asl. The 2002 vent was chosen because inside it there are some steam fumaroles characterized by large gas emissions both of CO_2 and of CH_4.

In 2019 it was observed that shortly before a strong explosive episode on 8 September at the NE summit crater there was a decrease in measured CO_2 concentrations that could not be attributed to changes in environmental factors (mostly wind speed and barometric pressure). In that occasion, the observed fluctuations could be related with the fast dynamics of magmatic fluids into Etna's conduits. In the following years we had the opportunity to test and better evaluate that preliminary hypothesis, as numerous paroxysmal episodes occurred on Etna.

It is noteworthy that during the first two years of the station operation, until about mid-July 2021, CO_2 anomalies (mostly in terms of strong and short-lived negative peaks) were systematically followed after about 24-48 hours by increases in volcanic activity in the summit craters (Strombolian activity at Northeast Crater in 2019 and Strombolian activity at Southeast Crater in 2020) or by more intense eruptive events (as in the case of the 2021 cycle of paroxysms at the Southeast crater.

From this point of view, negative CO_2 anomalies are interpreted as due to sudden movements of gas-rich magma from a reservoir located between 1 and 6 km below sea level towards a shallow reservoir located between 1 and 2 km above sea level.

Finding the best protocol to characterize the rheological behavior of fine volcanic sediment suspensions

Tranquilino C.*[1], Dioguardi F.[1], Gentile L.[2], Caballero L.[3] & Sarocchi D.[4]

Keywords: rheology, lahars, fine suspensions.

The rheological characterization of fine sediments suspensions has been carried out over time through various rheometers geometries. The geometries can be classified in absolute and relative geometries. The absolute geometries, such as concentric cylinders, plate-plate and cone-plate can vary depending on the measuring gap and the size of the tools. These scales determine the sample volume, the maximum sediment size, and the strain condition (range of shear rate) applied as well as the measurement time. Most studies on the rheological characterization of fine sediments suspensions have been performed in small-scale rheometer geometries, which consist of a gap of a few millimeters between the measurement systems. One requirement for employing this measurement scale is that the gap must be at least 10 times greater than the largest particle size of the material. So, the selection of the best protocol for the rheological characterization of fine sediment suspensions is not trivial; it depends on the rheometer geometries and on the sample conditions. Numerous works have aimed at constructing and discussing theoretical models that allow to describe the rheological behavior of fine sediment suspensions. Throughout this work, a comprehensive database of the principal rheological properties (viscosity and yield strength) has been compiled by collecting the work of various authors from the academic literature. The database comprises measurements of samples with a maximum clast size of 63 microns (silt and clay) and small-scale geometries with various shapes. A significant variability in the measurement protocols proposed by different authors was observed (O'Brien & Julien, 1988; Jeong, 2010). From this database, arose the need to establish an appropriate protocol for the rheological characterization of homogeneous suspensions of volcanic sediments from lahars of the Popocatepetl volcano, Mexico. The samples were collected from deposits of representative eruptive events, which are classified as the three lahar hazard scenarios (Martín-Del Pozo et al., 2017). Those hazard scenarios are established based on their magnitude and probability of occurrence (low, medium and high probability). Also, they were related to different compositions of clasts, mainly composed by pumice, pumice and lava, and lava fragments. Therefore, knowing the rheological behavior of these volcanic sediment suspensions will allow us to go deeper in particle transport and sedimentation processes inside different types of lahars to propose a transport and sedimentation model for these eruption events. As an initial result of this research, we compared data obtained using our proposed measurement protocol for the rheological characterization of fine volcanic sediment suspensions in an Anton Paar rheometer (small-scale concentric cylinder geometry) with those from a Fungilab viscometer (Tranquilino, 2023), under similar conditions. We discuss the instruments' advantages and disadvantages, along with proposed improvements to the measurement protocol.

ISOBatA's contribution and strategy to Antarctic Seabed Exploration

Accettella D.*[1], Savini A.[2], Cuffaro M.[3], Diviacco P.[1], Muccini F.[4], Zgur F.[1], Buca M.[1], Cova A.[1], Facchin L.[1], Santulin M.[1], Romeo R.[1] & Viola A.[1]

Keywords: bathymetry, anderway data, Antarctic.

The ISOBatA project, supported by the Italian National Antarctic Research Program (PNRA), is designed to enhance knowledge of the Antarctic seabed in crucial areas for the Italian Antarctic community and contribute to the Seabed2030 and the International Bathymetric Chart of the Southern Ocean (IBCSO) initiatives (Dorschel B. et al., 2022).

Over the last three PNRA expeditions, the project utilized voyages of the R/V Laura Bassi between Antarctica and New Zealand to focus on opportunistic data collection in geodynamically significant areas, such as the Macquarie Triple Junction and the Emerald Fracture Zone, as well as in relevant zones at the Italian mooring sites in the Ross Sea (MORSEA observatory and LASAGNE project), critical to investigate oceanographic patterns and dynamics. Our main objective was to optimize data collection during transit times by adapting our methods to the constraints of each expedition, without compromising other research projects. ISOBatA allocated dedicated ship time to reduce speed and redirected navigation along designated corridors to explore uncharted regions. Strategic replanning, using the IBCSO coverage map and metadata from prior PNRA expeditions (e.g., Seismic Data Library, PNRA Core Sites), enabled us to enhance our data collection techniques. We acquired comprehensive datasets, including bathymetric, magnetometric, sub-bottom profiling, and ADCP data. Established best practices and workflows ensured high-quality data acquisition, processing, analysis, and archiving.

Peliminary results include:

A discrepancy of up to 1200 meters, compared to the IBCSO map, in the proximity of the Emerald Fracture Zone, featuring a masked tectonic structure. This highlights how gaps in bathymetric knowledge can obscure our understanding of geodynamic processes.

In the Ross Sea, the strategic use of metadata from previous PNRA surveys was instrumental in our planning process, allowing for a more nuanced understanding of the complex interactions between the seafloor, ocean currents, and ice sheets. Particularly at the Mooring G sites, spiral geometries, carved by gouging icebergs, show the interaction of tidal rise and geostrophic currents on huge icebergs paths (Newton et al., 2016).

The expeditions highlighted the challenges of high speed underway data collection, especially in regions frequently affected by adverse weather as well as sea ice, which sometimes compromised data quality for comprehensive mapping. Nonetheless, the dataset not only fills significant bathymetric gaps but also enhances our understanding of the surveyed areas. This experience underscores the importance of adopting appropriate best practices and workflows tailored to the expeditions aims, weather condition, the geomorphological setting of the study areas and available dataset.

Keywords: nitrate, bioaugmentation, fertilizers.

Intensive farming practices can negatively impact the environment, with consequences on both soil and water quality. As an instance, excessive fertilizer use and animal manures can be primary sources of nitrate leaching into groundwaters. High nitrate concentrations can cause adverse effects on human health and impacts aquatic ecosystems by promoting algae growth and depleting oxygen levels in water bodies (Sing & Craswell, 2020). To mitigate nitrate contamination, various strategies can be employed, including improved agricultural practices (e.g., precision farming and reduced fertilizer use), and proper waste management (Power et al., 2001). Plant Growth-Promoting Bacteria (PGPB) are beneficial microorganisms that colonize the rhizosphere and enhance plant growth and health through various mechanisms. PGPB exert positive effects on plant growth by facilitating nutrient uptake (e.g., nitrogen fixation, phosphate or potassium solubilization), producing phytohormones, and enhancing tolerance to biotic and abiotic stresses (e.g., pathogens, drought, salinity) (Pathania et al., 2020). The present study investigates the effect of bioaugmentation on plant growth and soil/water quality, with the aim to assess the potential use of biofertilizers as substitute for chemical fertilization and the consequent advantageous for both farmers and environment. For this purpose, a tailored microbial formula, composed by eight indigenous strains selected from a soil sampled at Cooperativa Santa Margherita (SW Sardinia, Italy) for their PGP functions, was developed as biofertilizer. The comparison between bio and chemical fertilization effects on plant productivity was performed by means of greenhouse experiments carried out with several tomato varieties (i.e. Camone, Oblungo, Cherry) and the same soil used to develop the PGPB formula. Results indicated that bioaugmentation may substitute chemical fertilizers without compromising yield, thus improving the sustainability of the agroecosystem (Paganin et al., 2023). Ongoing greenhouse pot experiment aims to assess the effect of the different above-mentioned fertilization methods on both plant growth and productivity (plant height, fruit weight and number) and quality of percolation water (e.g., nitrate concentrations). Greenhouse pot experiment will be carried out using different soils: i) the soil sampled from Pula (Azienda Agricola Siclari Gianfranco) and ii) a second one collected from an area (Campidano area, SW Sardinia, Italy), interested by intensive agricultural practice and groundwater nitrate pollution. Achieved results will be very useful to implement sustainable agricultural practices, i.e. to reduce the use of chemical fertilizers and optimize the use of PGPB for enhancing crop sustainability, allowing agriculture to move towards more eco-friendly practices thereby enhancing soil and water health.

Keywords: Middle Triassic, Permo-Triassic mass extinction, tetrapod fossil record.

The aftermath of the Permian-Triassic Mass Extinction (PTME) left Earth's terrestrial ecosystems in disarray, with only a fraction of species surviving the biotic crisis. The Early-Middle Triassic transition witnessed a gradual recovery, characterized by the emergence of novel ecological niches and the establishment of more complex ecosystems (e.g., Bernardi et al., 2017; Romano et al., 2020). This contribution presents the findings of a comprehensive review of Middle Triassic terrestrial tetrapod faunas worldwide, through a semi-quantitative taxonomic analysis approach to elucidate patterns of diversity and distribution. Our results delineate three primary clusters: firstly, the Gondwanan fauna in the Southern Hemisphere, dominated by therapsids, showing a similar distribution to that of the Late Permian and the Early Triassic; secondly, the Asian fauna, spanning Russian and Chinese regions, clustering with the Gondwanan fauna, as opposed to the results obtained for the Early Triassic (see Romano et al., 2020); lastly, the European-North American-North African fauna, occupying the Western part of the Northern Hemisphere, exhibiting dominance by derived archosauriforms and lepidosauromorphs. The highest biodiversity is observed in the Northern Hemisphere sub-equatorial zone, reminiscent of Late Permian patterns. Temnospondyls, though ubiquitous, display a preference for higher warm-temperate latitudes across hemispheres. Avemetarsalians are notably present in both the North-Western and Gondwanan faunas but are absent in Asian regions. Pseudosuchians are predominant in the Northern Hemisphere, showing an antithetical distribution to therapsids. By visually delineating the biogeographic distributions of terrestrial tetrapod groups, our contribution aims to provide a clearer understanding of how the recovery shaped the evolution and establishment of stable terrestrial ecosystems during the Middle Triassic.

A geological and geotechnical modelling of Alpine sulphates: the SALT project

Bonetto S.[1], Caselle C.[1], Frasca G.[2] & Mosca P.*[2]

[1] Dipartimento di Scienze della Terra, Università di Torino. [2] Istituto di Geoscienze e Georisorse, CNR, Torino.

Corresponding author email: pietro.mosca@cnr.it

Keywords: sulphates, tunneling, Alps.

The excavation of underground infrastructures in geological sequences containing sulphates represents a tough challenge. Excavation indeed causes swelling phenomena, water weakening, creep deformation and karst phenomena in these rocks, leading to technical problems that are nowadays not completely addressed. However, the deformation mechanisms and behavior of the evaporites are not perfectly understood and modelled, and this arises problems in ground-support designs to geo-engineering projects especially in tectonically complex areas such as the Alpine orogenetic belt. In the Alps, masses of evaporite, mainly consisting of sulphate minerals, acted as main décollement units in the growing of the belt and now outcrop all over the arc mainly in correspondence of main regional shear zones. Alpine evaporites usually have irregular lateral continuity and variable thickness through the mountain chain due to the complex tectonic history and their mechanical response need to be evaluated contextually to the complexity of fracture network and 3D geometries.

In this contribution we present the first results obtained by the recently started SALT project (MultiScale and interdiSciplinary characterization of Alpine sulphates for geologicaL and geotechnicaL modeLing: applications for Tunneling and underground energy sTorage - PRIN bando 2022), aimed at investigating the sulphate units of the Alpine chain. The project focuses on two selected sites in High Susa Valley (Western Alps) and Brenner region (Eastern Alps), and merges several approaches and investigation scales:

- the 3D geometries and volumes of sulphates will be estimated through on-site geological and geo-structural surveys;
- the mechanical behavior of the material will be experimentally assessed at the laboratory scale through compression tests;
- the miner-petrographic and micro-structural characteristics of the rock will be investigated through analytic techniques (namely, scanner electron microscope with energy dispersive spectroscopy - SEM-EDS - and X-ray powder diffractometry);
- the micro-mechanisms involved in the swelling process will be studied by X-ray computed tomographies.

The integration of these different data will offer a thorough understanding of the behavior of the investigated sulphate units, producing new theoretical perspectives on the geomechanics of these materials. This will represent a fundamental contribution for risk mitigation in underground infrastructures, including tunnels and salt caverns.

Exploring the relationship between the microseism long-term energy trend and wave power in the Mediterranean Sea during the period 1996-2023

Borzì A.M.*[1], Cannata A.[1-2], Panzera F.[1], D'Amico S.[3] & Aster R.C.[4]

[1] Dipartimento di Scienze Biologiche, Geologiche ed Ambientali, Università di Catania. [2] INGV, Osservatorio Etneo, Catania. [3] Department of Geosciences, University of Malta, Msida.
[4] Department of Geosciences, Warner College of Natural Resources, Colorado State University, Fort Collins, USA.

Corresponding author email: alfio.borzi@phd.unict.it

Keywords: microseism, Mediterranean Sea, climate change.

In this study, we combined seismic data collected from nine stations installed along the Mediterranean coastal areas with the wave characteristics derived from hindcast data spanning from 1 January 1996 to 15 October 2023. Specifically, we explored the relationship between microseisms (the most continuous and ubiquitous seismic signal on the Earth generated by the interaction between the hydrosphere, atmosphere, and solid Earth) in terms of spectral properties, root mean square amplitude time series, and microseism power spectral density, and the main sea wave features (e.g. significant wave heights, wave periods, and wave power that is an indicator of wave energy). To investigate the correlation between microseisms and sea conditions, we performed a correlation analysis between the root mean square amplitude time series and significant wave height time series across the entire Mediterranean Sea from 1996 to 2023. Moreover, to identify significant variations in microseism amplitude and wave power associated with climate change and their interrelation, we determined long-term trends for both microseism energy and wave power by using singular spectrum analysis algorithms. In addition, we calculated the Spearman correlation coefficient between the microseism energy and wave power trend time series to explore the relationships among these two parameters.

Despite the limited number of stations used in this study (just nine), which is insufficient for robust statistical analysis, our exploratory analysis provides insights into the potential of microseisms and their relationships with sea states and wave power over the long term analysis. This research serves as a pioneering effort for the Mediterranean Sea region. With the recent expansion in the number of seismic stations, increased data-sharing, and the escalation of climate-related extreme events, the findings from this study can be further refined and expanded in the future to enhance coastal monitoring efforts both in the Mediterranean Sea and at a global scale.

Mapping of *Posidonia oceanica* meadows in the Capo San Marco offshore (Sciacca, Sicily): evaluation of the lower limit using geophysical methods

Corradino M.*, Lo Presti V., Cassataro R., Agate M. & Sulli A.

Dipartimento di Scienze della Terra e del Mare, Università di Palermo.

Corresponding author email: marta.corradino@unipa.it

Keywords: habitat mapping, Posidonia oceanica, Sciacca offshore.

Posidonia oceanica, one of the most important and abundant endemic seagrass in the Mediterranean Sea, forms large meadows from the sea surface down to about 40 m, colonizing rocky and sandy substratum. Environmental factors (e.g. salinity, temperature, turbidity, chlorophyll A) influence the spatial configuration of *P. oceanica* meadows. In particular, the literature suggests that the increase in turbidity results in a decrease in lighting and, consequently, the rising of the lower limit of the seagrass meadow.

In this work, we map the *P. oceanica* meadows in the Capo San Marco offshore (Sciacca, Sicily), using geophysical data acquired by a Side Scan Sonar (SSS) and Multibeam sonar system from about 20 m to 45 m of water depth. Several video and photo images were acquired in selected locations to validate acoustic data. SSS images revealed the presence of acoustical facies related to rocky substratum colonized by the *P. oceanica* as patchy zones and dense, extensive meadows. An anomalous signal of the multibeam image overlaps to with the SSS acoustical pattern, revealing that the *P. oceanica* meadows extend up to about 35m of water depth. This value represents the lower limit of seagrass meadows in the Capo San Marco offshore and differs from the depth of 25 m documented in the literature (Andaloro et al., 2007; Perzia et al., 2011). Photo and video images, acquired up to about 33 m of water depth, showed *P. oceanica* meadows of turbid water and zones of widespread suspended sediments.

This research documents the deepening of the lower limit of the *P. oceanica* in the study area, which is a key factor in evaluating the extension/regression balancing of the meadows. Also, this work would imply a re-evaluation of the influence of the turbidity in the *P. oceanica* growth and could allow for a better estimate of the extent of meadow in turbid water.

Corresponding author email: marta.corradino@unipa.it

Keywords: coastal boulders, columnar joints, extreme waves.

Coastal boulder accumulations are the result of the detachment of blocks from the rocky shore platform, their transport and deposition along the coastal area under the action of extreme waves. We examined the distribution, dimension, geometry and lithology of boulders detected in the volcanic island of Pantelleria (Sicily Channel, Mediterranean Sea), highlighting the relationship between the boulder production and the volcanic rock features (i.e., columnar cooling fractures and horizontal layers defined by ignimbrite flows). We used geological data for 125 boulders and 21 rupture surfaces, integrated with the fracture analysis, two radiocarbon dating, numerical hydrodynamic analysis, and hindcast numerical model of the wave characterization. The boulder field extends up to ~60 m from the shoreline of Punta Sidere (NW coast of Pantelleria) and consists of isolated blocks or groups elongated obliquely, perpendicular or parallel to the coast. Boulders are composed of ignimbrite and, to a lesser extent, basalt. The average dimension is ~120×85×40 cm on the major (A), medium (B), and minor (C) axes, respectively. Boulders were dislodged from the rocky platform as suggested by 1) the correspondence between the lithology of boulders and the rocks outcropping along the coast and 2) the compatibility between the shape of the boulders and the rupture surfaces carved out in the rocky platform. The morphometric analysis of the characteristics of boulders and outcropping rocks demonstrates that the columnar fracture set and the thickness of horizontal planes within the ignimbrite flow controlled the polygonal surfaces and size (A- and B-axis) of the boulders and their thickness (C-axis), respectively. The numerical hydrodynamic analysis indicates that the quarrying, transport and deposition of boulders was mainly the result of storm events characterized by wave heights ranging from ~2 m to ~8 m. The comparison between the storm wave heights computed by hydrodynamic equations and the results of the hindcast numerical model confirms that the waves approaching the coastline can reach heights of ~8 m. The storm events occurred at different times, even very recent, as suggested by two radiocarbon dating of biogenic encrustations collected from the boulders surface and presence of woods and plastics embedded within the boulder deposits.

The evolution of the Mortorio submarine canyon (Eastern Sardinia Margin): preliminary ideas from a process-oriented morphologic interpretation of a shelf-indenting canyon

De Carlo C.*[1], Ferrante V.[2], Longhitano S.G.[1] & Gamberi F.[2]

[1] Dipartimento di Scienze, Università della Basilicata, Potenza. [2] Istituto di Scienze Marine, CNR, Bologna.

Corresponding author email: catrine.decarlo@studenti.unibas.it

Keywords: submarine canyon, morphology, sub-bottom profiles.

In this contribution we present an initial interpretation, resulting from a Master's degree thesis work, of the processes that contribute to the shaping of a submarine canyon located along the Sardinian Margin. In particular, our poster focuses on the study of the Mortorio Canyon located along the Eastern Sardinian Margin. Our analysis has been carried out through the integrated interpretation of multibeam bathymetric data and CHIRP sub-bottom profiles.

The Mortorio submarine Canyon, located in the northeastern part of the Sardinian margin, has its head 15 km from the coastline, deeply incises the external shelf and then mostly develops in the Olbia Basin slope.

A preliminary morphological analysis was carried out to identify the elements that could be represented in a morphologic map in order to highlight the processes that have contributed to the evolution of the canyon. This has led to the construction of a legend were all the erosional and depositional features in the canyon head, flanks and floor are symbolized. Successively, the interpretation of the canyon morphology was complemented with the analysis of CHIRP sub-bottom profiles. The latter allowed the analysis of the most superficial layers of the seabed, the definition of their character and geometries and the interpretation of their sedimentary significance. In summary, the present analysis sheds light on the processes -landslides, gullying, axial thalweg entrenchment, bottom currents- that lead to canyon excavation. It shows that also depositional processes occur in some portion of the Mortorio Canyon. Our analysis highlights a complex spatial interplay of erosional and depositional processes that leads to marked longitudinal variations in the morphologic architecture of the canyon. Thus, it can aid in the interpretation of similar environmental settings in fossil examples exposed on land or imaged on seismic data. The preliminary results of the Master's degree thesis may contribute to the definition of the geological hazard associated with a canyon. In addition, they show the large variability of environments that must be considered when addressing studies on biodiversity development in submarine canyons.

Drone remote sensing and geopedological analyses for precision farming viticulture in the area of Montalcino (Siena, Italy)

Keywords: precision agriculture, UAV remote sensing, vineyard crops health management.

Precision agriculture has emerged as a crucial approach in modern farming, leveraging advanced technologies to optimize crop management practices (Samreen et al., 2022). Among these technologies, remote sensing plays a pivotal role in providing valuable insights into crop health and facilitating informed decision-making (Khanal et al., 2017). This article explores the integrated use of remote sensing techniques and geopedological analysis for studying vegetation health, focusing on vineyard crops in Montalcino area (Siena, Italy). In this context, the utilization of drones equipped with multispectral and thermal sensors allowed the creation of thematic maps, which provide valuable information on crop health, soil moisture content, and water stress. These data serve as input for the generation of prescription maps for either irrigation or fertilization, enabling precision agriculture practices tailored to specific crop requirements (Sishodia et al., 2020). However, despite the potential benefits, further research is needed to deepen remote sensed info and to address relevant mathematical indices for disease identification, water content assessment, and water quality evaluation (Hunt & Daughtry, 2018). Close-range hyperspectral data can be particularly useful in this regard, allowing for the identification of wavelengths correlated with vegetation health indicators and soil moisture content. Moreover, remote sensing enables the estimation of soil moisture variability, facilitating the differentiation of areas with high electrical conductivity due to either water content or clay minerals. Achieving optimal soil moisture content is essential for agricultural productivity and water conservation efforts, especially in the context of climate change adaptation and socio-economic dynamics. By integrating remote sensing and laboratory geopedological analyses, precision agriculture practices can contribute to sustainable farming production while addressing challenges related to water scarcity and climate variability.

Keywords: Quaternary alluvial deposits, Gargano.

Gargano is a morphostructural karstic high of Apulia (Southern Italy) affected by severe uplift and active seismicity. Locally, due to uplift, alluvial deposits perched on rocky sea-cliff cutting incised valleys may be observed along the eastern coast of Gargano. Up to about 20 m-thick natural sections exposed at Mattinatella locality show that alluvial sediments alternate with eluvial/colluvial deposits, in which several generations of paleosoils and some tephra layers may be observed. According to preliminary age obtained by some handmade objects found in a soil layer, studied sections should represent the sedimentary record of the last glacial period, probably characterized by a significant rate of relief erosion and by active sedimentation at the toe of the morphostructural karstic high. Present-day alluvial basins seem to be starved and the main active process is the erosional retreat of sea-cliffs. A detailed facies analysis, currently in progress, and new awaited dating could contribute both to better understand the sedimentological evolution and to constrain the age of these continental deposits.

From waste to resource: recovery of quarry by-products for zinc foliar fertilization

Keywords: zinc biofortication, zeolite and pumice, rain leaching.

Zinc (Zn) is an essential micronutrient for plants, particularly involved in bolstering disease tolerance of crops. When plants require more Zn than the amount available in the soil, using Zn fertilizers (biofortication) becomes essential (Cakmak, 2008). However, conventional methods often rely on soluble Zn salts, that once applied to the soil are easily subject to complexation with soil components or precipitate, becoming unavailable to the root system. Even when applied as foliar treatments, these salts (commonly $ZnSO_4$) are prone to leaching (Chen et al., 2022).

We therefore propose a novel controlled-release formulation that involve the adsorption of Zn in reactive zeolites: mineral phases known for their capacity to separe and recover cations from aqueous solutions (e.g., Galamini et al., 2024), and their subsequent use as carriers for Zn foliar application. The process involves the reutilization of mine wastes (pumice and lapillus) along with zeolitized tuff. Different proportions have been tested for Zn adsorption, and the subsequent release, identifying a 70% zeolite-rich tuff and 30% pumice (containing significant amount of zeolite species) as the most viable.

A greenhouse test was performed on Vitis vinifera, comparing the most promising formulate with conventional $ZnSO_4$. The aim was to assess differences in the permanence of Zn on plant leaves after several treatments and a simulated rainy event. The results showed a greater resistance of the formulation respect to conventional $ZnSO_4$, also concurrently suggesting the potential for dosage reduction. Furthermore, the incorporation of 30% pumice scraps in the formulate may allow to revaluate important fractions of mining byproducts.

Climate variations and crop yields: a sustainability issue illustrated by a case study from the Abruzzo region, Italy

Keywords: climate variations, crop yield, climatic trend, correlation analysis, sustainability.

Climate variations, of short- and long-term, pose a major sustainability challenge, with potential far-reaching economic and social impacts, including fluctuations in agricultural yields and subsequent volatility in prices and the availability to populations of essential food resources. To investigate the effects of short- and long-term climate variation on crop yields, the four provinces of the Abruzzo region, in central Italy, were studied in terms of temperature, precipitation and agricultural yields of wheat, olive and grape.

This study illustrates a detailed statistical analysis involving climatic variables and crop yields over the time range 1952-2014, at a provincial scale in the Abruzzo Region. To individuate variations in the correlation between agricultural production and climatic condition over time, the statistical correlation was analyzed between indices, such as standardized precipitation indexes (SPI and SPEI) calculated over different months of the year, with the oscillations of crop yield around the trend, described by standardized residual yield series (Guerriero et al., 2023). Such correlation has been calculated for several time windows, each of thirty years wide, over the time range 1952-2014.

The results are summarized as follows:

- In the studied provinces, the maximum and minimum daily temperatures show variation in the trend over the past 60 years;
- In the studied provinces, climate is moving from temperate towards temperate-arid, with an increase in drought intensity and persistence, starting from the 1980s;
- The correlation analysis highlighted an increase in correlation between crop yield and climatic fluctuations, over the past 60 years. Such rise can be interpreted as an increasing sensitivity of the agricultural production system to climate fluctuations, over time.

Although the considered agricultural production system exhibits a progressive yield growth, an increase in correlation between production and climatic fluctuations highlights, on the one hand, an inability of the system itself to maintain high performance even in unfavorable climatic conditions. On the other hand, yield fluctuations (even positive ones) always represent a potential disturbing element of related market equilibria.

From emplacement to exhumation of a granitic intrusion in a highly extended continental crust: insights from the Pliocene Gavorrano granite (Northern Apennines, Italy)

Keywords: magma emplacement, granite exhumation, Gavorrano pluton.

Granites emplaced in the upper crust during Neogene-Quaternary, and now exposed at the surface, bear witness to fast or rapid exhumation and can provide insights to understand the relationship between magmatism and exhumation. Unravelling the depth and timing of their emplacement and the processes favoring their exhumation, has become worthwhile. Recent chronological constraints on cooling histories indicate that extremely high rates of tectonic exhumation are feasible, particularly during late orogenic extension when crustal anatexis, detachment faults and thermo-rheological perturbation produced by the granitic intrusions are active. The Gavorrano pluton, one of the Neogene granites of the Tuscan Magmatic Province (Italy) emplaced in the inner Northern Apennines during the Neogene extensional tectonics, is well suited to determine and quantify the exhumation process. Integration of petrological and geochronological (Zircon U-Pb) data revealed that the Gavorrano granite was emplaced at 4.9±0.2 Ma ago, before the end of the earliest Pliocene (Zanclean), under a minimum crustal pressure of 120 MPa corresponding to a minimum depth of c. 4.5 km. On the other hand, Apatite (U-Th)/He thermochronological data indicate an exhumation age of 4.21±0.46 Ma for the pluton representing the time of cooling below the established closure temperature in response to exhumation. Even before the ascent and emplacement of the Gavorrano granite, the region must have been characterized by a high thermal gradient due to the lithospheric thinning that affected the northern Tyrrhenian domain. After the emplacement of the granitic magma, this high thermal gradient is further increased. Given an exhumation timing of c. 1.35 Myr, the minimum estimate of the average exhumation rate for the Gavorrano pluton is 2.6 mm/yr down to 1 km below the surface. The emplacement and exhumation of the granite was driven by the interplay between the SW–NE striking left–lateral regional transfer zone and top–to–the ENE and WSW low–to middle–angle normal faults. The near vertical permeability favored by the transfer zone allowed the magma to be emplaced, while the normal faults favored the condition for uplift and exhumation.

Keywords: energy transition, global warming, critical minerals.

The energy transition is one of the hottest topics both in the scientific world and in social media and coffee shop discussions. Despite this important nature, unfortunately the approach adopted is generally superficial. When the reasoning is instead based on scientific argumentations, it is easy to see how it is based on unrealistic to easily refutable hypotheses. The arguments can be grouped in two main reasoning styles. One is of conspiracy-type, and considers the possibility of moving to a decarbonized world immediately as a real thing, hindered only by oil lobbies and old-style oil industrialists (e.g., Jacobson, 2023). The other considers, with a greater dose of realism, that the energy transition is extremely difficult, very expensive and certainly impossible to achieve except in a few decades of gradual adaptation (e.g. Smil, 2022).

The transition to a decarbonized society is certainly possible, but only if we accept a long-lasting and very painful degradation of our life styles. Developing countries would significantly delay the transition to better living conditions, as instead envisaged by the United Nations' Sustainable Development Goals. We certainly could not ask them to make the sacrifices that OECD countries will have to face. Rich countries, even in light of the immeasurable wealth they have accumulated especially since the Second World War due to the easy access to immense energy source exemplified by fossil fuels, will be called upon to make the greatest contribution to change their socio-economic models. This possibility, even if spread over a few decades, will be hardly accepted by society and very few political parties will be willing to set their communication strategies in this direction.

Society is not well aware of what a transition to a completely decarbonized world or to a world with net zero CO_2 emissions could imply (a topic that is still very poorly defined, as no valid industrial-scale options for neutralizing or safely confining CO_2 are yet available). The first step to follow would be to limit consumption, and immediately after start thinking about how to diversify energy sources to continue obtaining goods for our well-being. Renewable sources will never be able to satisfy the lifestyles of rich countries in any way because they are intermittent, inconstant and have poor energy density expressed per unit of surface area or unit of volume. Indeed, the problem of modern societies is not the availability of energy, considering that solar radiation alone could satisfy all current energy requirements by many hundreds of times. The fundamental problems we will face are of two types: the availability of energy when we need it, not when it is most abundant, and the availability of matter, which will be transformed through renewable energy into the objects of our desires.

Sedimentological analysis of the Jurassic pelagic "oolites" (Buccheri Formation, Western Sicily): paleoenvironmental and paleogeogra phic implications

Petrella F.* & Todaro S.

Dipartimento di Scienze della Terra e del Mare, Università di Palermo.

Corresponding author email: francesca.petrella@unipa.it

Keywords: Jurassic, oolites, paleoenvironment.

The sedimentological analysis of the Jurassic limestones outcropping in Western Sicily provided new data on a lithofacies containing pelagic "oolites" whose genetic origin is still debated.

The pelagic "oolites" (Jenkyns, 1972) is a lithofacies of the Buccheri Formation, informally known as "Rosso Ammonitico", a condensed pelagic succession that was deposited at the top of the drowned carbonate platforms of Western Tethys during the Early-Middle Jurassic. This formation exhibits differences in terms of texture, fossil content and geometry documenting variation in the sedimentation processes.

The pelagic "oolites" facies usually occurs along the lower (e.g. Monte San Calogero area, Sciacca, southwestern Sicily) or the upper member (e.g. Monte Maranfusa, central-western Sicily) of the Buccheri Formation and sometimes reaches thickness up to 25 m. It is represented by packstone/grainstone, with small spheroidal ooids, exhibiting a diameter always < 0.4 mm, planktonic foraminifera (*Globuligerina* sp.), crinoid fragments and rare benthic foraminifera (*Lenticulina* sp.). The "ooids" (or "microonkolites"; Jenkyns, 1972) sometimes exhibit a well-preserved tangential micritic lamination and the nucleus is in some cases represented by *Globuligerina* sp. The lower boundary is often sharp on the underlying lithofacies represented by a thin-shelled bivalves (*Bositra* sp.) packstone or by crinoidal packstone/grainstone. The upper boundary is transitional to the ammonitic-rich limestone or to *Saccocoma* limestone.

As regard the genetic origin, the presence of planktonic foraminifera included at the nuclei may indicates that they have formed by particle adherence, meanwhile the preserved concentric lamination is consistent with a genetic origin linked to sediment trapping by algae, as suggested by Jenkyns (1972). The *Globuligerina* sp. probably acted as nuclei around which those ooids grew. The presence of pelagic faunal elements indicates that they were primarily formed on top of submarine paleotopographic high. Sometimes, the "pelagic oolites" exhibit downlap termination, for the first time observed along the Western Sicily successions, on the underlying lithofacies (Monte San Calogero area) suggesting the occurrence of reworking and risedimentation processes, probably related to bottom current activity, that determined their redeposition. These features represent a useful tool in paleogeographic and paleoenvironmental reconstructions.

Keywords: magnetite, reactive oxygen species, simulated biological fluids.

Biogenic magnetite nanoparticles (NPs) have been found in the human brain (Kirschink et al., 1992). At the same time, exogenous ferrimagnetic NPs have also been detected in the human brain, mainly derived from anthropogenic activities such as combustion processes (Maher et al., 2016). After inhalation, exogenous NPs or pathological biogenic NPs can accumulate in several organs, including the brain. Bioaccumulation of ferrimagnetic NPs can cause an overproduction of reactive oxygen species (ROS). Indeed, ferrimagnetic NPs can produce ROS in several ways, such as the release of metal ions, adsorption of metals or compounds, interaction with carbon dioxide, water, or molecular oxygen, or by cellular inflammation. ROS can lead to various toxic effects, including cancer (Schoonen et al., 2006). The listed ROS production mechanisms are all influenced by the ferrimagnetic NP mineralogical phase. To examine in depth the pathways with which ferrimagnetic NPs can produce ROS in humans, it is crucial to investigate the evolution of the physicochemical state of these minerals and their possible transformations while present in different body compartments. In this regard, simulated biological fluids (SBFs) are useful in studying the dissolution kinetics and ROS formation processes of ferrimagnetic NPs inside the human brain.

The presented research aims to investigate the interaction between magnetite NPs and SBFs (a phosphate buffer saline solution - PBS) and related physiochemical transformation of NPs. The experiments were thus divided into three main steps. First, we characterized magnetite NPs (50-100 nm) through the following techniques: XRPD for identifying all mineral phases, SEM to determine the dimensional distribution of NP aggregates, HR STEM to collect morphological and crystallochemical information on single NPs and perform dimensional measurements, Dual-EELS for determining the Fe-valence state, and 4D STEM to identify any local inhomogeneities in the NPs. Secondly, following the initial characterization, magnetite NPs were placed in PBS at various concentrations (0, 50, 100, 200, 300, 400, 600 µg/ml), and then sampled at different times (0.5, 1, 12, 24, 48, 96, and 168 hours). ICP-MS was used to analyze filtered PBS to detect Fe released into the PBS solution. Lastly, magnetite NPs retrieved from the solution after 168 hours of interaction were subjected to the same characterization as the starting material. Preliminary results indicate no significant differences in morphology, dimensions, and crystallochemistry of both individual NP surfaces and NP aggregates, and ICP-MS revealed no release of Fe to the PBS. These first results suggest that Fe cations may be locally released from the NPs after interaction with SBFs, but these cations rapidly precipitate and rearrange on the surface of the NPs.

Organobentonites as perspective adsorbents for nonsteroidal anti-inflammatory drug - diclofenac sodium

Smiljanić D., Daković A.*, Marković M., Ožegović M. & Obradović M.

Institute for Technology of Nuclear and Other Mineral Raw Materials, Belgrade, Serbia.

Corresponding author email: d.smiljanic@itnms.ac.rs

Keywords: clays-surfactant composites, diclofenac, adsorption.

Various chemical substances found in natural water sources and wastewater are considered as emerging contaminants since they exhibit resistance to traditional water treatment methods and persist in treated effluents. Of particular concern are pharmaceuticals, given to their widespread use and potential adverse effects on human health, especially when they contaminate drinking water (Rivera-Utrilla et al., 2013). Nonsteroidal anti-inflammatory drugs (NSAIDs), such as diclofenac, ibuprofen, and naproxen, commonly used in both human and veterinary medicine for pain relief, are frequently detected in various water bodies, raising concerns about their environmental impact. Diclofenac has attracted global attention as an emerging contaminant, especially after its veterinary use was linked to the decline of scavenger bird populations. Additionally, studies have emphasized the adverse effects of diclofenac on aquatic organisms, further highlighting its environmental significance (Lonappan et al., 2016). Different methods have been explored for removal of emerging contaminants from water sources, including advanced oxidation processes, activated sludge, adsorption, membrane filtration, and others (Rivera-Utrilla et al., 2013). Among the techniques for effective removal of NSAIDs from polluted water, adsorption onto different materials such as activated carbons, clays, and zeolites is a promising approach (Smiljanić et al., 2020; Obradović et al., 2022).

This research aims to investigate the potential of modified bentonite in the removal of diclofenac from water solution. The natural bentonite from the Šipovo deposit in Bosnia and Herzegovina underwent modification using dodecylamine - an aliphatic primary amine, and di(hydrogenated tallow)dimethylammonium chloride - a quaternary ammonium salt known under a tradename Arquad®2HT-75. Both surfactants were used in quantities equivalent to 50% and 100% of the bentonite's cationic exchange capacity. Analysis of the prepared samples via Fourier-transform infrared spectroscopy and simultaneous thermal analysis confirmed the presence of the surfactant in the modified bentonites. Adsorption isotherms demonstrated that the adsorption of diclofenac increased with the increase of surfactant amount, as well as with the increase of the initial pharmaceutical concentrations. The highest adsorption of the drug occurred with bentonite containing the highest surfactant concentration, with slightly higher adsorption reported for composites with Arquad®2HT-75. Considering that natural bentonite exhibits minimal affinity for diclofenac removal, these findings indicate that organobentonites have significant potential as effective adsorbents for eliminating diclofenac from contaminated water sources.

Synthesis and structural characterization of a new high-pressure and high-temperature $CaSiO_3$ polymorph

Chrappan Soldavini B.* & Merlini M.

Dipartimento di Scienze della Terra "A. Desio", Università di Milano.

Corresponding author email: benedetta.chrappan@unimi.it

Keywords: CaSiO3, Multianvil, single-crystal diffraction.

The $CaSiO_3$ system represents one of the most abundant pure calcium silicates on the Earth and the third most abundant phase in the Earth's mantle, after bridgmanite and Fe-periclase. Despite having such a simple chemical composition, its phase diagram is characterized by a wide number of different polymorphs and polytypes in the pressure interval 0-9 GPa (Mazzucato & Gualtieri, 2000; Milani et al., 2021). At pressures lower than ~3 GPa, this system exhibits a Si-tetrahedra chain structure, corresponding to the minerals wollastonite and parawollastonite. The high temperature polymorph pseudowollastonite (ps-woll), commonly found in cements, has a 3-fold rings configuration. At mantle conditions another 3-fold structure named breyite, is stable and it is widely found as inclusion in diamonds (Brenker et al., 2021).

In the low-temperature stability field of breyite, a single study (Chatterjee et al., 1984) reported a potential new polymorph with unknown structure, named wollastonite-IIm (woll-IIm), further increasing the complexity of the system.

In this study, we conducted multianvil syntheses in the PT stability field of the new polymorph to stabilize single crystals and obtain structural information. The first synthesis was performed at 4 GPa and 700°C and resulted in sub-micrometric crystals not suitable for standard X-ray diffraction. 3D electron diffraction allowed the determination of a triclinic unit cell with parameters compatible with woll-IIm, but no structural information could be obtained due to nanometric scale twinning and strong streaking in diffraction. Consequently, a second synthesis has been conducted at higher temperature conditions (4.5 GPa, 800°C) and additional water content as fluxant, to increase the kinetics of crystal growth. Crystal grains with 50x50x50µm3 dimension suitable for single crystal X-ray diffraction were successfully isolated and their diffraction were indexed thanks to the unit cell determined by 3D ED.

Structural resolution confirmed the triclinic symmetry with space group $P\bar{1}$ and unit cell parameters a=8.1911(10) Å, b=9.3441(9)Å, c=10.4604(10)Å, α=73.901(8)°, β=89.814(9)°, γ=77.513(9)°. Woll-IIm is characterized by a 3-fold rings tetrahedra configuration with different tetrahedra orientation with respect to the breyite structure.

To compare the thermo-elastic behaviour of the two high pressure ring-structures, PV and VT equation of state for woll-IIm have been determined through in-situ single crystal X-ray diffraction. We observed that there is no direct structural relationship between woll-IIm and breyite, being the latter quenchable, further suggesting that the natural occurrence of one of the two ring structures could provide insights on the temperature conditions of its formation. To assess the possibility of discriminating between the two polymorphs in mineral inclusions, we also present the first Raman spectrum of woll-IIm.
