a cura della Società Geologica Italiana

BARI 2024

Geology for a sustainable management of our Planet

PRESIDENTS OF THE CONGRESS

Luisa Sabato (SGI), Emanuela Schingaro (SIMP).

VICEPRESIDENT OF THE CONGRESS

Marcello Tropeano (SGI).

SCIENTIFIC COMMITTEE COORDINATOR

Sandro Conticelli (Università di Firenze).

SCIENTIFIC COMMITTEE

Lucia Angiolini (Università di Milano), Giuseppina Balassone (Università di Napoli), Domenico Calcaterra (Università di Napoli), Angelo Camerlenghi (OGS), Serafina Carbone (Università di Catania), Chiara Cardaci (Protezione Civile), Domenico Chiarella (Royal Holloway, London), Angelo Cipriani (ISPRA), Paolo Conti (Università di Siena), Giovanni De Giudici (Università di Cagliari), Patrizia Fiannacca (Università di Catania), Diego Gatta (Università di Milano), Guido Giordano (Università di Roma Tre), Lara Maritan (Università di Padova), Annalisa Martucci (Università di Ferrara), Ilaria Mazzini (CNR-IGAG), Stefano Mazzoli (Università di Camerino), Barbara Nisi (CNR-IGG), Stefano Poli (Università di Milano), Giovanna Rizzo (Università della Basilicata), Laura Scognamiglio (INGV), Mauro Soldati (Università di Modena e Reggio Emilia), Mario Tribaudino (Università di Torino), Chiara Varone (CNR-IGAG).

ORGANISING COMMITTEE

Donato Belmonte (SIMP), Bernardo Carmina (Università di Pisa), Fabio Dioguardi (Università di Bari), Giacomo Eramo (Università di Bari), Lorenza Fascio (SIMP), Vincenzo Festa (Università di Bari), Marilena Filippucci (Università di Bari), Fulvio Franchi (Università di Bari), Salvatore Gallicchio (Università di Bari), Giulia Innamorati (SGI), Maria Lacalamita (Università di Bari), Isabella Serena Liso (Università di Bari), Stefania Lisco (Università di Bari), Piernicola Lollino (Università di Bari), Daniela Mele (Università di Bari), Patrizia Maiorano (Università di Bari), Nadia Malaspina (SIMP), Virginia Marchionni (SIMP), Giuseppe Mastronuzzi (Università di Bari), Ernesto Mesto (Università di Bari), Francesca Micheletti (Università di Bari), Mario Parise (Università di Bari), Fabio Massimo Petti (SGI), Angela Rizzo (Università di Bari), Giovanni Scardino (Università di Bari), Giovanni Scicchitano (Università di Bari), Luigi Spalluto (Università di Bari), Simona Tripaldi (Università di Bari), Alessandro Zuccari (SGI).

COMMUNICATION COMMITTEE

Giovanna Agrosì (Università di Bari), Giulia Innamorati (SGI), Christian Leo (Università di Bari), Fabio Massimo Petti (SGI), Virginia Marchionni (SIMP), Nicola Venisti (Museo di Scienze della Terra, Università di Bari), Martina Zucchi (Università di Bari).

ABSTRACT BOOK EDITORS

Bernardo Carmina, Lorenza Fascio, Giulia Innamorati, Virginia Marchionni & Fabio Massimo Petti.

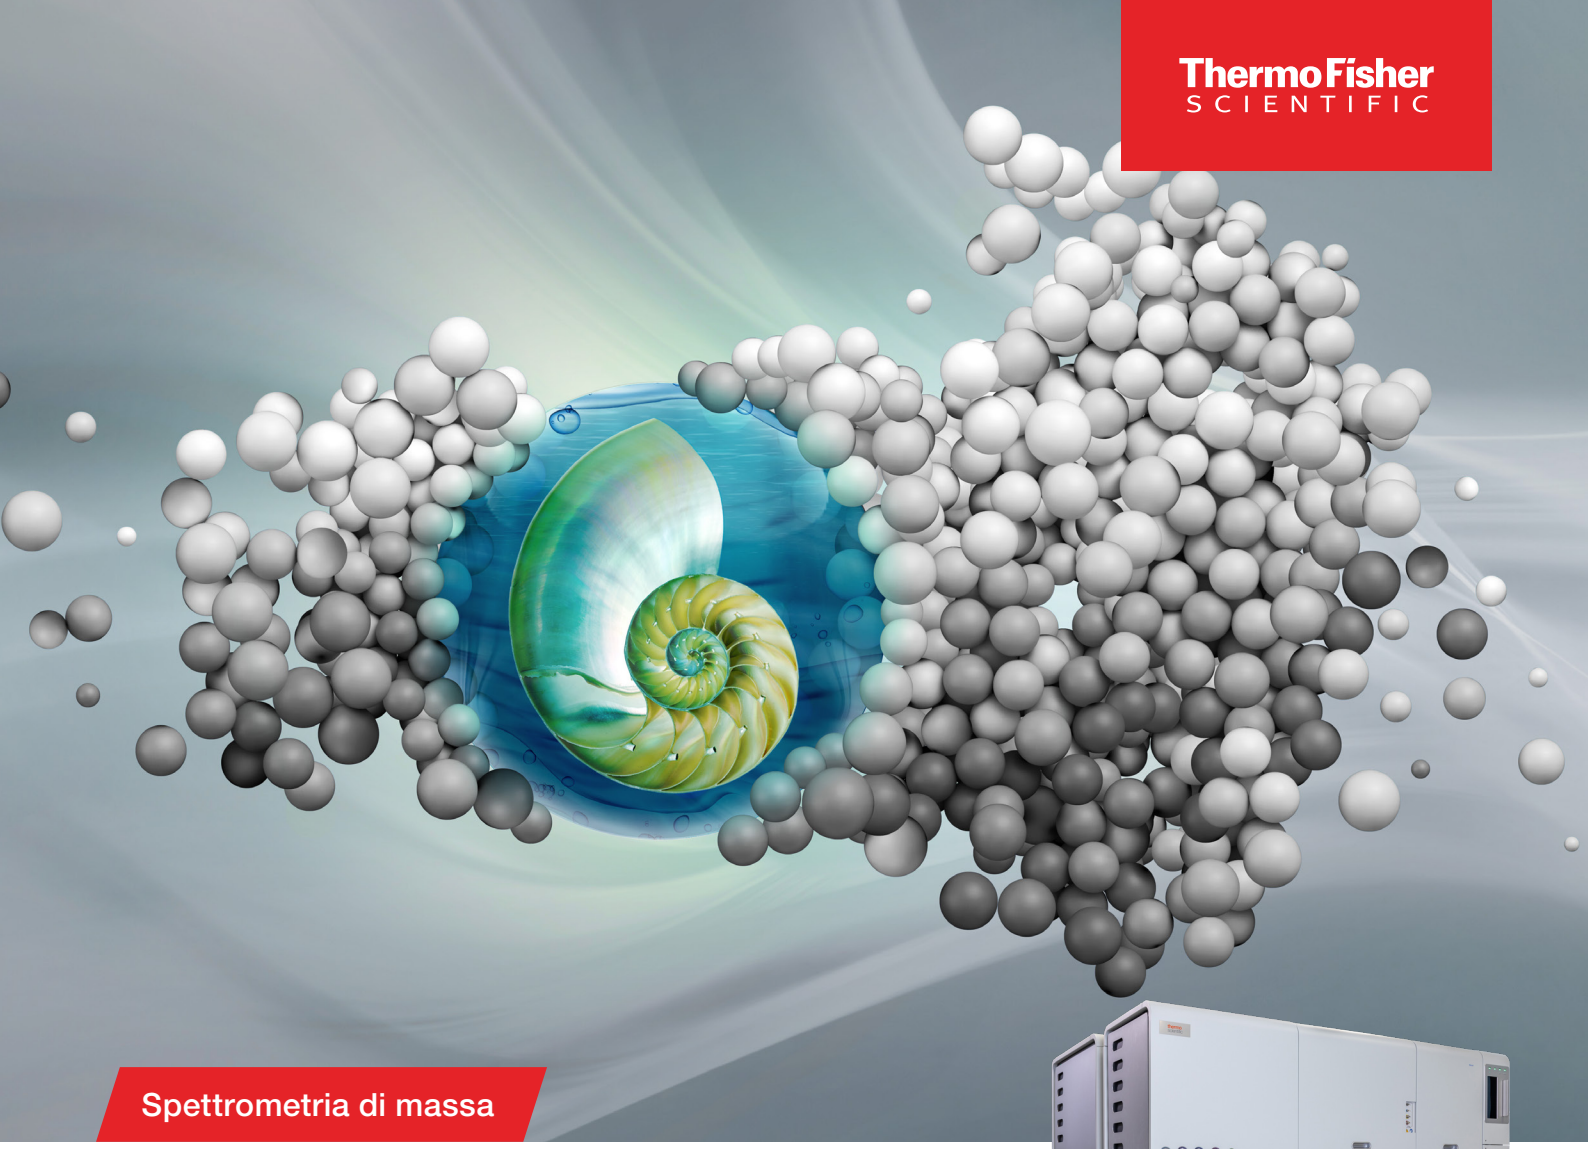
ThermoFisher SCIENTIFIC



Spettrometria di massa

Rompe il muro del rumore

Uno strumento, un mondo di possibilità

Ricerche complesse non significano analisi complicate. Thermo Scientific™ Neoma™ MS/MS MC-ICP-MS filtra il rumore di fondo per fornire rapporti isotopici di eccezionale qualità con una chiarezza sorprendente.

L'esclusiva tecnologia MS/MS all'interno di Neoma MS/MS MC-ICP-MS consente la separazione delle interferenze isobariche utilizzando un filtro di massa pre-cella combinato con una cella di collisione/reazione dedicata.

Neoma MS/MS MC-ICP-MS consente di misurare sia in modalità standard MC-ICP-MS che utilizzando la tecnologia MS/MS. **Supera i confini della tua ricerca!**

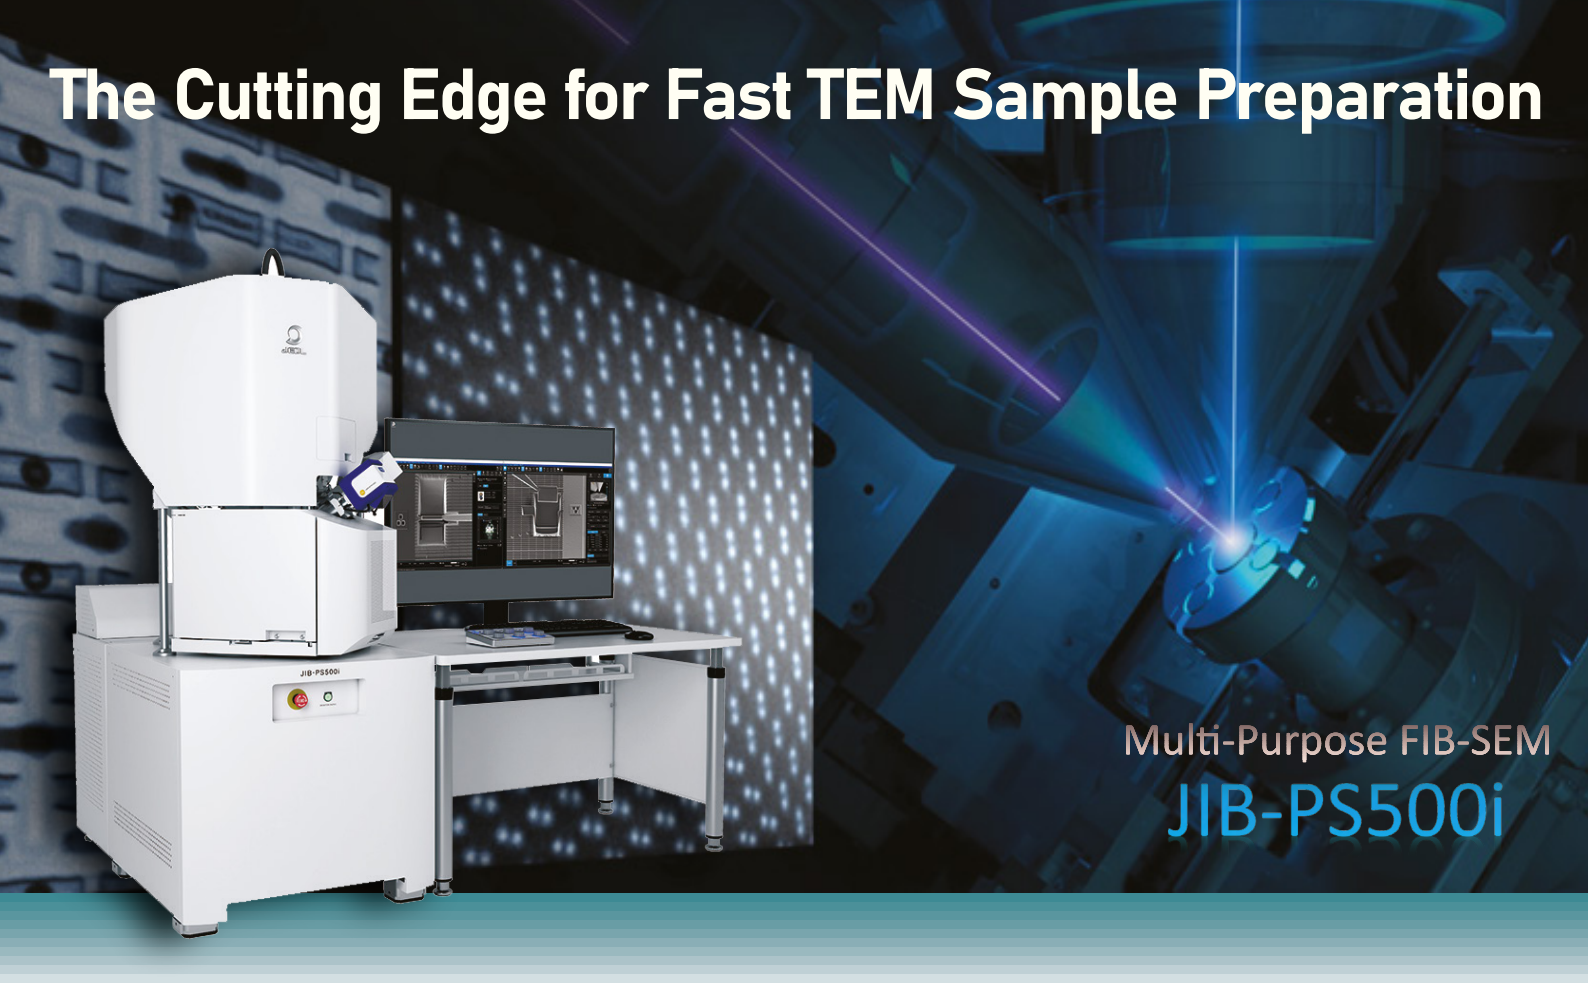
The Cutting Edge for Fast TEM Sample Preparation



Robust Workflow for High Quality TEM Sample Preparation

Atomic Resolution STEM and TEM Sample Preparation

The all-new JIB-PS500i from JEOL delivers fine milling capabilities essential for fast, high quality lamella preparation. This multi-purpose FIB-SEM enables high throughput sample preparation, high resolution STEM-in-SEM imaging, and analytical analysis.

Robust Workflow for Large Samples

Featuring a large specimen chamber with easy-access door and large high-tilt stage, the JIB-PS500i offers a truly flexible workflow. Transfer from the FIB-SEM to the TEM is seamless with TEM-Linkage, JEOL's double-tilt cartridge.

OPENING CERIMONY

Geoscience Communication During the Energy Transition

Jackson C.A-L.

Department of Earth Science & Engineering, Imperial College, London

Geological issues related to the Earth's subsurface increasingly intruding on the everyday lives of ordinary people. Whether it is the subsurface injection of water for geothermal power, the deep storage of waste such as CO_2 or spent nuclear material, or the storage and recovery of H_2 and O_2, the global public are being confronted with complex, often controversial, and yet critical (in terms of tackling the linked issues of global warming and lower-carbon energy provision) geological interventions beneath their homes. Communicating these complex scientific and technical issues is made more challenging by the general public's unfamiliarity with the geological realm, with cognitive studies highlighting that the public is anxious about what they perceive as tampering with nature. Relatively recent events have shown that this anxiety is not misplaced, given geothermally- and fracking-induced seismicity, and mine tailings dam failures.

The natural response of scientists is to assume that technical rigour and the simple conveyance of facts will allay the public's concerns and gain them 'licence to operate'. However, values and beliefs may trump data, particularly when filtered through the lived experience of individuals who not only have limited understanding of the Earth beneath their feet, but who have also experienced poor conduct by companies. Shaping public perspectives on controversial geoscientific issues are thus challenging, yet it is critical that companies are prepared for these discussions. With a growing recognition that it is social rather than technical factors that stir public unease and fuel community outrage, geoscientists need to develop new strategies to engage the sometimes-hostile public, underpinned by a culture change in geocommunication from conveying 'matters of fact' to brokering 'matters of concern'.

In this talk I will review several studies with the intent of how we might better communicate "contested geoscience"!

Geology and the Sustainble Development Goals

Adiyaman Lopes O. & Sabo R.

Section on Earth Sciences and Geoparks, Division of Ecological and Earth Sciences, Natural Sciences Sector, The United Nations Educational, Scientific and Cultural Organization (UNESCO)

Geology, with its quiet wisdom, reveals the connection of all life, showing that sustainable development is rooted in humans' mutual relationship with the Earth. UNESCO recognises that neglecting to understand our planet's geological framework could undermine 2030 the Sustainable Development Goals (SDGs). UNESCO, which holds the unique United Nations mandate for geoscience, directs a global network of geologists and sites working on projects related to the SDGs through its International Geoscience and Geoparks Programme (IGGP).

Geoscientists Unite for Planetary Challenges: The International Geoscience Programme (IGCP)

In collaboration with the International Union of Geological Sciences (IUGS), the IGCP programme harnesses the intellectual capacity of a worldwide network of geoscientists to lay the foundation for our planet's future, highlighting the importance of SDG 17: Partnerships for Goals amongst other. The IGCP supports projects under six themes: Earth resources, global changes and the evolution of life, geohazards, hydrogeology, geodynamics, and geoheritage, addressing global challenges and sustainable development. The programme also supports female scientists, youth, and those from developing countries.

As an illustration, IGCP project 767: Environmental Dynamics of Western Rwanda focus on SDG 3: Good Health and Wellbeing. This project conducts a comprehensive study of the Mount Nyiragongo region in Rwanda to understand potential health risks to inhabitants, particularly regarding volcanic emissions, soils, and lakes.

Geological Heritage for Everyone: UNESCO Designated sites and geosciences

UNESCO designated sites, World Heritage, Biosphere Reserves and Global Geoparks (UGGp), aim to protect our heritage, which is deeply connected with geology. Italy is home to the largest number of world heritage sites, with 59 inscribed properties, all of which relate to the geoheritage of Italy.

Humans have always been connected to Earth, and the 213 UNESCO Global Geoparks across 48 countries, as of 2024, uniquely embody this connection. Geoparks empower local communities to understand and nurture their territories. A UGGp integrates the protection and promotion of geological heritage with sustainable local development, focusing on conserving geological heritage alongside other heritage types to enhance community living conditions. Thus, the three pillars of a UGGp are geoconservation, education, and local sustainable development (Fornaro & Fernandes, 2018).

Concerning sustainable development, geoparks implement projects that benefit local communities through a "bottom-up" approach, which is demonstrated in the 11 UGGps in Italy (2024) . For example, Rocca di Cerere's UGGp in Italy, established a Local Development Strategy focusing on enhancing the area's sustainability by improving local environmental and cultural heritage, as well as agricultural resources. In the short term, it aims to improve residents' quality of life and social inclusion, while long-term goals include preventing depopulation and strengthening the social fabric.

UNESCO Global Geoparks make geology accessible to all and highlight the importance of connecting with local geological features for sustainable development.

Geology: as fascinating as difficult to describe

Bignami L.

Journalist and science communicator

The history of mankind is tied to the history of the Earth. The birth of our Planet, its evolution, the ongoing geological processes have allowed and allow the Planet to be alive and host life. Yet we know very little about what happened during Earth's 4.5 billion years of life, and we know even less about what lies beneath the surface. While all this is fascinating, the lack of knowledge of many geological processes makes it difficult to explain geology to non-geologists.

Luckily, sometimes nature comes to our aid: this is the case of Calabria, for example, where tectonic thrusts have bent the "layers" of the Earth by 90 degrees. It's as if instead of having a book to read page after page, you had a vertical book that allows you to see all the pages from above, from the first to the last one. Crossing Calabria from east to west across the verticalized layers, it is possible to walk from the rocks that were at the transition between crust and mantle up to the more superficial rocks of the crust. An example of how anyone can travel down to the depths of the Earth's structure while standing on its surface.

But explaining geology is also difficult because we are not used to imagining in three dimensions what is under our feet. And this is fundamental because the layers of the Earth are not always parallel to each other, and their chronological order is often reversed. In fact, buried "folds", "faults", and "thrusts" could have folded everything and brought very old rocks on top of younger rocks. The trained eye of a geologist can sometimes picture all this complexity, but for the layman things become simply too complex to understand. It takes knowledge and imagination, and a good dose of interpretation and creativity to properly convey the beauty of geology. In this way, a good geology communicator can show how, in addition to being useful, geology can lead to see the "beauty" of our Earth.

If geological dissemination can achieve this ambitious goal, it will lead us on the right path to understanding why the beauties of the Planet sometimes become destructive for mankind. Especially if and when mankind is unable to read the geological clues around us.

The storytelling of natural beauty to learn how to recognize and share it

Casalini E.

Journalist, writer, radio and television host

Italy, this privileged country where we are surrounded by beauty since our birth. And perhaps for this reason our eyes have become accustomed to absorbing all this beauty while our hands, words, actions, thoughts are less used to it.

Art, museums, archaeological areas, religious and civil buildings which made our cities, towns, villages with their amazing historic city center and squares like hearts. They are part of the incredible cultural heritage that we share with the world. This is the reason why people land here from every part of the world. And we can add music, speeches, culture, food and wine, craftsmanship, including fashion. All this, and much more, is the opera of human beings.

But also nature it's an absolute protagonist of our story. Even if we forget about it and it's a shame, because it has so much to tell.

In stones which gave substance to all architectures designed over the centuries and of which we are rightly proud. From Carrara marble that provides the material for Jago and Michelangelo's artworks, to the raw materials used to make the colors that filled our imagination. Like the most famous fresco in the world, the Last Judgment of the Sistine Chapel, whose blue has reached us with that intensity because it is made with lapis lazuli, a mineral extracted for 7 thousand years in Afghanistan's mines of Sar-e-Sang. And getting it there cost an arm and a leg and only a Pope could afford it.

So, the storytelling of that wonder becomes much richer if there is also the voice of a geologist in addition to the one of an art expert.

Thus our landscapes, our lands, from Sienna to the small spheres of Is Arutas' beach in Sardinia, become the reason for a trip. Better appreciated if told in any aspect.

To discover the beauty hidden within the mineral life that surrounds us.

PLENARY SESSIONS

Digital classroom for petrology and mineralogy

Antonucci M.

Carl Zeiss S.p.A.

Corresponding author email: marco.antonucci@zeiss.com

Keywords: digital classroom, connected microscopes, interaction.

Teaching is the art of passing knowledge of the few on to the many. For this you need a good overview of all the learners, a deep insight into the individuals, and the option of networking them all together. A digital classroom with connected microscopes is a valuable tool in teaching today. It enables endless opportunities to create hands-on, customizable learning experiences and build deep understanding in the classroom. Students learn easily from each other and experience learning successes in a playful way. Connected microscopes offer an interactive, digital platform which increases attention and motivation, and also gives freedom to the teacher. During the education, larger groups of students are required to spend several days per week in a microscopic lab. Learning time is always limited and the course leader often needs to set-up and dismantle the systems in shortest time. The microscopes must be robust and easy-touse. A digital classroom is a major benefit to course leaders it allows them to use microscopes that are connected to each other, and digital tools to support and enhance teaching and learning. The images and videos can be shared directly with students. This allows open discussion and the explanation of the visible components. Fast acquisition, taking notes and annotating, saving and sharing the results are necessary. Direct access to each student's microscopic live image for the course leader makes the classroom more interactive. Students, as well as course leaders, should be inspired and have fun.

How Geoscientists can make the difference in industrial carbon storage projects

Della Moretta D.*

ENI SpA.

Corresponding author email: davide.della.moretta@eni.com

Keywords: CO_2 storage, basin geology, geological modeling, structural geology.

The underground storage of CO_2 is considered one of the most effective strategies to mitigate climate change by removing CO_2 from the atmosphere, with special reference to the so-called 'hard-to-abate' industries. The search for a safe pore space is a huge problem for any company interested in reducing their emission profile. Subsurface knowledge and understanding are therefore key factors in finding suitable sites which must be able to store a significant amount of CO_2. To be effective, an industrial storage project must tackle a series of geological issues which are more complex than the traditional O&G workflows. Therefore, the Geoscientist has a key role in designing effective storage solutions, from regional screening to site monitoring, providing the scientific basis for regulatory frameworks and public assurance.

The birth of the modern ocean and its first 180 million years of crises, speciations and extinctions

Erba E.*

Dipartimento di Scienze della Terra "A. Desio", Università di Milano.

Corresponding author email: elisabetta.erba@unimi.it

Keywords: ocean ecosystems, coccolithopores, Mesozoic, biodiversity, resilience.

Along with diatoms, cyanobacteria and dinoflagellates, coccolithophores are responsible for primary productivity, energy transfer, export of biogenic particles, and exchanges with the atmosphere. Coccolithophores are the most abundant calcifying organisms in the oceans, and their fossils are key for tracking global climate-ocean changes.

The rise of coccolithogenesis is a profound ecological innovation in the ocean ecosystem. Early Triassic nannofossils from South China help understand the circumstances prompting (or allowing) phytoplankton to mineralize calcite, marking the birth of the modern ocean. Coccolithophore origination shortly after the Permian mass extinction reset marine ecosystems, forcing biota to adapt to extreme climatic and chemical conditions and novel niches. The onset of coccolithogenesis began a long and successful evolutionary trajectory that influenced oceanic ecosystem dynamics, biochemical processes, and sedimentation. The geological history of coccolithophores indicates Mesozoic evolution characterized by increasing diversity, punctuated by speciations, extinctions, and turnovers that led to 25 coccolith/nannolith families and 5 groups Incertae sedis, peaking before the end-Cretaceous mass extinction.

Times of accelerated rates or drops in nannofossil diversification correlate with global changes in the geosphere, hydrosphere, and atmosphere, linking evolutionary patterns to environmental perturbations. Significant events in Mesozoic nannoplankton evolution align with changes in CO_2 concentrations, nutrient availability, ocean chemistry, and climate. Global environmental changes are interconnected with geological processes, and biosphere evolution should be linked to the Earth's interior. However, it is challenging (and contentious) single out causes triggering coccolithophore evolution and calcification; a combination of environmental changes likely drives evolutionary innovations and stability.

Mesozoic coccolithophore biodiversity and calcification patterns can assess their resilience: calcareous nannoplankton as a whole showed high resistance to global disturbances maintaining diversity, while individual taxa varied in resilience. Calcification patterns reveal moderate to lowered resilience, with species-specific sensitivity and resistance: timing, magnitude, and recovery dynamics aids understanding the impacts of current global changes and thresholds leading to ecological crises. Improved chronology of paleobiological and geological events is crucial for understanding evolutionary processes.

L'analisi qualitativa e quantitativa del rischio geomorfologico e la sua gestione tramite sistemi di allertamento lungo le infrastrutture ferroviarie

Foria F. & Pantaneschi S.

ETS Ingegneria

Keywords: rischio geomorfologico, sistemi di allertamento, analisi quantitativa.

La mappatura del rischio geomorfologico è fondamentale per la valutazione di innesco di eventi e delle relative conseguenze. L'analisi può essere affrontata con approcci qualitativi, volti alla prioritizzazione delle strategie e degli interventi, e approcci quantitativi basati sulle curve di probabilità e l'analisi delle conseguenze. I sistemi di valutazione del rischio necessitano, inoltre, dell'integrazione con i Sistemi di Allertamento (EWS) per l'innesco di eventi pluvio indotti consentendo anche una gestione in tempo reale del rischio quantitativo. Nella relazione sono illustrate tecnologie all'avanguardia per l'acquisizione di dati lungo le infrastrutture (ARCHITA) e algoritmi di calcolo che permettono l'analisi a diverse scale e livelli di dettaglio, integrando l'approccio qualitativo e quello quantitativo tramite (MIRETS, modulo di Mappatura Idrogeologica).

Contourites and mixed depositional systems: a paradigm for deepwater sedimentary environments

Hernández Molina F.J.*

Andalusian Earth Sciences Institute, Spanish Research Council, Granada, Spain.

Corresponding author email: fj.h@csic.es

Keywords: contourites, mixed depoositional systems (turbidite-contourite), deepwater depositional systems.

Along-slope bottom currents and a series of secondary oceanographic processes interact at different scales to form sedimentary deposits referred to as contourite and mixed (turbidite-contourite) depositional systems. Recent proliferation of both academic and industry research on deep-marine sedimentation documents significant advances in the understanding of these systems, but most non-specialists remain unaware of the features in question and how they form. Contourites and mixed depositional systems represent a major domain of continental margin and adjacent abyssal plain sedimentation in many of the world's oceans. They also appear in Palaeozoic, Mesozoic and Cenozoic stratigraphic sections. The growing interest in these systems has led to a refined but still evolving understanding of them. In addition to resolving their exact origins and evolutionary trajectories, research must also continue to ascertain their role in deep-sea ecosystems, geological hazards, environmental policy and economic development. Key gaps in understanding persist regarding their formation, their function in oceanographic systems and their evolution over time.

This Plenary Session summarises current conceptual paradigms for contourite and mixed depositional systems, lists global geographic examples of these systems and discusses their identification and interpretation in terms of diagnostic features as they appear in 2D and 3D seismic datasets and at sedimentary facies scale. It also considers the role that bottom currents play in shaping the seafloor and controlling the sedimentary stacking patterns of deepwater sedimentary successions. The growing interest in, and implications of, contourite and mixed depositional systems demonstrates that these systems represent significant deep-marine sedimentary environments. Combined efforts of researchers, industry partners and policy-makers can help advance understanding and responsible stewardship of deepwater depositional systems.

Sustainable mining of critical raw materials: opportunities and obstacles for geoscientists

Hudson-Edwards K.A.*

Camborne School of Mines and Environment and Sustainability Institute, University of Exeter, Penryn, UK.

Corresponding author email: K.Hudson-Edwards@exeter.ac.uk

Keywords: mineral resources, CRMs, sustainability.

The 'green' energy transition away from carbon-based fuels is driving a resurgence in mining because Earth materials are needed in renewable technologies such as battery-driven vehicles, solar panels and wind turbines. These technologies require specialist materials, many of which are known as critical raw materials (CRMs). CRMs have high economic importance and a high supply risk. Variable CRM lists have been defined by different countries and regions (US, EU, Canada, Australia, etc.) but the lists often include metals such as Li, Co, REE and tungsten, and materials such as graphite and fluorspar. Globally, significant exploration and development of CRM deposits is in progress, with the aim of mining many of these to increase the supply of CRMs. To reduce the negative aspects of mining, and to respond to pressures from consumers, many companies have adopted a 'sustainable mining' policy to undertake mining that is profitable and maximises the flow of resources into circulation while protecting the environment and human rights and health. This presentation outlines opportunities and obstacles for geoscientists with respect to sustainable mining of CRMs. Opportunities include developing geomodels for previously understudied CRM orebodies and working in multidisciplinary teams to deliver innovation technologies and procedures along the whole mining value chain for the industry. Time constraints and integration of natural, engineering and social science research are some of the obstacles that will be discussed. Overall, geoscientists have a major leading role to play in the global sustainable mining of CRMs.

Carbon isotope analyses on dissolved inorganic carbon of seawater samples: sample preparation and analysis using the GasBench Plus system

Pellegrini M.* & Fischer M.

Thermo Fisher Scientific

Corresponding author email: maura.pellegrini@thermofisher.com

Keywords: $\delta^{13}C$ analyses, sample preparation, GasBench Plus System.

The $\delta^{13}C$ isotope composition of the dissolved inorganic carbon (DIC) content of natural water samples helps to better understand carbon cycling and gas exchange in various hydrogeological systems. The biggest challenges of the $\delta^{13}C$ analysis of DIC samples are often connected to sample storage and sample preparation before the analysis with the IRMS and this is based on the fragility of the carbonate balance in water samples.

Extraction and analysis of $\delta^{13}C$ of DIC water samples can be done using the Thermo Scientific™ GasBench Plus universal on-line gas preparation and introduction system that features TriPlus™ RSH SMART Autosampler which enables automatic helium flushing and sampling. Two sample preparation procedures were tested on DIC water samples to investigate their effect on the $\delta^{13}C$ results: method A) Acid-Flushing-Sample and method B) Sample-Flushing-Acid. The selected DIC water samples comprised authentic seawater (spiked with $HgCl_2$). Here we present GasBench Plus System overview and features supporting an optimized workflow for achieving high precision carbon isotope data of DIC in water samples.

Keywords: mine tailings, characterization, nannochloropsis sp.

Mine tailing soils pose a potential threat to the environment due to their long-term disposal with toxic metal pollution and adverse eco-toxicological impacts (Chen et al., 2023). The present study aimed at characterizing four samples of mine tailings from different active mining sites in China, by X-ray fluorescence (XRF) and assess elemental recovery after aqua regia digestion (ARD) followed by Inductively Coupled Plasma Mass Spectrometry (ICP-MS) determinations. Total elemental contents by XRF showed relatively high Co, Cr, Ni, V, Zr, and REE concentrations in all samples. ARD results showed potentially toxic elements in all samples can be mobile. In the context of minimizing environmental impacts through sustainable decontamination options, we tested phycoremediation using *Nannochloropsis oceanica* strain CCMP1779 in the four mine tailings samples. The mine tailings treated with *N. oceanica* led to a slight increase in metals (Pb, Cr, Ni, and Zn) concentration compared to the control experiment. After four days incubation, microalgal growth was observed in gold- and iron-based mine tailings whereas no growth was observed in the copper- and lead/zinc-based mine tailings. The successful biomass growth and microalga ability to perform leaching showed promises in environmental-friendly phycoremediation of contaminated sediments, with twofold benefit of high biomass-to-bioenergy conversion potential, which is seen as an asset in process sustainability (Kholssi et al., 2023).

Keywords: phosphorites, microbialites, carbonate fluorapatite.

In the early Jurassic Prerif succession of the External Rif chain (Northern Morocco), phosphatic-carbonate sandstone deposits were for the first time recorded. These latter are represented by moderately to well sorted fine-grained mixed arenites with sub-angular to well-rounded clasts cemented by sparitic to microsparitic calcite. The phosphatic grains represent ca. 25-30% of the total, whereas the remaining are dominantly made up of carbonate (mostly micritic grains and foraminiferal tests) and secondarily by siliciclastic grains (primarily quartz and secondarily feldspars). The phosphatic grains can be grouped into two main classes: phosphatic peloids in majority and phosphatic bioclasts (as fish bone, representing less than 5% of the total). XRD data revealed the presence of a complex mineralogical assemblage composed by: calcite, present as cement, bioclasts (e.g. formainifera tests) and micritic peloids; quartz, as dominant terrigenous clasts; and phosphate, made by carbonate fluorapatite (CFA). The phosphate grains host multiple witnesses of a precursor biogenic relationship with the mineral structures. In particular, all the phosphate grains result characterized by the densely packed and compressed aggregation of minute nanospheres (ca. 30 - 40 nm in diameter), forming most of the volume of the phosphate grains, except for isolated and sparse zones where these latter gradually aggregates to form assemblages of rod-shaped crystals (ca. 4- 5 μm in length and ca. 1 μm in diameter). The rod-shaped crystals are present both as single and as geminate with a bi-radial structure commonly showing the presence of relicts of small central voids. Both the nanospheres and the rod-shaped crystals are closely associated to organic matter relicts that commonly appear as planar and sheet-like membranes (< 1 μm thick) and rarely as filamentous. Very common microborings with both a spherical up to filamentous unbranched morphology also occur. These latter centripetally penetrate into the bioclasts showing a mineralized dense phosphate rim and an internal hollow structure sparsely filled by acicular phosphate crystals that still leave central internal voids. The microborings can greatly alter or up to completely destroy the original structure of the precursor grain. Understanding the main mechanisms or phosphate deposition and microbial bioerosion can have significant implications for palaeoenvironmental and taphonomic reconstruction, up to possibly define correlations with the Jurassic-Palaeogene large phosphogenic province extending from Middle East to North Africa.

Role of microbes in the the Pliocene giant cold-seep system of the Crotone Basin

Borrelli M.*[1], Perri E.[1], Heimhofer U.[2], Umbro B.[1], Santagati P.[1] & Le Pera E.[1]

Keywords: cold seep, conduit, pavement.

The giant Pliocene cold seep system of the Crotone Basin (South Italy) represents a key-site for dimension, outcropping exposure and quality. It is composed by a large carbonate (calcite) body (350 m long, 100 m wide, 40 m thick), and characterized by a conduit facies made of authigenic calcite interpreted as previously active gas/fluid escape pipes and by a pavement facies, depicted as the surrounding early calcite-cemented bioclastic and siliciclastic sediments. Pavement facies are commonly colonized by chemosymbiotic and non-chemosymbiotic macrofauna (Lucinids and Solemyids bivalves, gastropods, serpulids). The conduit microfacies is characterized by the inward accretion of dark micritic laminae alternating with whitish sparitic layers. The micritic laminae show a microbial peloidal to dendrolitic fabric, which commonly incorporates planktonic foraminifera and coprolites, whereas the crystalline layers are made of microsparitic and sparitic crusts of prismatic zoned calcite crystals. The pavement facies shows more variability, as it is typified by laminated microbial boundstones, chemosymbiotic-bivalves packstone, foraminiferal packstone/wackestone and hybrid arenites. The stratigraphic constrain coupled with the foraminiferal assemblage (planktonic taxa) suggests a deep-water setting occasionally affected by siliciclastic sedimentary flows. The pavement facies also shows common brecciation features, suggesting the establishment of post-depositional overpressure conditions due to the early cementation of the conduits, which triggered localized rock failure. Stable isotopes analysis of the different facies reveals overall negative $\delta^{13}C$ values (-6.8 to -37.4‰ VPDB) indicating the presence of a complex mixture of methane with other hydrocarbons consumed microbially via anaerobic oxidation of methane. Whereas δ18O is relatively positive (0.0 to 3.4‰ VPDB) suggesting the possible dehydration of clay minerals and/or destabilization of gas hydrates. This study, besides helping in the definition of the migration pathways and modality of accumulation of hydrocarbon-rich fluids, can also help in building more and more realistic models for the complex genesis of cold seep carbonates.

ROV-based sampling as tools for geobiological determination of recent marine bioconstructions

Keywords: bioconstructions, sampling, technological innovation.

Mediterranean Sea hosts a wide range of biogenic "reefs" originated by the growth and stabilization of several organisms. They are distributed in different marine settings, from shallow to deep water and from open to confined sectors (especially vermetid reefs, sabellariid build-ups, polychaeta/bryozoan biostalactites from submarine caves, coralligenous build-ups and deep-sea cold-water corals) and constitute important archives of recent environmental and climate changes. Among these, the coralligenous habitat represents an important "hot spot" of biodiversity (Ballesteros, 2006) characterized by a low accretion rate and a high sensitivity to natural and anthropic impacts, including the ongoing climate change (Basso et al., 2022).

During the project "CRESCIBLUREEF" and according to principles of the Europe Blue Growth Strategy, a ROV-based innovative technology for minimally invasive sampling of marine bioconstructions has been developed and tested. This underwater coring device is characterized by three main modules: (i) core drilling head, (ii) anchoring system and, (iii) tool change mechanism. Moreover, it is driven via a specifically designed control interface which contains information such as core rotation speed, drilling depth and tool magazine positioning.

Using the protocol proposed by Cipriani et al. (2024), coralligenous core samples, collected from off Marzamemi (Sicily, Italy), are characterized from a geobiological perspective and compared with data obtained from coralligenous build-ups sampled in the same area by scuba-drives the method of Bertolino et al. (2014).

This comparison will assess core-samples obtained with ROV-based technique as representative of the entire bioconstruction. If representativeness is confirmed, the new tool would be used for sampling marine bioconstructions, with minimal invasiveness and preventing unnecessary damage to these slow-growing and delicate ecosystems.

Corresponding author email: francesco.delapierre@unito.it

Keywords: authigenic carbonates, elemental sulfur, lipid biomarkers.

Carbonate concretions accompanied by elemental sulfur were found in an early Messinian (Late Miocene) marine succession of NW Italy. The rocks were studied with an integrated approach including sedimentological, petrographical, stable isotope (carbon, oxygen, and multiple sulfur isotopes), and lipid biomarker analyses. Unlike other examples from Messinian strata of the Mediterranean area, the studied carbonate and sulfur concretions did not derive from the diagenetic replacement of sulfate minerals. Three lithofacies were distinguished: a) laminated lithofacies representing aphotic carbonate stromatolites enclosing fossils of filamentous sulfide-oxidizing bacteria; b) brecciated lithofacies deriving from the brecciation of carbonate stromatolites by mud injections; c) sulfur-bearing lithofacies deriving from the precipitation of thin laminae of elemental sulfur at or close to the sediment-water interface. The carbon and oxygen stable isotope composition of authigenic carbonate minerals and lipid biomarkers indicate that the initial formation of the laminated lithofacies was favored by organoclastic sulfate reduction in the shallow subsurface close to the sediment-water interface, producing sulfide that sustained dense microbial mats of sulfide-oxidizing bacteria at the sea floor. Calcification of the mats and consequent formation of stromatolites were possibly favored by nitrate-driven sulfide oxidation at the sea floor. The subsequent brecciation of the stromatolites was apparently the consequence of sulfate-driven anaerobic oxidation of methane (SD-AOM) in an underlying sulfate-methane transition zone (SMTZ). Focused fluid flow from below, possibly resulting from destabilization of gas hydrates, was not only responsible for the brecciation of the stromatolites, but also for the delivery of bicarbonate ions and the consequent precipitation of additional, 13C-depleted calcite (d13C values as low as -52‰). Along with bicarbonate, also hydrogen sulfide was produced by SD-AOM at the SMTZ and was transported upwards. The oxidation of hydrogen sulfide at or close to the sea floor promoted the formation of elemental sulfur characterized by higher d34S values and lower D33S values than coeval seawater sulfate.

Biomineralization of As-schwertmannite in acid mine drainage

Guerrieri S.*[1], Borrelli M.[1], Medas D.[2], De Giudici G.[2] & Perri E.[1]

[1] Dipartimento di Biologia, Ecologia e Scienze della Terra, Università della Calabria, Rende (CS).
[2] Dipartimento di Scienze Chimiche e Geologiche, Università di Cagliari.

Corresponding author email: salvatore.guerrieri@unical.it

Keywords: As-schwertmannite, biomineral, acid mine drainage.

Iron and arsenic extraction occurred at the San Blasio mine, near the village of Caulonia (Southern Calabria, Italy), until it was finally abandoned in the XIX century. A whitish/orange muddy precipitate was identified where acid water, showing pH ca. 3 and main ions (mg/L) SO_4 590, Ca 140 and Fe 55.3, outflows from the mine. This precipitate is mainly composed of amorphous As-schwertmannite (FeO 69%, SO_4 14%, As_2O_5 11%), and in very minor amount of hematite. Amorphous As-schwertmannite mineral nanoparticles (<10 nm) represent the most common basic mineral structure, which form roughly homogeneous mineral aggregates, or, more commonly, subspherical nanospheres in the range of 100-300 nm in diameter. Nanospheres are mostly hollow with a solid mineral wall ca. 30 nm thick in average, appearing like single elements or coalescing to form more complex clusters. Furthermore, mineral nanofibers (100-300 nm in length and 5-30 nm in width) can cover the outer portion of the nanospheres with a radial orientation, while the inner part can be filled with homogeneous mineral nanoparticles.

A microbial community, mainly consisting of prokaryotes cells (mainly streptobacilli and filaments, and less spirochete) commonly enclosed within the extracellular polymeric substance (EPS), occurs, strictly associated with all types of mineral precipitates. In fact, mineral nanoparticles nucleate on the external cell walls or inside the EPS mass, up to replacing the whole organic structures. Moreover, abundant bacterial outer membrane vesicles (OMVs), consisting of spheroidal bodies with diameter of ca. 100-200 nm, and characterized by a double-layered wall have been also observed. OMVs appear partially to totally mineralized, being, most likely, the organic substrate replaced by the As- schwertmannite to form the nanospheres.

In the light of what has been said so far, the San Blasio mine case can represent an interesting site of research, since less is known about the mechanisms involved in As-schwertmannite biomineralization. Finally, the understanding of the microbial communities and the biotic processes that mediate the biomineralization of this mineral phase, could drive to the possible development of water treatment plants, finalized to avoid toxic elements dispersion in the environment.

Heavy metal-minerals microbial mediated coprecipitation in mine tailings drainage

Guerrieri S.*[1], Borrelli M.[1], Medas D.[2], De Giudici G.[2], Sedda L.[2], Musu E.[2] & Perri E.[1]

[1] Dipartimento di Biologia, Ecologia e Scienze della Terra, Università della Calabria, Rende.
[2] Dipartimento di Scienze Chimiche e Geologiche, Università di Cagliari.

Corresponding author email: salvatore.guerrieri@unical.it

Keywords: biomineral, hydrozincite, mine tailings.

The Rio Roia Cani (Southern Sardinia, Italy) is a seasonal stream draining mine tailings and residues of the Montevecchio mine. Along a limited sector (ca. 300 m) of the stream through the mine dump, water chemistry composition (sampling November 2023), is characterized by a circumneutral pH, and a roughly constant mean amount of the main ions: (mg/L) SO_4 = 730, Zn = 132, Ca = 130, and HCO_3 = 55. Moreover, a variable number of other metals is present in the short upstream part (µg/L): Mn = 370, Pb = 81, and Cd = 1580; and in the downstream part: Fe = 550, Mn = 1350, Pb = 490 and Cd 990, as the influx of sunk water.

Along the stream course, three distinct biomineral phases have been observed, strictly associated with microbial biofilms: hydrozincite $Zn_5(CO_3)_2(OH)_6$ in the upper stream part and Mn-Pb hydroxides associated with Fe-Mn-Pb oxides in the downstream part.

Hydrozincite is present as whitish/ochreous soft to hard crusts forming small relief barriers, transversal to the water flow, with small upstream pools and downstream lobes. The crust exhibits a stromatolitic fabric, characterized by sub-millimetric thick, cryptocrystalline laminae, variably covering the streambed, rock clasts and river plants. The mineral is covered by a widespread living microbial biofilm, and the lamination is due to the alternance of solid mineralized laminae with less dense ones, characterized by disperse globular crystal aggregate. Both types of laminae are rich of well-preserved to fully mineralized microbial cells and Extracellular Polymeric Substances (EPS) that formed a biofilm community, which are particularly abundant in the less dense laminae. Hydrozincite mineral nanocrystals constitute the basic mineral structure, forming roughly irregular particle or fibrous crystals aggregates tens of nm in size. Nanocrystals nucleate along the external cell walls or inside the EPS, sometimes replacing the entire organic tissues.

As the water composition downstream varies, hydrozincite almost disappears, while two new distinct amorphous biominerals precipitate. One is represented by a reddish mud mainly composed of a Fe-Pb-Mn oxide phase (hematite?) with minor amount of hydrozincite, characterized by 30 to 200 nm nanospheres. The second amorphous biomineral consists of a dark mud, frequently found underneath the reddish mud or streambed clasts, composed of a Mn-Pb hydroxide (ranciéite?). The basic mineral structure of this precipitate consists of fibrous nanocrystals (ca. 20 nm thick) which aggregate to form clusters. In both cases, mineral nucleation and growth is again associated with the biofilm components, such as diatoms, bacteria, and EPS, implying their biologically mediated origin.

Microbial activity involved in aluminosilicate mineralization in an arsenopyrite mine

Keywords: biomineralization, aluminosilicate, bacteria.

The mechanisms underlying eukaryotic biosilicification have been intensively investigated. By contrast, prokaryotic biosilicification has been less studied. It is known that bacteria are involved in the formation of siliceous deposits through both extracellular and intracellular biosilicification with passive and active processes respectively (Ikeda, 2021). Considering the extremely wide variety of bacteria and archaea, it is plausible that more prokaryotes could be involved in silicate precipitation than those already recognized. In the frame of this topic here we investigate the possible role of bacteria in aluminosilicate mineralization.

Aluminosilicate biomineralization is a complex process that involves different stages of metal–microbe interactions, metal substitution, and crystallization (Sánchez-España et al., 2018). Depending on water chemistry and the bacterial species involved in the biomineralization process, aluminosilicate of bacterial origin can show different morphologies, from amorphous to submicron or nanometric in size, and exhibits a variable composition (e.g., kaolinite-like, halloysite-like, nontronitic, and chloritic). These so-called biosilicate form under both experimental and natural conditions, but until now they are not described forming bioconstruction-like bodies.

Here we describe unusual dendritic fabric forming in natural environment, inside the Macariace arsenopyrite mine, near the Mammola village (Southern Calabria, Italy). These fruticose structures develop in a decimetric fracture of the cave wall characterized by sub-photic conditions. They appear white and formed by an intricate frame of millimeters convolute tubular structures. The set of micromorphological and biogeochemical/mineralogical data of optical microscopy observations, SEM and TEM electron microscopy characterization, XRD analyses, EDS microanalyses, thermal analysis and UV-Epifluorescence observations, confirm the aluminosilicate nature of these structures and suggest unusual biomineralization processes involved in their deposition. Whether this mineral precipitation is a process influenced by EPS taphonomy or represents an induced mechanism linked to specific metabolic processes is currently unknown, but the chemical characteristics of the water system, characterized by low pH values (up to 4.8) and Ca-SO_4 compositions suggest the possible role of acidophilic communities involved in the biomineralization processes.

Keywords: underwater habitat mapping, multibeam echosounder, coralligenous.

In temperate waters of the Mediterranean Sea, calcareous red algae (CCA) form endemic algal reefs known as Coralligenous build-ups, which represent a major hot spot of biodiversity in the Mediterranean basin. Coralligenous has a prominent role in submarine landscape formation and demise through geological times, producing various morphotypes on the seafloor. Based upon the nature of the substrates, Coralligenous have been categorized mainly in two groups: banks and rims. Furthermore, Bracchi et al. (2017) proposed a new categorization for Coralligenous morphotypes on sub-horizontal substrate: tabular bank, discrete relief and hybrid bank.Although Coralligenous bioconstructions are present along almost all Mediterranean continental shelf, their distribution is still underestimated and has been mapped only in few areas. In addition, Coralligenous is a fragile and threatened habitat (Cipriani et al., 2024), characterized by a low accretion rate and a high sensitivity to natural and anthropic impacts, including climate changes (Basso et al., 2022). For these reasons, acoustic instruments, such as Multibeam Echosounder (MBES), represent optimal tools because they allow to quickly recognize and identify the extension of benthic habitats on the seabed and thus map their regional distribution without perturbation of this delicate ecosystem.

In this work, a semi-automated GIS-based protocol for benthic habitat mapping were proposed and tested in shallow coastal water of Capo Bianco, within the Isola Capo Rizzuto Marine Protected Area. This method firstly combines high resolution bathymetric and backscatter data obtained by Multibeam Echosounder with geomorphological and geomorphometric indices (es. slope, profile curvature, topographic position index, terrain ruggedness index, etc.) to develop innovative approaches for eco-geomorphological and geobiological studies. The obtained results provide a powerful instrument, with centimetric resolution, capable not only of discriminating coralligenous bioconstructions from Posidonia oceanica meadows and surrounding seascape, but also of quantitatively define the 3D distribution of build-ups in terms of area, volume and heigh relative to the substrate from which they develop.

Keywords: geomicrobiology, microbe-mineral interactions, geobiology dissemination.

The growing awareness of the strict interconnection between minerals and microorganisms has largely impacted the geosciences in the last decades. Microorganisms have been recognized to play a fundamental role in aquatic and terrestrial biogeochemical cycles that results in the precipitation of minerals (i.e. "biomineralization and organomineralization"; sensu Dupraz et al., 2009) and in the formation of peculiar rocks (e.g. microbialites, stromatolites) that punctuate the geological record. Moreover, the Earth history has been characterized by episodes of massive accumulation of biogenic material on the ocean floors resulting in the formation of biogenic deposits (i.e. biosiliceous and carbonate oozes) that represent natural archives of paleoenvironmental and paleoclimatic information (Berger & Wefer, 2009). Finally, the rapid growth of minerals can act as a trap for microorganisms that can be perfectly preserved within the crystal lattice or fluid inclusions for millions of years (Lowenstein et al., 2011)

Such strict connections between the geosphere and the biosphere are mostly unknown to the general audience, although the impact of microbial (microorganisms) and nanoscopic (viruses) life is emerging more and more in our society.

The GEOMICROBI project aims at showing the microbial life enclosed in minerals and rocks, elucidating its role in the modification of the natural environments in the geological past and nowadays. Improving people awareness about the role of microorganisms in shaping the Earth will contribute to understand the importance of life as a "geological force" (Westbroek, 1992). The project GEOMICROBI will contribute to raise such awareness throughout imaging (mostly by SEM photomicrographs) the "invisible life" hidden within minerals and rocks. Main targets of the project are the creation of a photographic exhibition accompanied by informative conferences on the theme "Minerals & Microorganisms". This presentation is intended to attract the attention of the geological community on this dissemination initiative and to look for amazing, high-definition images on mineral-microorganism interactions.

Keywords: goethite, metals, siderophores.

Microorganisms interacting with the surrounding environment may mediate the precipitation of biominerals, bioaccumulate metals, and promote bioleaching processes favoring mineral dissolution. In the last decades, key mechanisms ruling geomicrobial processes received increased attention with a particular focus on their applications to environmental remediation strategies and sustainable mining, such as biomining.

Metal-mining areas in SW Sardinia (Italy), dismissed in the last decades of the last century, keep reaching the public audience due to i) the presence of critical raw metals and their potential extraction from mining wastes, ii) environmental pollution, and iii) the naturalistic and archaeological industry beauty of strong interest to local and regional communities. These areas are extreme environments with high concentrations of contaminants in waters, sediments, and wastes. At Rio Irvi (Montevecchio Mine), drainage outflow from Casargiu Gallery connects underground mining to riverine water with an estimated output of 900 kg/day Zn into the Mediterranean Sea. Variation of redox and pH (4-6) conditions generates precipitation of non-crystalline Fe(III)-(oxy)hydroxides and sulfate-bearing green rust (Frau et al., 2015). Here, Fe biogeochemistry and the role of microorganisms in its mobility were investigated to understand mineral stability and potential biomining applications. Microbiological investigations isolated and identified the indigenous bacteria *Pseudomonas protegens* FeIIC1 able to extrude siderophores and chelate Fe^{3+}. Laboratory experiments studied the bacteria capability to mobilise Fe^{3+} from nano to microscale crystals of synthetic goethite α-FeO(OH). The bacteria were added to a Fe-deficient medium, and after reaching a growth plateau, goethite was added with a 1 mg to 2 ml ratio. The bioleaching was observed for three weeks by monitoring i) Fe concentrations in the medium, ii) siderophore production, iii) bacteria colony formation unit, iv) pH and redox parameters. Scanning electron microscope images showed biofilm on mineral surfaces. The monitoring of Fe concentrations in the medium highlighted a continuous bio-mediated dissolution and maximum concentrations towards the end of the experiment, with an apparent recovery of about 20%. Preliminary output encourages applications to mining wastes often bearing other metal(loid)s, namely Zn, Cd, As, and Ni. Understanding the naturally occurring bio-mechanism ruling metal leaching and precipitations in mining areas will shed light on microorganisms' potential as environmental remediation or metal sourcing from wastes.

Microbial micritic cementation in a Late Pleistocene (MIS 5.5) mid-latitude shallow-water calcarenite (Gulf of Taranto, central Mediterranean)

Santagati P.*, Borrelli M., Guerrieri S. & Perri E.

Dipartimento di Biologia, Ecologia e Scienze della Terra, Università della Calabria, Rende.

Keywords: MIS 5.5, microbial micrite, central mediterranean.

Higher sea level and sea surface temperature than at present are inferred for the Last Interglacial (MIS 5.5, 135-116 ky), which is considered a good analogue for Earth's climate response to global warming in near future. The MIS 5.5 deposits cropping out along the Gulf of Taranto are mainly composed of few meters thick bioclastic calcarenite layers, representing a locally vegetated shallow sandy seabed, with relatively high energy conditions (Santagati et al., 2023). These deposits are affected by limited post-depositional diagenesis, allowing the study of early cementation processes. The clasts are composed of medium-coarse sandy skeletons and fragments deriving from a varied biota, including large molluscs that lived in the sediment, and of a negligible quantity of siliciclastics.

Most bioclasts are variably micritized, and micritic cements are common and show various micromorphologies and textures: non-isopachous aphanitic and filamentous rims, aphanitic micro-mounds, vacuolar peloidal meniscus, and aphanitic matrix filling the porosities. All these microbial mediated cements consist of submicrometer anhedral or nanospheroidal crystals of low-Mg calcite, mixed with a smaller amount of irregular plate-like crystals of saponite. All cement fabrics are rich in mineralized filamentous, tubular, and subspherical bacterial bodies, evidencing the occurrence of an epilithic to endolithic biofilm-forming microbial community, that stabilized the mobile sediment and mediated early cement precipitation.

The process of microbial mediated early cementation led to the formation of a relatively hard substrate, which allowed the settlement of cemented epilithic taxa, such as *Spondylus gaederopus*, oysters, and minor serpulids and barnacles, which represent a minor component of the paleocommunity. However, as testified by the dominant presence of burrowing molluscs, the process was not pervasive, or was volumetrically limited along the sediment column.

Similar processes of microbial micritic cementation are common in modern tropical carbonate platforms (Diaz & Eberli, 2022), whereas are substantially absent in the modern Mediterranean. Their occurrence in the MIS 5.5 central Mediterranean deposits confirms warmer water temperatures, estimated at +2°C than today (Santagati et al., 2024), and suggests that such process of early cementation of shallow-water sediments could become more widespread in response to the global warming.

Capo Colonna (Crotone Basin – Southern Italy) MIS 5 calcareous bioconstructions: an association of algal, metazoan, and microbial framebuilders

Santagati P.*, Guerrieri S., Borrelli M. & Perri E.

Dipartimento di Biologia, Ecologia e Scienze della Terra, Università della Calabria, Rende.

Corresponding author email: pierluigi.santagati@unical.it

Keywords: biocostructions, late pleistocene, microbial micrite.

The Last Interglacial (MIS 5) transgressive-regressive deposits of the marine terrace of Capo Colonna (Crotone Basin) provide a good fossil example of infra/circa-littoral environments of the central Mediterranean, characterized by low-relief bioherms and biostromes dominated by calcareous red algae, analogous to the modern coralligenous and mäerl habitats respectively (Nalin & Massari, 2009; Bracchi et al., 2014).

The primary framework of the bioherms consists of laminar to massive encrusting red algae that act as the main bioconstructors, with secondary bryozoans, foraminifera, and serpulids. The tabular mäerl bed is composed of free-branched coralline red algae rudstones. A variable amount of sandy bioclastic sediment is laterally interbedded with the bioconstructions and is trapped in their cavities and pockets.

All bioconstruction sedimentary subfacies and associated sediments are rich in microbial-mediated syn-sedimentary autochthonous micrite, with aphanitic, peloidal, clotted peloidal, and filamentous fabrics. Microbial micrite can also trap and bind variable amounts of grains or be a secondary component of detrital sediment with micritic rims enveloping the clasts. All these early lithified micrites show the typical nanostructure of microbial-mediated primary carbonates, rather than of an accumulation of detrital mud particles, since they are made up of nanospheres that coalesce into subhedral microcrystals, replacing and mineralizing both the microbial cells (present with different morphological types) and extracellular substances (e.g., Perri et al., 2012).

This implies the widespread presence of lithifying microbial biofilms that colonized both the cavities of the bioconstruction frameworks and the intergranular space of the associated sediment. These microbial communities, thanks to the metabolic processes of the microorganisms that induced the precipitation of carbonates, contributed significantly to the early cementation of all the studied deposits.

Keywords: serpentinisation, nanoscale, geochemistry.

Hydration of ultramafic rocks (serpentinisation) is a low-temperature, low-pressure process driven by water-rock interaction and changes in variables such as H fugacity ($fH_{2,aq}$). Serpentinisation starts at low water-rock ratios, where Fe released from olivine and pyroxene oxidises, to form abiogenic $H_{2,aq}$ and reducing conditions (Frost, 1985). $H_{2,aq}$ can react with C and water to form methane, carbon dioxide and organic acids (Templeton et al., 2021). Therefore, serpentinisation may have facilitated the initiation of early life (Cardace & Hoehler, 2009) but few studies have investigated the availability and cycling of nitrogen in serpentinising environments. The present work investigates natural systems where conditions were sufficiently reducing to form native metals and, potentially, biogenic or abiotic hydrogen.

This work used nanoscale techniques, such as Atom Probe Tomography (APT) and Time of Flight-Secondary Ion Mass Spectroscopy (ToF-SIMS), to search for evidence of biotic activity in sulphides and Cu-alloys from the Wadi Tayin ophiolite, Oman. Mineral assemblages and nanoporosity suggest that native-Cu formed during serpentinisation, and we speculate that the nanopores acted as fluid traps and hosted microorganisms. ToF-SIMS maps show that native-Cu and partially dissolved magmatic chalcopyrite are enriched in cyanide-complexes, offering insights into the nanoscale nitrogen cycle.

APT analyses show Ag segregation along grain boundaries in native-Cu, consistent with literature reports of transfer of Ag from magmatic sulphides to alloys and native metals during serpentinisation (Lawley et al., 2020). This previously undocumented concentration of Ag in defects provides new insights into mechanisms of Ag transfer. Taken together, the results suggest that Cu acts as an electron acceptor during early serpentinization and supports the idea that early life may have thrived in serpentinising environments.

Integrated Geochemical/Geobiological approach for the identification of environmental proxies in Coralligenous bioconstructions

Vespasiano G.*[1], Cipriani M.[1], Maruca G.[1], Apollaro C.[1], Ponte M.[1], Dominici R.[1], Bruno F.[2], Muzzupappa M.[2], Rosso A.[3], Sanfilippo R.[3], Bracchi V.A.[4], Basso D.[4] & Guido A.[1]

Corresponding author email: giovanni.vespasiano@unical.it

Keywords: geochemistry, biomineral, environmental proxies.

Coralligenous is the most important marine ecosystem in the Mediterranean Sea because of its extent, complexity and heterogeneity (Basso et al., 2022; Bracchi et al., 2022). Moreover, it is a prominent geobiological system and a unique hot spot of biodiversity (Cipriani et al., 2024), object of special interest by the UNEP RAC/SPA and considered among the priority habitats for monitoring and conservation by the European Community.

Since the last century, coastal ecosystems have been increasingly threatened by human activities due to the discharge of contaminants which leads to an overall deterioration of the environmental quality. Several studies have been conducted to demonstrate the relationships between metal contents (physico-chemical parameters of seawater) and the occurrence of aberrations in marine organisms. However, these researches focused mainly on the incorporation and effect of major, minor, and trace in the soft tissues of recent taxa (e.g., foraminifers, brachiopods, molluscs and algae). To date, only a few studies (see Deias et al., 2023) have investigated possible correlations between the composition of skeletal and non-skeletal components of marine bioconstructions with the chemistry of the surrounding seawaters. The research suggests that biominerals can serve as good proxy for environmental studies, capable of recording short- and long-term variations in the geochemistry of marine environments.

Here, an integrated geochemical/geobiological approach has been utilized to investigate the balance between reef status and environmental parameters and to identify possible proxies for short- and long-term environmental studies. This multidisciplinary approach showed an evident relationship between chemical composition of the carbonate minerals and the waters in which coralligenous forms. Positive anomalies in heavy metals were found in bioconstructions and surrounding seawaters. Such enrichments could result from pollutants introduced into the marine system by human activities and recorded by the components of the bioconstructions. These data, although preliminary, allow to consider coralligenous build-ups as environmental database that continuously record environmental disturbance (both natural and anthropic), enabling temporal reconstruction of the marine environment over time.

Keywords: Madina Kouta basin, petrography, stromatolites.

These structures are described for the first time in the Madina Kouta basin (Walidiala valley) on the hill of Pélel in the vicinity of the Nandoumari flat (10 m) where it is overlain by the clay-sandstone deposits of the Dindéfélo Formation and at the base of the Tanagué hill (40m), unconformably overlain by the Neoproterozoic glacial formations (Youm, 2019). These are algal bioconstructions, made up of greyish-white stromatolites, centimetric to decimetric, linked by a strongly ferruginous carbonate matrix and very weakly sandstone, which caps the Pelel Formation. There are allochthonous debris of algae (*Algal limeclasts*), oncoids in irregular nodules with convex and concave contours, large pelloids (>2 mm), simple and composite ooliths, sometimes in fragments, multiform concentric stromatolitic structures, more or less associated.

Microscopically, the presence of stromatolites is distinguished by a stacking of thick hemispherical layers, nested together in a very clear manner. Two types of layers alternate more or less regularly: i) clear and limpid layers, most often made up of sparitic carbonate crystals. They are generally the most developed; ii) grey, dark, more intensely pigmented layers (clays or organic matter or iron), sometimes reduced to a single dark line or curved lenses of micritic carbonates, associated with detrital quartz, feldspar debris, zircon and mica flakes. The phenomena of recrystallization and dolomitization (sparite, calcite and dolomite) are very extensive, which sometimes completely masks the structures. Stromatolites are very often pellet and oolith traps. The bonding phase is a carbonate matrix of micrite, dolomicrite, microsparite and quartz of very small size as well as a sparitic and ferruginous cement (sparite or dolosparity and iron oxides). The texture is packstone-like (Dunham, 1964) with sparite recrystallization fractures. These are ferruginous stromatolite reefs or ferruginous stromatolite limestones with oncoliths and pellets. As carbonates are very little studied, sometimes even omitted in the descriptions, this work will allow a better understanding of the stromatolite emplacement processes and will be the outline of a more in-depth study of bioconstructions, particularly in the Madina Kouta basin and in Senegal, since other levels of stromatolites have already been identified but not yet studied.

Keywords: plastics, marine pollution, foraminifera.

Plastic pollution poses a significant threat to oceans and marine life globally. Microscopic plastic particles entering aquatic environments can disrupt benthic communities by altering their distribution and activity. Despite the undoubtedly harmful long-term effects on microbiota, the impact of microplastics, chemicals, and synthetic molecules on marine microorganisms remains poorly investigated (Baztan et al., 2018; De Sá et al., 2018). Benthic foraminifera are crucial components of marine ecosystems, playing key roles in ecosystem functioning and biogeochemical cycles. Their sensitivity and rapid response to environmental stress make them effective environmental indicators of past and present changes. To better understand the effects of emerging pollutants on oceans and their interaction with marine organisms, we studied the impacts of plastics and bio-accessible plasticizers (specifically DEHP, bis(2-ethylhexyl) phthalate) on selected benthic foraminiferal species using μ-FTIR (Fourier Transform Infrared) spectromicroscopy.

Our analysis revealed the following key findings: i) certain foraminifera species (*Cibicidoides lobatulus*, *Rosalina bradyi*, and *Textularia bocki*) can grow on plastic remnants; ii) plastic-related molecules and debris can be incorporated into the cytoplasm and tests of foraminifera, altering biomineralization processes; iii) DEHP can be incorporated into the cytoplasm of calcareous foraminifera cultured in vitro (*Rosalina globularis*), potentially entering biogeochemical cycles (Birarda et al., 2021).

We hypothesize that plastic waste and associated additives may affect the biomineralization process in foraminifera, compounding the effects of ocean acidification and potentially reducing their biogenic carbon (C) storage capacity.

Furthermore, we conducted experiments exposing benthic foraminifera to high concentrations of DEHP over three months in sediment cores from the Santa Gilla lagoon (Cagliari, Italy) and comparing them with the foraminifera from other cores that were left in natural conditions. After the experiment, surviving benthic foraminifera were cataloged. Gas chromatography coupled with mass spectrometry was used to identify and quantify plastic pollutants in the lagoon sediment.

Next steps will involve the study of the incorporation of plastic pollutants into foraminiferal tests and the possible modifications in foraminifera shell (e.g., changes in density) using Scanning Transmission X-ray Microscopy, Low Energy X-ray Fluorescence, and X-ray computed microtomography. These analyses will validate foraminifera as reliable proxies for monitoring ongoing human-generated pollutants. The presence of associated molecules in foraminiferal shells (such as total particulate matter and plastic) could provide insights into anthropogenic pollution history spanning several decades, given foraminifera's ability to fossilize.

Keywords: microplastics, coastal environments, sediment analysis.

Coastal-lagoon environments are highly vulnerable and subject to multiple stressors, among which marine litter (ML) is a serious global issue. The predominant category of ML recorded along coasts mainly consists of artificial polymeric materials (Le et al., 2024). In the environment, macro-ML degrades into smaller items due to photo-thermo-oxidative degradation: Large Micro Plastics (LMP, 5 - 1 mm), Small Micro Plastic (SMP, 1 mm – 20 μm), nano Plastics (nP, ≤ 20 μm). These microplastics are defined as secondary. However, primary microplastics can also be found in the environment, which are produced in microscopic sizes for specific purposes and various applications (Saeedi, 2024).

Many protocols have been developed to study and quantify the presence of SMP in various types of coastal environments. Quantifying SMP along the sandy coasts of the northern Adriatic Sea remains challenging due to the very fine dimensions of the sediments in which microplastic items are trapped. Therefore, the gravimetric separation of microplastics from sediments using non-toxic and cost-effective saline solutions presents some practical difficulties. The protocol conventionally used in the Adriatic area for sampling and analysis of SMP (Palatinus et al., 2015) suggests adding 200 mL of saturated NaCl solution (density 1.2 g/cm^3) to 50 mL of sampled sediment. This mixture is then stirred for 2 minutes to suspend the microplastic items embedded in the sediments. According to the protocol, a waiting time of 4 minutes is required for sediment precipitation, and then the supernatant can be collected and filtered in order to collect the microplastics on borosilicate glass fiber filters (Whatman® microfiber filetrs GF/D, mesh size 2,7 μm).

However, the mentioned protocol does not provide information correlating sediment grain size with an optimal waiting time to perform this procedure. From various tests conducted by our team, it has been observed that the indicated waiting times are not sufficient to achieve the complete settlement of non-plastic particles, particularly for samples containing an average of 69% fine sediments, rich in muddy fraction (d < 0.250 mm).

With this work, we suggest a possible integration to the protocol based on preliminary tests useful for verifying the optimal waiting times for collecting the supernatant to be filtered, in relation to the textural and compositional characteristics of the sediments. This integration helps to avoid both the deposition of a compact solid matrix on the filter, which could mask the presence of the microplastics to be observed, and the damage to the equipment used for vacuum filtration.

Nanoplastics in the environment represent one of the emerging problems of our time, with widespread and harmful impacts on global aquatic ecosystems. These plastic particles, less than 1 μm in size, derive from various sources, including improper disposal of plastic waste and spoilage of synthetic articles. Their ubiquity in aquatic environments and their persistence and bioaccumulation ability raise severe issues for human health and the marine ecosystem (Arif et al., 2024). Growing awareness of the widespread of nanoplastics and their harmful effects has prompted the search for innovative solutions to address this particular pollution. Among various proposed strategies, photocatalysis emerges as a promising option for the degradation of nanoplastics, exploiting the ability of photocatalysts to activate advanced oxidation reactions under the irradiation of sunlight (Llorente-García et al., 2020). However, the need for highly selective and efficient photocatalysts remains a critical challenge in converting this technology into practical solutions. In this context, we investigated the efficiency of several TiO_2 microstructures for the photocatalytic degradation of nanoplastics. Our methodology focuses on the controlled hydrothermal synthesis in 5M, 6M, and 7M HCl of TiO_2 (Zhou et al., 2011) to obtain at least three different microstructures (spheres, nanoflowers) able to degrade nanoplastics. The results showed that performing the hydrothermal synthesis at 150°C and different HCl concentrations led to three different microstructures, such as two types of spheres and nanoflowers. All microstructures are composed of rutile TiO_2 and present different surface area values, which correlate with their differences in the efficiency of the nanoplastics photocatalytic processes. The results of this work show that photocatalysis can significantly contribute to solving nanoplastic pollution environmental challenges.

Plastic uses increased more and more in the last decades, thanks to its characteristics (malleability, lightness, durability, and versatility). In fact, it is the third material produced by the man on Earth, after steel and concrete. Nevertheless, in the last years academic and non-academic people are worried about the destiny of these materials because their chemical, physical, and biological degradation leads to the dispersion of microplastics (MPs). These particles are little fragments with dimensions reaching up to 5 mm, that can potentially accumulate in the environments and in the organism tissues, man included. MPs have been identified in different human tissues, as lungs, blood, placenta, urine, breast milk. Their accumulation can trigger physical and biological effects, that are responsible of damages to cardiovascular, digestive, and respiratory systems. In fact, their toxicity depends on different biological mechanisms (e.g.: absorption and distribution processes inside the human body, metabolism, and excretion ways) and physical factors (e.g.: morphology, dimensions, surface charge, concentration, and their ability to bond themselves to organic and inorganic pollutants).Biomonitoring is a method utilized to evaluate human exposure to different environmental pollutants; it is carried out characterizing a determined chemical substance, its metabolites, or transformation products in biological samples. This evaluation considers the combination of the potential contaminated elements (e.g.: air, food, water, industrial products) with the different exposure pathways (inhalation, ingestion, skin contact). MPs absorption evaluation inside human tissue is made difficult because of the data lack about both population exposure and MPs distribution and dynamic in the human tissues. Moreover, scientific demonstration about MPs presence and the correlation with different diseases and the research of possible exposure sources are still at an early stage. In this work, a MP evaluation by optical microscopy and micro-Raman spectroscopy inside different human media (serum, urine, and tissues) will be presented. The patients involved in this study are people living in Alessandria province (Italy) and admitted to the Azienda Ospedaliero-Universitaria SS. Antonio e Biagio e Cesare Arrigo and to the Santo Spirito Hospital of Casale Monferrato, Italy. The enrolled population will include different patients (e.g.: pregnant women, hemodialysis patients) to determine whether microplastics are detectable inside their fluid or tissues and if there is any difference in MPs presence depending on where patients live and their lifestyles or considering different times during the therapies (e.g., levels before and after hemodialysis sessions, in order to assess extraction). The chemical analyses will be coupled to exposure questionnaires to investigate possible exposure sources.

Extraction of microplastics from marine environmental matrices: density separation protocol validation

Keywords: microplastic, density separation, protocol validation.

Microplastics (MPs) differently concentrate within marine sediments depending on transport and accumulation agents as well as chemical-physical properties of plastic compounds (Chaukura et al., 2021). When MPs occur within marine sediments they can be utilized by agglutinated organisms, as Sabellariid polychaets, to build arenaceous reefs, thus MPs can also accumulate in bioconstructed substrates. Heterogeneity of MPs accumulated in different environmental matrices, rising interest in the last years but the lack of standardized guidelines for extraction brought us to a widespread inconsistency of data due to different recovery and quantification protocols.

Size, shape, floating behavior and density of plastic particles are handful information to correctly recognized true MPs from other grains in environmental matrices. Particularly, density of plastic materials, ranging from ~0.8 to -1.4 g cm^3, makes MPs lighter then sedimentary grains made of lithic fragments, minerals and biogenic remains (Ruggero et al., 2020) allowing a density separation. The aim of this work is to validate the extraction protocol using Sodium Iodide (NaI) brine solution (Kedzierski et al., 2017) applied to two types of environmental matrices: coastal marine sediments (mainly sands) and arenaceous bioconstructions built by the honeycomb worm *Sabellaria spinulosa* (Leuckart,1849). Extraction efficiency of NaI brine solution was compared with the extraction efficiency of sodium chloride (NaCl). The comparison was applied to both sediment and bioconstruction samples also using two different quantities (10 g and 40 g). Moreover, each sample was previously added with microplastics of known quantity and type: plastic particles with sizes from 250 µm to 500 µm, made of plastic compounds commonly produced by industry in a wide range of densities, such as polyethylene terephthalate PET (1.38 g cm^{-3}), polypropylene PP (0.855–0.946 g cm^{-3}), and polyvinyl chloride PVC (1.1–1.35 g cm^{-3}). Manipulated samples were put in 200 ml solution of NaI and NaCl, mixed and sonicated. After 6-12 hours, the obtained solutions were filtered through a 0.23 µm membrane for MPs isolation. Identification and quantification of MPs on the filters were performed under a stereomicroscope. Results documented a higher quantity of recovered MPs for the samples treated with NaI, confirming the higher extractive capability of this salt. On other hand, there were no statistically significant differences in tested sample quantities (40 g vs 10 g) nor in the number of extracted MPs with respect to the type of analyzed matrix (bioconstruction and sediment), indicating that the proposed protocol correctly works for different environmental matrices also using very small quantity of material.

Keywords: microplastics, Ionian Sea.

Microplastics (MPs) have become a complex problem in coastal areas in terms of pollution, human health and risk for marine flora and fauna ecosystems. The majority of MPs found in coastal areas are produced in terrestrial environments. A lot of activities are responsible for their production and their direct or accidental dispersion into environmental matrices. MPs arrive to marine environment carried by wind, rainy events and water bodies (like rivers or aquifers), to be retained in marine sediments.

Pino di Lenne is a beach located near the mouth of the river Lenne. On the one hand it holds great value due to its rich fluvial biodiversity and uniqueness. On the other hand a river is one of the means that most contributes to the transport of MPs from land to sea. Therefore this location was chosen for our research for the specific position near the river mouth. The aim is to understand how the presence of a river can influence the concentration of MPs.

A series of sediments samples were collected along the backshore locations, at each step of the morphological profile, and in offshore locations, selected after preliminary analysis of the marine substrate.

The evaluation of MPs in coastal and marine samples was carried out following the international standard procedure. Sediment grain-size analysis were conducted for sediments with fraction up to 63 μm, coulter analysis were performed for sediments with fraction < 63 μm. The MPs were separated from sediments and classified by shape, size and color. A new innovative method was applied for the automatic identification of microplastics with size smaller than 10 μm and automatic characterization of polymers. μ-FTIR and μ-Raman techniques were employed to evaluate the origin of polymers.

The distribution of MPs contamination was assessed to determine what is the river mouth influence on it, and how the distribution changes in relation to the location.

Imaging of microplastics in bio-engineered marine substrates: a neutron tomography approach

Lo Bue G.*[1], Musa M.[1], Kaestner A.[2], Di Martino D.[3], Busi M.[2], Shakoorioskooie M.[2], Riccardi M.P.[1] & Mancin N.[1]

Keywords: microplastic, Mediterranean reef, neutron imaging.

Microplastics (MP) are an ubiquitous pollutant that can be considered a planetary boundary threat. The persistence and durability of this synthetic material in the environment allows MP to easily enter the food web and the sedimentary record. Several freshwater (e.g Trychopteran insects) and marine benthic species, such as Sabellariid polychaetes, rely on natural occurring materials as biogenic fragments and sandy grains to build their agglutinated cases. Particularly, Sabellariid polychaetes build arenaceous reefs in the intertidal and subtidal zone along the temperate Atlantic and Mediterranean European coasts. The reef consists of a myriad of arenaceous packed tubes made up of sandy particles mobilized by waves. Sabellariid reefs are dynamic engineered habitats that constitute nutrient and sediment storage (Lisco et al., 2017), thus they play a crucial role increasing local biodiversity and enhancing coastal protection.

Recently MP abundance within Sabellaria spinulosa (Leuckart, 1849) reefs from Mediterranean Sea has been investigated (Lo Bue et al., 2023), but the applied method has required a destructive approach: the arenaceous tubes forming the bioconstruction have been digested in hydrogen peroxide and MP particles have been separated from the arenaceous matrix by density. As a result, MP quantification was provided as number of particles per gram of dry sediments. Unfortunately, information on MP distribution within three-dimensional bioconstruction samples was irremediably lost.

This work aims to perform neutron tomography, combining non-destructive X-ray and neutron imaging, on two portions of S. spinulosa reef. A similar approach had been previously utilized to identify microplastics (MP) in sediment samples (Tötzke et al., 2021). During our study, small reef portions, collected from the Torre Mileto bioconstruction (Gargano promontory, Southern Adriatic) were placed in two laboratory tanks: the first sample was manipulated with the addition of MPs at known concentration and size (up to 2 mm); while the second one, utilized as a control, was not manipulated.

After one month of exposition, both reef samples were analyzed at ICON, the cold neutron imaging facility at the neutron spallation source, Paul Scherrer Institut (Kaestner et al., 2011).

Results showed that most of MP agglutinated within the samples were easily identifiable, but the real content was probably overestimated. Unfortunately, our bioconstruction samples showed additional complexity with respect to sediments previously observed with a similar technique. The agglutinated grains forming the bioconstruction are bounded by an organic glue used to aggregate the tubes. Furthermore, remains of the worm organic tissues could persist partially filling the tube cavities. As additional beamtime has been obtained at PSI facility, further analyses addressed to refine the analytical procedure will allow us to overcome this problem.

Keywords: microplastics, Mediterranean reef, arenaceous tubes.

The Mediterranean Sea stands out as a semi-enclosed basin with high density of population who lives along the coastlines: this implies a high concentration of microplastics (MPs) originating from land sources. For this reason it can be considered a "Plastic Soup" (Suaria et al., 2016), with marine sediments playing the role of primary MPs sink.

The impact of MPs extends beyond their presence in the sedimentary record and their effects on marine life are still largely unknown: for example, the recent record of MPs incorporated into the arenaceous bioconstructions of sedentary marine worms (Sabellariid polychaetes) has arisen interest (Mancin et al., 2022; Lo Bue et al., 2023).

Sabellaria spinulosa (Leuckart, 1849) reefs, thriving in subtidal littoral environments, are formed bya myriad of packed arenaceous tubes, meticulously built using agglutinated sand particles. This engineered substrate not only serves as a vital habitat for the polychaete and associated biota, but also plays a crucial role in the coastal ecosystem dynamics as a nutrient and sediment storage (Lisco et al., 2017). In this context, this works aims at understanding the dynamics of MPs interactions within the seafloor environment associated with Sabellariid reefs, and specifically to assess the accumulation of MPs within the largest known Mediterranean *S. spinulosa* reef in the South Adriatic Sea. Samples of sea-floor sediment and bioconstruction (36 replicates in total) were collected along six transects from the Torre Mileto reef (41◦55045.3" N; 15◦37012.37" E) to compare the abundance of MPs in both substrates. MPs were extracted by density difference and submitted to census count using a stereomicroscope equipped with a UV light. Suspected MPs and other anthropogenic particles sized 2µm to 5000µm were identified based on morphology, colour, fluorescence, and physical response (for example to a hot needle). Quantitative data were reported as number of particles per gram of dry sediment; MPs were classified into size classes and morphological categories. Furthermore, µRaman spectroscopy was performed on twelve samples (33% of the total samples) to obtain validated data on MPs composition.

Results document MPs presence in all the collected samples, with fibers more abundant than fragments. The absolute abundance of MPs resulted comparable between sediment and reef substrates. Data suggest a mutual influence between the reef and the neighbouring sediment: the peculiar dynamic status of the larger Sabellariid reefs, characterized by an alternation between growth and erosion phases during the year, can control the abundance of MPs in the associated sediment. In particular, while the ancient, more stable portion of the reef are acting as sinks, the younger unstable one can become source of sediment and MPs.

Keywords: plastic dispersion, protected areas, plastic colonization.

Following the report of an accumulation of waste on the seabed of the island of Giannutri by divers working in Tuscan Archipelago zone, a multidisciplinary project to study this peculiar accumulation was born, involving institutes of the CNR, ENEA, INGV, University of Pisa and Toulon. The accumulation, noted for several years, is in a circumscribed area at a depth of 15 meters, in front of the island of Giannutri, Tuscan Archipelago. In August 2022, the conspicuous presence of anthropogenic material, mostly of polymeric type (bottles, vials, etc.), was verified. In November 2022, in collaboration with the CNeS (Nautical and Diving Center of the State Police of La Spezia), an underwater photographic mapping and geophysical characterization were performed, video/photographic footage taken and samples retained for subsequent laboratory analysis. In July 2023, the intervention of CASTALIA fleet allow the removal and disposal of all the material, except for a number of retained samples. On all the November and July samples we identified different species of bryozoans and benthic foraminifera, and we analyzed the degradation and aging of the polymeric matrix, in collaboration with Pisa PolyGreenLab group of CNR-IPFC, involved since years in these kind of studies (De Monte et al., 2022).

The first results did not reveal the presence of NIS species among those found in the bottles, and instead confirm that all detected species belong to the ones living in Posidonia prairies, suggesting the local origin of these concretions. This would lead to the assumption of an arrival of the material by sea from other areas, their subsequent sinking there (probably due to fouling resulting in a change in the density of the object) and then colonization by local species (Zettler et al., 2013). Interestingly, there was a low taxonomic homogeneity and the presence of a dominating species shown by each of the analyzed bottles; this introduces potential danger, as if bottles leave the Gulf of Spalmatoio of Giannutri and join a larger current to be transported far from the accumulation area, this could lead to some species being carried into uncolonized areas, inducing competition with other species and leading to what is known as a bio-invasion phenomenon (Kiessling et al., 2015). To test this hypothesis, in parallel with the chemical/physical state of the recovered objects, a study of the dynamics of the currents in the area is being conducted through Lagrangian models to understand what forcing factors led to the presence of such an accumulation. In the next few days (April 6 - 10) a campaign will be conducted to check, about 10 months after removal, whether any finds are present in the area again, and quantify them, and at the same time dispersal experiments will be carried out using specially made drifters that have already been tested for the study of surface movements of marine litter in coastal areas (Merlino et al., 2023).

Keywords: microplastics, Arno river, urban impact.

Crossing anthropized inland areas, riverine systems undergo the addition of a wide array of contaminants. Among them, microplastics (MPs), defined as plastic particles of 1-5000 µm in size, are ubiquitous and worthy of interest due to their potential health risks and impact on ecosystems (Thompson et al., 2004). Here, the Arno River (Central Italy) was investigated to evaluate MPs contributions from urban landscapes (2.5 million inhabitants live in the area) and to estimate the MPs discharge from the river to the Mediterranean Sea. Shallow river waters were collected in April and July 2022 at seven sites located upstream of the main pollution sources (i.e., urban centres) up to the river mouth. Differently from most studies, a specific protocol (sampling, extraction, analysis) was developed to allow the investigation of almost all MPs sizes (5-5000 µm). Samples containing MPs > 60 µm and MPs < 60 µm were simultaneously collected and analysed by µ-FTIR and fluorescence microscopy (Nile red dye), respectively. River flow rates were also recorded to allow calculations of MPs fluxes. By far the most abundant material were MPs < 60 µm, representing >99% of particles found all-river-long and reaching concentration peak (5×10^4 items/L) across the city site of Florence. Pre-urban sites displayed concentrations of 1×10^4 items/L, while the lowest concentrations were observed at the river mouth (1 to 3×10^3 items/L). Among MPs < 60 µm, an inversely proportional relationship between size and abundance was observed; the fraction 5-15 µm (61-70%) was the most abundant, followed by 16-30 µm (18-30%), 31-45 µm (6-8%), and 46-60 µm (3-4%).

MPs > 60 µm (<0.5% of total) were mostly classified as processed fibers of cellulose (68%) strictly connected to textile products (i.e., garments) (Islam et al., 2020). Synthetic polymers (32%) were associated with textiles (i.e., PET, PA, PAN), automotive and building components (i.e., Neoprene rubber, ABS, PMMA).

The yearly average discharge of MPs (MPs > 60 µm plus MPs < 60 µm) into the Mediterranean Sea was estimated to 4.6 quadrillion ($4.6\pm1.3\times10^{15}$) Items/year.

Compared with rivers worldwide (Kumar et al., 2021), the Arno River waters are affected by a significant MPs contamination, mainly associated with domestic-industrial laundry effluents from urban areas, and mostly characterized by MPs smaller than 60 µm. The latter micro-litters represent a risk for fluvial and marine ecosystems being the most bio-accessible (Lehtiniemi et al., 2018) and easily transported fraction to the sea, where it may persist for a long time. The methodological approach developed in this research allowed i) to identify the key role of the smallest MPs to assess the Arno River water quality and, ii) to quantify MPs discharges into the Mediterranean Sea. To avoid relevant underestimation, the quantification of plastic particles belonging to the whole range size of MPs is strongly recommended in similar studies.

Keywords: microplastics spatial heterogeneity, Po river delta, processes.

Deltas are the locus of river-borne sediment accumulation, however, their role in sequestering plastic pollutants is still overlooked. By combining geomorphological, sedimentological, and geochemical analyses, which include time-lapse multibeam bathymetry, sediment provenance, and μFT-IR analyses, we investigate the fate of plastic particles after a river flood event providing unprecedented documentation of the spatial distribution of sediment as well as of microplastics (MPs), including particles fibers, and phthalates (PAEs) abundances in the subaqueous delta. Overall sediments are characterized by an average of 139.7 ± 80 MPs/kg d.w., but display spatial heterogeneity of sediment and MPs accumulation: MPs are absent within the active sandy delta lobe, reflecting dilution by clastic sediment (ca. 1.3 Mm3) and sediment bypass. The highest MP concentration (625 MPs/kg d.w.) occurs in the distal reaches of the active lobe where flow energy dissipates. In addition to MPs, cellulosic fibers are relevant (of up to 3800 fibers/kg d.w.) in all the analyzed sediment samples, and dominate (94%) concerning synthetic polymers.

Statistically significant differences in the relative concentration of fiber fragments ≤ 0.5 mm in size were highlighted between the active delta lobe and the migrating bedforms in the prodelta. Fibers were found to slightly follow a power law size distribution coherent with a one-dimensional fragmentation model, thus indicating the absence of a size-dependent selection mechanism during burial. Multivariate statistical analysis suggests traveling distance and bottom-transport regime as the most relevant factors controlling particle distribution. Our findings suggest that subaqueous prodelta should be considered hot spots for the accumulation of MPs and associated pollutants, albeit the strong lateral heterogeneity in their abundances reflects changes in the relative influence of fluvial and marine processes.

Source-to-sink propagation of marine plastic and accumulation in seafloor sediments: the role of sedimentary gravity flows

Keywords: plastic, submarine canyons, sedimentary gravity flows.

Plastic litter is nowadays ubiquitous in all environmental compartments of the world's oceans and sequestration in deep-sea sediments is considered its long-term sink. However, several knowledge gaps exist about the processes driving the dispersion and the ultimate fate of this pollutant in the marine environment. Since the physical processes that control the distribution of sediment and water masses in the oceans have a prominent role also on the transport and deposition of plastic, the source-to-sink approach applied in sedimentary research could bring significant advances to elucidate land-to-sea linkages of marine pollution, to identify pathways and plastic accumulation hotspots. Submarine canyons, acting as preferential conduits connecting shallow to abyssal depths, are widely recognized as main vectors for plastic transport from land to the deep sea, and are also focal points for accumulation of plastic litter derived from fishing gears. While the occurrence of fishing-related plastic is linked to fishing activities, which can be quite intense in and around canyons due to the high productivity often associated with these features, the accumulation of plastic along canyon axes can be related to different transport mechanisms, encompassing enhanced bottom currents, dense water cascading and especially sediment gravity flows. The efficient transfer capacity of sedimentary gravity flows is supported by ongoing evidence of large litter piles at great water depths and seems to be influenced by the proximity of canyon heads to shore and to riverine inputs, recognized as main entry points for plastic at sea. Along with the transport of plastic at great depths, sediment gravity flows can also determine its burial, as demonstrated by the recovery of plastic items enclosed within coarse-grained turbidite deposits at 2.5 m below the seafloor in a core retrieved from a prodelta channel. Overall, the paucity of studies relating plastic distribution to transport and depositional processes and the paucity of data from deep sea-setting, such as the lower reach of canyons, which may represent main depositional areas for land-based plastic, strongly limit our capability to assess the real extent of plastic accumulation on the seafloor. This, along with the lack of specific devices and strategies for the reckoning of buried plastic, raise the quest on the magnitude of the plastic storage on and within seafloor sediments, which may represent the largest plastic depocenters in the oceans.

Litter distribution in marine and coastal environments: highlights from ongoing research projects

Keywords: coastal monitoring, beach litter, microplastics.

This study illustrates ongoing research activities carried out in the frame of the "RETURN" Project (funded by the National Recovery and Resilience Plan) and "Riparti" Project (funded by the Apulia Region) and focused on the assessment of beach litter (BL) distribution on sandy beaches and microplastics (MPs) in sediments. BL analysis is performed by applying both standard in-situ procedures and innovative methods, which are based on the exploitation of UAVs aero-photogrammetric surveys and the application of both manual and automatic imaging classification approaches, (Sozio et al., 2023). Such analyses are integrated with the evaluation of the predominant morphodynamical processes (coastal erosion and/or accretion), to support the identification of coastal zones affected by the accumulation and burial of BL items. For what concerns the MPs analyses, tailored sampling procedures are applied. Following the European guidelines, beach samples are collected at different points along the backshore while marine sediments are sampled at different depths in the shoreface and offshore. MPs classification is performed through both standard and innovative approaches. The latter are based on the exploitation of hyperspectral imaging (HSI) working in the short-wave infrared range (1000-2500 nm) (Fiore et al., 2022).

Test sites are located in the Apulia region along the Adriatic and the Ionian coast. BL monitoring activities have been carried out in 100 m long beach sectors at Torre Guaceto (Brindisi) and Capitolo (Bari); the first site is included in the Marine Protected Area and for this reason, it is not subject to scheduled cleaning activities due to the lack of tourist and recreational services; the second site is an important touristic destination, especially during the summer season. Sediment samples for MPs analyses have been collected at Torre Guaceto beach, in the Gulf of Taranto, and offshore the city of Bari. Results show BL density values ranging from 0.04 to 0.47 items/m^2 and plastic represents the most abundant material identified along the investigated beaches. BL items tend to accumulate in the upper part of the backshore, along the embryo/foredune limit, where density reaches a value of 1.24 items/m^2 (Rizzo et al., 2023). MPs concentration in marine sediment samples ranges from 1246 to 209 MPs/kg. The results of the μ-FTIR and μ-Raman analyses revealed that a large proportion of MPs in marine sediments derived from textile fibers (Cofano et al., 2023). Finally, different HSI-based procedures were developed. A ground-based hyperspectral system has been used at Torre Guaceto to evaluate the recognition of different types of plastic BL directly in situ. Regarding the sediment samples collected at Torre Guaceto and in the Gulf of Taranto, two effective laboratory-scale protocols have been developed to identify and classify the different polymers constituting the MPs directly on the matrix surface without the need for their preliminary extraction.

Effect of plastics on marine ecosystem: preliminary findings of Phthalates (PAEs) on Gromiids

Keywords: marine pollution, DEHP, benthic organisms.

Plastic pollution is one of the human-created severe threats on marine and coastal systems. Phthalates (PAEs) are a class of chemical compounds widely used in the manufacturing and processing of plastics (plasticizers) which are employed in a wide variety of industrial and consumer products (i.e., personal care products and food).

As PAEs do not form a covalent bond with polymers, they are easily released into the environment from such commercial products. For these reason, PAEs can either be absorbed by suspended particles that can sink to the bottom of aquatic ecosystems and build up in the sediments, or they can become readily available to marine organisms. Marine sediments can also act as an uptake source by benthic microorganisms in these ecosystems.

Among PAEs, di(2-ethylhexyl)phthalate (DEHP) is the most widely produced and used, as well as the most persistent phthalate found in seawaters and many studies have recently reported its negative effects on acquatic species.

This study examines the potential impact of DEHP on Gromiids, unicellular heterotrophic protozoa which are a common component of benthic marine communities. These organisms are characterize by the accumulation of a significant volume of stercomata (waste pellets), together with mineral grains and other extraneous particles, within the cell. In fact, they play a key role in benthic food webs by feeding on detritus and recycling nitrogen and carbon.

A chronic toxicity assay was carried out to assess the impact of this pollutant in the gromiids physiology and behavior. Contaminated colture were exposed and monitored for up 4 weeks, and at the end of the experiment all the live individuals were analysed by steomicroscopy and μ-FTIR (Fourier Transform Infrared) spectromicroscopy.

Under the microscope, some individual showed a discernible decrease in cellular turgor, which was most likely caused by sediment loss and cell membrane breakdown. Meanwhile, FTIR results revealed the presence of synthetic material inside the cell.

FTIR data allowed to answer the question whether there are any noticeable biochemical differences in the proteinaceous shells and the cytoplasm depending on the exposure of the cell organism to this bio-accessible plasticizers. As observed in other unicellular organisms related to gromiids, such as foraminifera, DEHP can induce similarly oxidative stress and protein aggregation. Additionally, this plasticizer can be assimilated into the gromiids cytoplasm, thereby entering biogeochemical cycles.

In summary, gromiids could be a good proxy of on-going emerging pollutants, highlighting the possibility that plastic pollution could enter the marine sedimentary record providing a unique signal that is unequivocally attributable to human activities.

It is essential to understand the mechanisms behind the interactions between plastic pollution and marine organisms, to develop effective mitigation strategies to safeguard marine biodiversity and ecosystem health.

Microplastics analysis from sediment samples collected at Capitolo Beach (Apulia, Italy)

Keywords: microplastics, coastal pollution, beach monitoring.

In the last twenty years, several scientific studies have been focused on the identification of microplastics (MPs) in marine ecosystems, particularly in marine sediments which turn out to be a collection point for them, thus defining a global environmental problem (Alomar et al., 2016). Based on this, different methodologies aimed at the extraction of MPs from sediment samples have been tested. These techniques differ mainly based on the efficiency and type of material used during separation, and some, such as density separation techniques, are very effective and capable of separating the most common polymers, but results are expensive and harmful to the environment and humans (He et al., 2021). Following the approach proposed in Scopetani et al. (2020), in this contribution we present preliminary results obtained using oil to separate MPs from sediments, taking advantage from the oleophilic properties of plastic. This method turned out to be fast and efficient and, at the same time, with low health and environmental risk.

Study area is located on the Adriatic side of Apulia region (Capitolo Beach), which is a popular tourist destination hosting recreational facilities (bathhouse), especially during the summer season. Due to its high anthropogenic exploitation, Capitolo Beach is prone to be affected by plastics and microplastics pollution along the beach and within the sea sediments.

Sand samples were collected along the backshore following the procedures indicated by the European guidelines (Galgani et al., 2023). Then, samples were dried at 50°C to perform granulometric analysis. Before the oil-based separation phase, it was necessary to perform organic matter digestion on all samples using a hydrogen peroxide (H_2O_2) solution. Finally, MPs were analyzed in order to define their predominant characteristics and polymer-composition.

The results of such activities allow to evaluate the distribution of MPs in the beach sediments and to distinguish primary or a secondary origin of MPs, supporting the assessment of the environmental quality of the investigated beach.

Keywords: coastal monitoring, beach litter analysis, machine learning.

The ever-increasing presence of pollutants and waste in the coastal environment has become one of the significant issues affecting marine-coastal areas worldwide, especially considering the continuous increase in the concentration of artificial polymers in environmental matrices (i.e., water, sediments, etc.) and the trophic chain. The effects they have on coastal environment are multiplied because of the combined action of meteo-marine processes and human activity. In this context, the Mediterranean basin is considered a "hot spot" for plastic pollution due to its peculiar hydrodynamic and geomorphological conditions. The presented study, which was carried out in the frame of the RIPARTI Project funded by Apulia Region, presents the results of the Beach Litter (BL) distribution analysis by applying different methodological approaches. In detail, standard in-situ surveys (Galgani et al., 2023) were coupled with indirect analyses performed by exploiting high-resolution images obtained from Unmanned Aerial Vehicles (UAVs) photogrammetric surveys and Machine Learning (ML) tools. Orthomosaics were used for manual screening in a GIS environment, and computer vision algorithms were employed to automatically detect BL items. The investigated sites are located along the Adriatic coast of the Apulia Region (Southern Italy). They include Torre Guaceto Beach (in the Marine Protected Area of Torre Guaceto, Brindisi) and Capitolo Beach (Monopoli, Bari). Results of the in-situ surveys show that the most abundant BL items measured at Torre Guaceto were represented by artificial polymers (32%), with a density of 0.5 item/m2 (Rizzo et al., 2021) as well as the case of Capitolo beach, where the artificial polymers represent the 90% of total items and with a density value of 2.5 item/m2. The manual screening also yielded similar results. At the Torre Guaceto site, plastic fragments were found to be the most abundant items, with a total of 336 out of 534 items. At the Capitolo site, 100 plastic items were identified out of a total of 143 BL items. The automatic identification and classification performed using the ML algorithm were conducted according to three classes of BL categories: "bottles", "worked wood", and "nets" (Sozio et al., 2023). Results show an underestimation of the total amount of only 45 items detected at Torre Guaceto beach and 63 items detected at Capitolo beach. The overall accuracy for both sites was 0.27 (mAP@IoU). This novel multidisciplinary approach comprehensively assesses the BL distribution and identifies the main accumulation zones. This information is crucial for designing tailored coastal management actions. Moreover, a specific flight protocol will be proposed to conduct aero-photogrammetric surveys to assemble datasets for automatic detection algorithms. Our future work will focus on improving the detection algorithm and expanding the classification classes, further enhancing the practicality and usefulness of our findings.

Keywords: underwater vehicles, water characterization, monitoring fresh and marine waters.

Fresh and marine waters pollution has emerged as a significant environmental concern over the past decade, also affecting marine sediments, due to potential and demonstrated negative effects on organisms, including humans. The present research aims to use and develop specific devices for autonomous underwater vehicles and underwater gliders to characterize and monitor the environmental conditions of fresh and marine waters. The investigation and sampling are performed to the full depth of the water column, in terms of microchemistry (e.g., dissolved oxygen), conductivity, temperature, pressure, pH, irradiation, acoustic/hyper-acoustic emissions, microplastics, micro-particles, sediments and further extended also to the biological content. The most employed techniques for sampling and subsequent laboratory analysis are discussed (e.g., Rickerby et al., 2000; Moro et al., 2021). This research also delves into the limitations and potential future developments of in-situ sampling techniques for micro-particles and microplastics. Traditional sampling methods, while effective, can be time-consuming and may not cover a sufficiently broad area to provide a comprehensive understanding of micro-particles and microplastics distribution. In response to these challenges, in this work we present a research that develops and uses innovative systems such as autonomous underwater vehicles, including ocean gliders (Helal et al., 2023; Helal et al., 2024), to sample and monitor the water column, both in fresh and marine waters, for a comprehensive 3D characterization (physical, analytical and biological) of its environmental conditions.

Keywords: heavy-minerals, petrography, provenance.

In glaciated regions, marine sediments represent a unique archive to infer the geology of source rocks, often hidden below thick ice or sparsely outcropping in the Antarctic continent interior. Clast distribution and composition are commonly used for provenance studies in Antarctica (Zurli et al., 2022). We present the preliminary results of the study of clast and sediment textural and high-resolution mineralogical and petrographic analyses, performed on marine sediment samples collected in 2022 by the PNRA19_00022 COLLAPSE project, in the continental slope and rise off the Cook and Ninnis glaciers. The study area preserves a record of environmental changes occurred during the recent past glacial and interglacial climate cycle in the offshore of one of the largest subglacial basin of the East Antarctic Ice Sheet. The method proposed consists in analysing sediments, from silt to sand to gravel, applying laboratory protocols described by (Andò, 2020), and optical identification analysis coupled with a Raman spectrometer (Andò & Garzanti, 2013). Mineral chemistry of single species in rock fragments was studied analysing olivine, amphiboles and feldspars. Most common rock fragments identified, indicate very low to medium grade metamorphic source rocks. Volcanic clasts are derived from Cenozoic volcanic centres of the West Antarctic Rift System rather than from the Jurassic Ferrar Large Igneous Province and are concentrated in sedimentary facies characterised by coarser grain size, IRDs and Diatom assemblages typical of warm environmental conditions. Heavy-mineral (HM) analysis on 12 samples show a higher concentration of HM in this sedimentary facies, that is preliminary interpreted as contouritic and deposited during the transition from glacial to interglacial conditions. The samples collected in the offshore of the Cook glacier are dominated by volcanic sources, with abundant clinopyroxenes (67-79%), minor garnets, amphiboles, apatite, tourmaline and trace of zircon, rutile, titanite and orthopyroxenes and reveals a sharp increasing in corrosion feature of amphiboles and pyroxenes in the surficial samples, indicating a possible influence of brine as weathering factor in this area. The samples collected in the offshore of the Ninnis glacier are dominated by volcanic sources, with less abundant clinopyroxenes (43-70%), minor garnets, amphiboles, tourmaline, apatite, epidote, titanite and trace of zircon, rutile, Al-silicates and orthopyroxenes. Further analyses are ongoing on the isotope composition of the silt fraction and on the biogenic component to better constraint the preliminary interpretation. These preliminary results show the high value of the data set and the importance of a multidisciplinary approach to understand past oceanographic and climate changes. This study presents the first paleoceanographic record in the offshore of the Cook and Ninnis glaciers that will provide new insights into their past dynamics since MIS5.

Keywords: provenance, glaciomarine sediments, Antarctic ice-sheets.

In recent years the advance in geochronological technique applied to provenance studies allowed better exploring the flux of glaciomarine sediments in polar regions and in turn to highlight events of increase and retreat of the Antarctic ice sheets.

In particular, the coupling between the classical thermochronological method of fission tracks in apatite with the less common U-Pb dating by LA-ICP-MS in the same apatite grain provides a powerful tool to constrain the rock source of the sediments. Moreover, during U-Pb dating through LA-ICP-MS it is possible to determine the major and trace elements (including REE) for the single double-dated apatite that can be statistically compared (O'Sullivan et al., 2020) to provide an affinity to the lithology source providing a further provenance discrimination factor.

We recently applied this multiproxy method on samples coming from two legacy DSDP drill cores (DSDP271, 272, 270) that cover a stratigraphic time window from the Oligocene to Present and are located close to latitude 180◦, considered the location of the present-day confluence between ice fed mainly by the EA and WA, respectively (Olivetti et al., 2023; Balestrieri et al., 2024).

Coupled with zircon U-Pb analysis, our multi-proxy study turned out to be a robust tool for the modeling of ice sheet volumes and ice drainage patterns from late Oligocene to Present.

Keywords: Antarctica, Ross Sea, IPSO25.

Ice cores have significantly improved our knowledge of short-term climate variability in Antartica over the last two decades and indicate an abrupt cooling event along the Victoria Land (western Ross Sea, Antarctica). However, no information isyet available from marine sediment. GRETA proposes to fill this knowledge gap by investigating the ocean response to a cooling event over Victoria Land (ca 1.3-1.9 ky CE). We present a new high-resolution sediment sequence collected in the western Ross Sea (JOIDES Basin), comparing the new data with existing data collected in Wood Bay and Edisto Inlet (Mezgec et al., 2017; Tesi et al., 2020; Battaglia et al., 2024). We are using a multidisciplinary approach that includes micropaleontological analyses (diatom assemblages), geochemical analyses (biomarkers such as IPSO25 and PIPSO25, organic carbon and stable isotope analyses, TEX86-L/RI-OH') and sedimentological analyses (grain size analyses and sortable silt determination). The ultimate goal of our project is to reconstruct sea ice dynamics, water mass properties (sea surface temperature, water mass circulation, upwelling) in the western Ross Sea during the last 2,000 years and its relationship with corresponding continental climate events. Finally, we will merge the information obtained from the marine domain with ice core and model data to provide new insights into the sub-millennial variability of atmosphere-ocean interactions.

Keywords: Weichselian glacial stage, deglaciation, Arctic.

The analysis of calcareous nannofossil (CN) assemblages has been proven to be a reliable approach for reconstructing paleoclimatic conditions along Arctic margins, given the high sensitivity of nannoflora to changes in water column parameters (e.g. temperature, insolation, and nutrient availability). The piston core GS191-01PC was collected from the Bellsund Drift crest on the west Spitsbergen margin during the PREPARED cruise (Lucchi et al., 2014). It was drilled at a water depth of 1647 meters and it consists of 19.67 meters of sediment characterized by a complex stratigraphy. This included bioturbated and laminated sediments, with sparse to massive Ice Rafted Debris, oxidized layers, and two tephra layers. Caricchi et al. (2019, 2022) have extendedly investigated the GS191-01PC core, establishing a robust age model for the region.

The CN assemblages were investigated in a 13.90 m bsf segment of the core, covering the last 30,000 years BP (140 samples at 10 cm intervals). The analysis focused on the distribution of species *Emiliania huxleyi* and *Coccolithus pelagicus*, alongside reworked specimens and data on total nannofossil abundance (number of specimens/10 mm^2). The *E. huxleyi/C. pelagicus* ratio (H/P; Carbonara et al., 2016) was calculated to investigate oscillations between the warmer West Spitsbergen (H/P > 1) and the cooler East Spitsbergen (H/P < 1) Currents. During the Late Pleistocene, the distribution of *E. huxleyi* and reworked specimens evidenced the onset of Heinrich (3, 2, 1) and the Melt Water Pulse-1A abrupt events. Throughout the Younger-Dryas and Holocene epochs, fluctuations in total nannofossil abundance and the overall assemblage composition provided insights into events such as the Holocene Thermal Maximum, and the 8.2, 4.2, and 2.8 cooler episodes.

Keywords: foraminifera, melting ice, Arctic.

Arctic regions are highly affected by global climate change because of polar amplification. Recent studies have demonstrated that Svalbard fjords are changing more quickly than most other marine environments due to continuos climatic changes. The key elements influencing sea ice coverage and the lengthening of the ice-free summer season in the Svalbard region are atlantification, and the increase in air temperature and precipitation.

Situated at 79°N 12°E near Ny-Ålesund, the Kongsfjorden is an essential site for studying environmental climate change in the Svalbard archipelago. Its noteworthy alterations over the last 10 years, especially the dramatic decline in the extention of winter sea ice, have attracted a great deal of attention. This phenomenon is partly attributed to the increasingly prolonged annual presence of Transformed Atlantic Waters (TWA), which are intermediate water masses originating from warmer Atlantic Waters (AW). Furthermore, this retreat of land-terminating glaciers in response to global warming has increased sediment inputs.

In the present study, we examined the distribution of living benthic foraminiferal assemblages to gain insight into how the climate change affect the strong environmental gradients of Kongsfjorden, leading to elevated physical and geochemical stress on benthic habitats.

The analyses of superficial sediment collected during the August 2021, allow us to identify 3 different assemblages in the innermost fjord: 1. The stations close to the glacier are dominated by monothalamids soft-shell species (>50%) as *Psammophaga zirconia* and the agglutinated species *Capsammina bowmanni*. These are stress-tolerant species, able to overcome the massive and frequent sediment and freshwater input from melting glaciers. 2. In the medial stations (about 5 km far from the glacier terminus), the increased organic fluxes resulted in the dominance of the calcareous species *Nonionellina labradorica*, typically associated with organic-rich sediments. *Micrometula* sp.. The important presence of*A. glomeratum* suggests a strong influence of Atlantic water intrusion in this part of the fjord.

As previously reported by Fossile et al. (2022) we observed distinct assemblage distributions along the Kongsfjorden in response to the environmental stress induced by glacier dynamics and for the first time we report that soft-shelled foraminifera are also sensitive to different environmental stress conditions in this region.

Fossile E. et al. (2022) - Influence of modern environmental gradients on foraminiferal faunas in the inner Kongsfjorden (Svalbard). Mar. Micropaleontol., 173, 102117, https://doi.org/10.1016/j.marmicro.2022.102117.

A lithostratigraphic reappraisal of a Permian-Triassic fluvial succession at Allan Hills (Antarctica) and implications for the terrestrial end-Permian extinction event

Keywords: stratigraphy, end-Permian extinction, Gondwana.

Between Permian to Triassic, the Earth experienced climatic and biotic crises, included the greatest mass extinction at the Permian-Triassic boundary. These climatic and biological changes are reflected in both marine and terrestrial depositional systems. Over this time span, the Gondwana supercontinent hosted numerous large basins that may preserve the paleoenvironment response to global changes in the sedimentary record. This study provides a lithostratigraphic reappraisal of the latest Paleozoic-Mesozoic alluvial Beacon Supergroup at Allan Hills (Convoy Range), which is one of the most complete sedimentary sequences in Antarctica. Fieldwork stratigraphic-lithological observation, facies analysis, and petrographic characterization of sedimentary rocks allow the identification of six depositional units. The investigations point out for a conformable relationship between depositional and lithostratigraphic units, characterized by changes in the fluvial style. The reconnaissance of a "transitional interval" showing intermediate features between the Permian Weller Coal Measures and the Triassic Feather Conglomerate strengthen the conformable nature of the sequence across the Permian- Triassic boundary in this region. The lithological features of such interval strongly resemble those observed in the coeval deeply studied Eastern Australia successions crossing the Permian-Triassic boundary as well as the end-Permian extinction event. More precisely, the uppermost coal occurrence, just above a glossopterid macroflora-bearing carbonaceous mudstone within the "transitional interval", marks the disappearance of coal-peat forming Permian vegetation which corresponds with the terrestrial end-Permian extinction, thus representing one of the few end-Permian extinction records in Antarctica.

Stratigraphic constraints on the Beacon Succession of the Transantarctic Mountains through palynological data

Corti V.*[1], Spina A.[2] & Cornamusini G.[1]

Keywords: palynology, end-Permian extinction, transantarctic mountains.

The Permian to Triassic-Lower Jurassic sedimentary sequences exposed along the Transantarctic Mountains play a crucial role in elucidating the evolution of the Gondwanan basins of the Antarctica plate. This study presents one of the most complete palynostratigraphic sequences of Permian to Middle Triassic deposits from Antarctica, in Southern Victoria Land. These deposits were laid down in alluvial settings, exhibiting changes in environment and depositional style over time. Additionally, the revealed continuity in sedimentation between the Permian Weller Coal Measures Formation and the Triassic Feather Sandstone and Lashly formations, allows the reconstruction of the microfloristic trend across one of the most crucial time intervals in Earth's history, the Permian-Triassic Boundary.

The sedimentological and palynological study provides biostratigraphic data for the age attribution of each formation and the correlation with coeval formations across the Transantarctic Mountains (TAM) and other areas of the southern Gondwana.

The sporomorphs assemblage in the Weller Coal Measures Formation, indicates a late Permian age. The upper part of the formation is characterised by a palynofacies mainly composed of long-shaped inertinite, which suggest the occurrence of paleo wildfires, to be linked with the EPE (terrestrial end-Permian Extinction). The uppermost occurrence of a microfloristic assemblage attributable to the *Protohaploxypinus microcorpus* Zone indicates an Early Triassic age. Furthermore, the sporomorphs assemblage, which is also supported by the paleobotany remains, has revealed a profound change in the flora between the Permian and Triassic time. The floristic turnover, which also been observed in many areas of Gondwana, is strictly linked to the deep change of paleoenvironmental conditions between the Permian and Triassic widespread all over the world due to a general greenhouse effect. Following a non-fossiliferous sandstone succession (Feather Sandstone Formation) deposited during Induan and Olenekian time interval, the flora returned to flourish in the Middle Triassic with the deposition of the Lashly Formation. Here different environmental conditions affected the sedimentary sequence, with an alternation of stable and instable landscapes evidenced by an alternation of coal, fine and coarse sandstone deposition, as well as numerous pieces of fossil trunks and other paleobotanical remains.

This study, which is based on the palynological and palaeobotanical composition of the Beacon Supergroup, has been supported by numerous lithological and stratigraphical data for a complete reconstruction of the paleoenvironmental condition that occurred during this fundamental time span. Finally, the palynostratigraphic revision of such crucial sequences, allows a more precise understanding of the evolution of the Gondwanan basins of the Victoria Land, in terms of paleoenvironmental changes and source-to-sink drainage systems.

Geodynamic processes at the Pacific margin of North Victoria Land (Antarctica): new evidence from offshore geophysical data on the crustal structure and seabed morphology (PNRA_BOOST Project)

Keywords: Antarctica, pacific margin, offshore geophysical data.

The interplay between the West Antarctic Rift System and the Australian-Antarctic plate divergence has played a crucial role in shaping the structure of the Antarctic lithosphere, growth of the cryosphere, formation of sub-ice topography, and uplift of the Transantarctic Mountains. At present, there still remain open questions and lack of data on rift-related structures and their Eocene to Recent geodynamic history. The PNRA2019_BOOST project (Bridging Onshore-Offshore STructures at the Pacific Coast of North Victoria Land, Antarctica: an integrated approach) was addressed to the study of the Pacific margin of the North Victoria Land (NVL), i.e. Oates and Pennell Coasts, a much underexplored area located in a critical position at the boundary region between East and West Antarctica. New offshore geophysical data (multichannel high-resolution seismics, bathymetry and magnetics) acquired on board the Italian R/V L. Bassi (38th - 39th Italian Antarctic Expeditions) as part of the PNRA_BOOST project, allowed the identification of morphological and tectonic features relevant for understanding the geodynamic evolution of the Antarctic continental margin and the influence of lithosphere dynamics on ice-sheet evolution and ice-sheet stability. Main promising new observations and discoveries are represented by morphological features of the seabed, regional scale tectonic structures and volcanic chains. We identified NW-trending fault-bounded basement highs on the shelf and on the continental rise associated with growth strata that point to a tentative dating of tectonic reactivation to Oligocene times. Moreover, a km-scale ridge of basement covered by drift deposits, revealed at a depth of about 2500 m, is bounded by faults pointing to a more recent tectonic activity. In the SW part of the study area, two linear volcanic zones (one belt is ca. 50 km long) occur with a roughly NNW-SSE direction. Various volcanoes and associated fluid-related features cut through the surrounding sedimentary successions showing evidence of recent activity. This volcanism may represent the NNW continuation of the Mid-Miocene to Quaternary Hallett Volcanic Province forming the Adare Peninsula, or may be related to the post-spreading Pliocene-Recent volcanism of the Adare Basin.

Sedimentologic and petrographic characteristics of beach ridges in Terra Nova Bay (Antarctica)

Dumon Steenssens L.*, Lisco S., Micheletti F. & Mastronuzzi G.

Dipartimento di Scienze della Terra e Geoambientali, Università di Bari "Aldo Moro".

Corresponding author email: lea.dumon@uniba.it

Keywords: beach ridges, Terra Nova bay, geomorphology.

Beach ridges, found around Terra Nova Bay (Antarctica) are primarily composed of sediments such as sand, gravel, and occasionally shell fragments. The material constituting these ridges can originate from both local and distant sources (Baroni, 1987). While some sediments may come from nearby beaches or eroded cliffs, others might be transported by rivers or ocean currents from more remote locations. The composition and characteristics of these sediments provide valuable insights into the history of deglaciation in the region (Baroni & Orombelli, 1991). Samples of beach sand were gathered from various elevations, encompassing both current and elevated beach areas. This sampling was part of the PNRA-DISGELI national project conducted between October 2022 and February 2023. By analyzing 33 thin sections, conducting granulometric analysis, and identifying both emerged and submerged morphologies, this study can unravel the complex processes of sediment deposition during different stages of deglaciation. Through meticulous sieving of grains and measuring the evolution of weight, it was possible to construct granulometric curves, aiding in understanding the temporal and spatial distribution of sediments and the dynamics of coastal evolution.

The petrographic characterization reveals the presence of abundant lithic fragments showing textural and mineralogical features referable to a large number of different rock types. Isotropic textures are recognizable for plutonic fragments deriving from acidic-intermediate rocks (granites-granodiorites-diorites) and for volcanic porphyritic mafic rocks (olivine basalts). Detritus from metamorphic rocks is also abundant: clasts from Opx-bearing granulitic rocks, Sill-bearing high-T ones and gneisses (Rocchi et al., 2004). In regard to the granulometric analysis, the distributions of grainsize suggest the existence of moraine deposits that are poorly sorted and have been influenced by wave activity.

Keywords: beach ridges, Terra Nova Bay, ^{14}C dating.

Terra Nova Bay, a significant inlet on the western margin of the Ross Sea along Victoria Land's coast, harbors both modern and ancient beach ridges within its bays and protected areas. Approximately 8000 to 7500 years ago marked the completion of deglaciation in Terra Nova Bay following the retreat of the grounded ice sheet in the Ross Sea Embayment (Baroni, 1987). The various phases of deglaciation resulted in the formation of elevated beaches ridges at different elevations in Tethys Bay and Adélie Cove, allowing the stepwise retreat of the grounding line (Baroni & Orombelli, 1991). Samples were gathered from various elevations, encompassing both current and elevated beach areas. This sampling was part of the PNRA-DISGELI national project conducted between October 2022 and February 2023. The samples underwent carbon dating analysis, including bioclast fragments, a fish specimen, shells, penguin feathers, bones, teeth, remains, and a vermulid (Hajdas et al., 2021). The primary objective of this study is to determine the uplift rates and scale associated with the undergone deglaciation that shaped these beach ridges.

Keywords: Antarctica, crust and lithosphere, ice sheets.

The Antarctic crust and lithosphere holds critical information to decipher geological influences on past, present and future Antarctic ice sheet behavior. Recent compilations of bed topography, bathymetry, aeromagnetic and aerogravity anomalies, and seismological networks and satellite data are transforming our ability to extrapolate geological information from the coast to the entirely ice-covered interior of Antarctica.

The Paleozoic to Cenozoic subduction system of the Antarctic Peninsula is well known. However, whether the tip of the West Antarctic Rift System (WARS) linked up to the subduction zone remains ill-constrained and this limits our understanding of the geodynamic drivers of rift evolution and changes in crustal and mantle dynamics. Recent progress has been made in imaging the WARS beneath the most rapidly changing part of the West Antarctic Ice Sheet in the Amundsen Sea Embayment, augmenting prior knowledge of the Ross Sea Rift and Siple Coast segments. Overall, we now have a more comprehensive view of the segmentation of the rift system, in terms of the distribution of sedimentary basins, crust and lithosphere thickness, effective elastic thickness, and partially also magmatism and geothermal heat flux. However, there are still open questions, particularly regarding the geological sources of aeromagnetic anomalies within the WARS. Traditional interpretations predict that they reveal huge volumes of Cenozoic rift-related magmatism. Nevertheless, this hypothesis is difficult to reconcile with evidence from glacial erratics and the amount of Cenozoic crust and lithosphere extension. Although the role of different tectono-thermal and ice sheet processes affecting the evolution of Cenozoic magmatism in the WARS has received considerable international attention, it clearly calls for further research.

Understanding the roles of tectonic, thermal, erosional and isostatic processes in the uplift of the Transantarctic Mountains (TAM) also requires further research. For example, whether the was a West Antarctic plateau and a vanished Mesozoic Victoria Basin is debated, and controversy centers on whether the Wilkes Subglacial Basin (WSB) resulted solely from lithospheric flexure linked to TAM uplift and glacial erosion, or if Mesozoic and Cenozoic extension occurred also within East Antarctica.

Aerogeophysical exploration has unveiled major sedimentary basins in East Antarctica, including the WSB, the Aurora Subglacial Basin, the Recovery and Pensacola Pole Basin. However, to develop new models of the crustal and lithospheric cradle of the largest ice sheet left on Earth we need more seismological stations and MT arrays to be deployed atop of these basins, New higher resolution aerogeophysical surveys also need to be flown over major subglacial lake districts, to enhance our knowledge of hydrological influences on East Antarctic Ice Sheet behavior.

Oligocene-Miocene structurally-controlled hydrothermal activity along the Transantarctic Mountains: evidence from apatite thermochronology

Keywords: Antarctica, fission-track thermochronology, hydrothermal fluid flow.

The Transantarctic Mountains (TAM) constitute the longest extensional mountain range on Earth, forming the Mesozoic-Cenozoic rift shoulder at the boundary between the Antarctic craton and the Ross Sea embayment. Wide rifting accompanied first the Gondwana breakup, characterized by horst and graben structures in the Ross Sea and by topographically high rift shoulder, shaped in time by fluvial and glacial erosion. During the Cenozoic, deep troughs, such the Terror Rift, developed at the front of the TAM following a transtensive reactivation, acting as intraplate termination of transform shear and propagating into inherited Paleozoic shear zones. Eocene to Present tectonics is well-constrained offshore, where thick Cenozoic glacio-fluvial sediments are faulted and invaded by the volcanic products of the McMurdo Volcanic Group during continuous rifting. Few direct time constraints of Cenozoic faulting exist onland, and are mainly available from the Northern Victoria Land. In Southern Victoria Land, fault activity is indirectly constrained by anomalies in age-elevation linear relationship as derived from low-temperature thermochronology data.

In this study, we focused on the Prince Albert Mountains sector of Southern Victoria Land, in the area between Mawson and Mackay glaciers, namely the Convoy Range block. This area has been poorly covered by field surveys; therefore, few thermochronological data are available and brittle structural data are lacking. Here we present results of a multidisciplinary approach aimed at reconstructing the Oligo-Miocene tectonic activity in the region that integrates: (1) multiscale structural analysis (from regional- to micro-scale); (2) geothermometry; and (3) apatite fission-track thermochronology.

Brittle deformation is accompanied by hydrothermal propylitic alteration (secondary chlorite, epidote and sericite) and carbonatisation of the intrusive magmatic host rocks. Chlorite thermometry constrains the temperature environment of rock alteration at ~ 230 ± 20°C. Samples collected along fault zones show fission-track ages as young as ~ 23 Ma, opposed to undeformed samples at similar elevation (from ~ 30 to ~ 50 Ma). Anomalous fission-track ages are correlated with the thermal overprint associated with the structurally controlled hydrothermal event. These results document a case of structurally-controlled hydrothermal fluid flow during the Cenozoic transtensive reactivation in Victoria Land, with important inference on the onset of Cenozoic volcanism in the region.

The use of macrofaunal microfossils to unveil past Holocene changes: a case study from Edisto Inlet (Ross Sea, Antarctica)

Keywords: Antarctica, Holocene, echinoderms.

Paleoenvironmental reconstructions are essential for the understanding of the evolution of past climatic conditions. These reconstructions rely on various proxies to gain a comprehensive view of environmental characteristics, ranging from geochemical to micropaleontological analyses. Traditionally, micropaleontological studies have focused on foraminifera, diatoms, and other microorganisms, relating changes in species compositions to changes in the physiochemical characteristics of the environment. However, the stratigraphical distribution of macrofaunal-related microfossils (150 µm – 1 mm) has been largely overlooked, particularly for the Holocene and within remote areas like Antarctica. In this study, we examine a Late Holocene (3.6 kyrs BP) high-resolution marine sediment core from a fjord in the northwestern part of the Ross Sea, Antarctica. With a core length of around 14 m, this record provides exceptional subcentennial resolution. Our findings demonstrate that macrofaunal remains, specifically echinoderms, can offer detailed insights into recent past environmental conditions. We identified two distinct echinoderm groups: ophiuroids, or brittle stars (*Ophionotus victoriae*), and irregular echinoids. Despite challenges in estimating population size due to the abundance of ossicles releases upon decay, we employed a statistical approach (Generative Additive Models) on presence/absence data to estimate the probability of occurrence of these organisms. By comparing results with other proxies derived from the same record and nearby cores, we successfully employed echinoderms as a novel proxy for polar environment reconstruction, tracing the evolution of the sea-ice cover. The presence of *O. victoriae* was associated with interannually stable sea-ice cycles with yearly organic matter deposition, owing to its peculiar reproductive physiology. Additionally, its presence indicated periods of a mature benthic community, as it is a widespread component of Antarctic benthos. Irregular echinoids were linked to organic matter presence on the seafloor. Through proxy comparisons, we distinguished a specific climatic phase (The Ophiuroid Optimum), providing additional insights into the environmental evolution of the area beyond standard proxies. In conclusion, this study offers compelling evidence that incorporating macrofaunal-related proxies in paleoenvironmental reconstructions is essential for capturing complex environmental dynamics.

Paleoceanographic changes suggested by planktic and benthic foraminifera in the Western Svalbard Slope (Bellsund Drift) during the last century

[1] Escuela Centroamericana de Geología, University of Costa Rica, San José, Costa Rica. [2] Dipartimento di Scienze della Terra, Università di Pisa. [3] Istituto di Scienze Polari, CNR, Bologna. [4] Istituto Nazionale di Oceanografia e di Geofisica Sperimentale, Sgonico (TS).

Corresponding author email: caterina.morigi@unipi.it

Keywords: sea ice, Svalbard, last century.

The objective of this study is to reconstruct the last century's climatic oscillations in the Western Svalbard Slope (Arctic region) using high-resolution analysis of planktic and benthic foraminiferal assemblages as proxies for surface and deep-water mass properties. In the studied area, warm Atlantic water masses are advected to the Arctic Ocean through the West Spitsbergen Current, representing the northernmost tip of the Global Thermohaline Circulation. The interaction between the cold Arctic and the warm Atlantic water masses significantly influences the entire foraminiferal community. The paleoenvironmental reconstruction obtained with the microfossil assemblages, together with data from satellite monitoring of the sea ice extent and the long-term record of the annual temperature of the West Spitsbergen Current measured over the last 50 years, support the evidence of a progressively rising heat influx into the Arctic Ocean due to an increasing Atlantic water inflow, forcing the consequent decay of the sea ice extent.

Mechanisms driving formation and preservation of the laminated sediments of Edisto Inlet, western Ross Sea (Antarctica): the sub-seasonal variability of particle composition and fluxes

Keywords: laminated diatomaceous sediments, sea ice dynamics, antarctica.

Laminated diatomaceous deposits have been documented in the Edisto Inlet (western Ross Sea). The sediments show alternating dark, rich in IPSO25 biomarker, indicative of fast ice, and light laminae, dominated by *Corethron pennatum* diatoms. Based on these observations, the dynamics of fast ice was reconstructed over the last 2.6 ka for the western Ross Sea. However, the lack of direct observations introduces uncertainty into the paleoclimatic and paleoceanographic interpretation of these laminated sediments.

The project LASAGNE (Laminated Sediments in the Magnificent Edisto Inlet, Victoria Land: What processes control their deposition and preservation?), funded by the Italian Program of Antarctic Research (PNRA), proposed a multidisciplinary study that integrates the characteristics of fast ice, water column, and surface sediment, aiming to obtain information on the factors influencing formation and preservation of laminated sediment in Edisto Inlet. The project integrates also biological data (phytoplankton, microzooplankton and foraminifera) collected in situ, and time series of satellite images of sea ice. The main goal was to provide new insights into the sub-seasonal formation of laminated sediments, offering a backbone for the interpretation of paleoclimatic sedimentary archives.

An oceanographic mooring was deployed between March 2022 and February 2023, to investigate the mechanisms driving the formation of sediment laminations. The purpose was to test whether the deposition of dark sediments (rich in sympagic diatoms such as *Berkeleya adeliensis*) occurs in late spring-early summer, while light sediment (mainly composed of *Corethron pennatum*) represents sedimentation in late summer-early autumn.

The mooring data reveals that sediment lamination arises from the significant seasonal variability of particle fluxes and composition. Additionally, the thermohaline properties and dynamics of water masses in Edisto Inlet exhibit pronounced seasonal changes. Similarly, diatom assemblages and sea ice cover also undergo significant seasonal variations.

Taken together, these environmental factors contribute to the formation of a pair of laminae (dark in late spring, light in late summer) during years characterized by the retreat of sea ice and the presence of open water conditions in late summer. The preservation of lamination is subsequently guaranteed by a high sedimentation rate, limited oxygen penetration, and reduced biological mixing.

IODP Expedition 403 Eastern Fram Strait Paleo-Archive: preliminary results from the last expedition of the International Ocean Discovery Program

Lucchi R.G.*[1], St. John K.[2], Ronge T.[3] & IODP Exp-403 Science Party

[1] Dipartimento di Geofisica, Istituto Nazionale di Oceanografia e di Geofisica Sperimentale, OGS. [2] Department of Geology and Environmental Science, James Madison University, USA. [3] International Ocean Discovery Program, Texas A&M University, USA.

Keywords: Arctic, paleoclimate, paleoceanography.

The North Atlantic and Arctic Oceans are unquestionably major players in the climatic evolution of the Northern Hemisphere and in the history of the meridional overturning circulation of the Atlantic Ocean. The establishment of the modern North Atlantic Water (NAW) transporting heat, salt, and moisture to the Northern Hemisphere, has been indicated as one of the main forcing mechanisms for the onset of the Northern Hemisphere Glaciation. NAW controls the extent and dynamics of circum-Arctic and circum-North Atlantic ice sheets and sea ice in addition to deep water and brine production. How the ocean system and cryosphere worked during past warmer intervals of high insulation and/or high atmospheric CO_2 content, is still largely unknown and debated and the required information can only be attained by offshore scientific drilling.

IODP Expedition 403 target high-resolution, continuous and undisturbed sedimentary sequences identified on the western continental margin of Svalbard (eastern side of the Fram Strait) along the main pathway and northern penetration of the North Atlantic Waters flowing into the Arctic Ocean. The area around Svalbard is very sensitive to climatic variability and it can be considered as a "sentinel of climate change". Further, the reconstruction of the dynamic history of the marine based paleo Svalbard-Barents Sea Ice Sheet is important as it is considered the best available analogue to the modern, marine-based West Antarctic Ice Sheet, for which the loss of stability is presently the major uncertainty in projecting future global sea level rise in response to the present global climate warming.

We present the preliminary results from the IODP Exp-403 that will take place on the drill ship Joides Resolution during 4th June – 2nd August 2024 (Amsterdam–Amsterdam) as the last expedition of the International Ocean Discovery Program.

The topography of the high latitude mountain chain and the enigma of high-standing plateau

Olivetti V.*, Cattò S. & Zattin M.

Dipartimento di Geoscienze, Università di Padova.

Corresponding author email: valerio.olivetti@unipd.it

Keywords: Greenland, north Atlantic margin plateau, detrital fission-track.

Most of the mountain chains located at high latitudes in both hemispheres, such as the Transantarctic Mountains and the North Atlantic continental margins, shows high-standing low-relief surfaces deeply incised by fjords. The origin of such topography in Greenland and Norway is largely debated, and two end-member hypotheses have been proposed. The first hypothesis proposes that the low-relief landscape was formed at low elevations during a Mesozoic peneplanation phase and then uplifted during the Cenozoic; in this context the low-relief surface thus represents a remnant erosional surface where the present erosion is negligible. According to the second hypothesis, the low-relief surface was formed at high elevations in response to a slow, continuous and ongoing process of widespread erosion at high altitudes. These two hypotheses imply different geological and geomorphological processes and different amounts of sediment production over time, especially in the last few million years.

Here we show detrital dating through apatite fission-track (AFT) method from Greenland emipelagic marine record. 10 samples have been collected from two ODP cores, the leg 152 site 918 and the leg 162 site 987, that cover a time interval from late Miocene to Middle Pleistocene. Mixture distribution of AFT ages have been decomposed into age populations, giving population in agreement with the insitu AFT ages.

We interpreted the observed trend as a consequence of relevant contribution of sediment from high-standing plateau that is characterized by older insitu AFT ages.

Contrasting provenance signals during Pleistocene interglacial periods influenced by West Antarctic Ice Sheet climatic response recorded at IODP Site U1524 exp. 37

Keywords: provenance studies, West Antarctic Ice Sheet, zircon dating.

The study of erosion, dispersal and deposition of sediments represent a useful tool for reconstructing Antarctica's ice sheets during the warmer-than-present interglacial periods of the late Pleistocene, with the aim of informing predictions of Antarctic ice sheet mass loss over the coming decades and centuries. Overcoming uncertainty in how the sedimentary system operates at IODP Expedition 374 Site U1524 could potentially reveal the evolution of the West Antarctic Ice Sheet (WAIS), resulting in improvements in ice sheet model predictions of future sea-level rise. We present new sedimentological provenance data from Site U1524, coupling U-Pb zircon dating (DZ), heavy mineral (HM) analysis, and Nd isotope compositions to reveal patterns of ice sheet erosion and sedimentary dispersal since ~400 ka. Zircon age distributions down the section are dominated by Ross and Nimrod Orogeny zircons, but younger populations of Cretaceous and Carboniferous ages from Marie Byrd Land allow detection of distinct sourcing from West Antarctica (WA) and the Transantarctic Mountains (TAM). HM suites indicate a general provenance from a recycled orogen due to the presence of diagnostic metamorphic and igneous minerals such as amphibole, epidote and garnet, but associated with a low tHMC (2.7 ± 0.6). A clear shift (possibly identified as the late-MIS9) towards a more mafic source is detected by the increase of clino and orthopyroxenes with abundant diopside and hypersthene, pointing to the erosion and contribution from gabbros and andesites. This is further supported by the presence of minor amount of high-pressure Al-silicate (kyanite) and prehnite-pumpellyite diagnostic of detritus from low grade metamorphic source (first cycle or metasediment erosion). The neodymium isotope dataset helps identify glacial periods, with consistent epsilon Nd values of ~-8.5 possibly representing reworked material from the continental shelf. In contrast, different interglacial periods show distinct epsilon Nd excursions; whilst all interglacial periods appear to contain an interval with epsilon Nd values of ~-7, only one has an interval (interpreted as late-MIS9), with epsilon Nd values approaching -10. The HM and DZ datasets concordantly indicate the TAM as the most probable sediment source for this interval. Furthermore, the two topmost samples show contrasting dataset interpretation of possible mixing of WA and TAM detritus. Paleoenvironmental sedimentary records provide new interpretations of the differing response of the WAIS to climatic and oceanic forcing in recent interglacial periods, but only the correct use of multiple datasets could identify source rocks and suggest sediment reworking, unveiling past sediment routing systems and therefore ice sheet extents.

Clast petrography from IODP 374 cores in the central Ross Sea (Antarctica): implications for sediment provenance and source terranes

Perotti M.[1], Zurli L.*[1], Marschalek J.[2], Mallery C.[3], van de Flierdt T.[2], Licht K.[3], De Santis L.[4], McKay R.[5], Kulhanek D.[6] & Expedition 374 Scientists

Keywords: IODPexp374, provenance, clast petrography.

International Ocean Discovery Program (IODP) Expedition 374 recovered high-quality cores at five sites on the Ross Sea continental shelf, slope, and rise to improve the understanding of the sensitivity of the Antarctic ice sheets to past climatic and oceanic conditions, especially during a warmer-than-present climate. Distribution of gravel-sized clasts along the glacimarine successions recovered in the sites U1521 (Early Miocene to Pleistocene) and U1522 (Late Miocene to Pleistocene) helps to discriminate source terranes and ultimately reconstruct the contribution of West Antarctic Ice Sheet expansion and retreat during past glacial cycles. Granule to cobble sized clasts present in the sedimentary record from both the sites have been counted and grouped into seven lithological groups based on macroscopic and microscopic recognition. Low grade metasedimentary rocks, the most common lithologies in both the drillcores together with granitoid rocks, reflect the main basement composition in the source terranes. In order to discriminate possible source regions of granitoid clasts, chemical analyses were carried out using SEM-EDS on biotite crystals. Biotite composition were then compared with those of the main intrusive formations cropping out along the Transantarctic Mountains and Marie Byrd Land. The less abundant lithologies such as volcanic and subvolcanic rocks, occurring only in specific lithostratigraphic units, are diagnostic in revealing Transantarctic Mountains or West Antarctica provenance. In particular, dolerites from the Ferrar Large Igneous Province, extensively cropping out along the Transantarctic Mountains, are present only in some units from both of the sites, indicating a major influx from East Antarctic Ice Sheet and a minor role of the West Antarctic Ice Sheet in delivering sediments at the drilling site. Instead, felsic subvolcanic rocks such as rhyolitic porphyries are common in late Miocene lithostratigraphic units of U1522 core, where dolerites are rare, pointing out to a terrane currently not exposed in the source region. Four pebbles from these sequences have been dated with zircon UPb geochronology and yielded a prevalently Early Jurassic age. This aspect highlights that the sediment source region, inferred in the West Antarctic Rift System, has been involved in Jurassic magmatism, apparently much more than what the sparce data from outcrops in West Antarctica suggest.

Assessing planktonic foraminiferal species from Antarctic sea-ice as a paleoceanographic proxy: preliminary insights

Keywords: proxy, foraminifera, Antarctic sea-ice.

Antarctic sea ice greatly impacts the Southern Ocean's biogeochemical cycles and ecosystem dynamics by providing a unique habitat through its intricate brine channels and pockets, known as the sympagic sea ice community. This community, abundant in diverse biota, plays a critical ecological role in the region. However, faunal components like microzooplankton, including foraminifera such as *Neogloboquadrina pachyderma* have been understudied despite their prevalence in contemporary high-latitude planktonic communities and Southern Ocean sediment samples. During the ANT29-7 expedition aboard the RV Polarstern from August 14 to October 13, 2013, ice cores were collected from three dive transects (EB, POL, ROV) on an ice floe at 60°47.76'S and 26°19.73'W in the Weddell Sea. Sampling involved obtaining three replicate ice cores at 2-meter intervals along each transect. The ice cores (each 100 cm long) were analyzed in two sections: the lower 0-10 cm representing the seawater-ice interface and the upper 10-100 cm. Planktonic foraminifera were studied quantitatively and qualitatively, focusing on density (n°/l) and biomass (µgrC/l) across three size fractions (> 150; 150-63; and 63-10 µm). The most common size fraction in both upper and lower sea-ice samples was between 63 and 150 µm. Density ranged from 2.8 n°/l to 97.2 n°/l in upper sea-ice and from 1.9 n°/l to 329.6 n°/l in lower sea-ice across all size fractions. Biomass values followed a similar trend, ranging from 0.4 µgrC/l to 8.9 µgrC/l in upper sea-ice and from 1.0 µgrC/l to 25.9 µgrC/l in lower sea-ice. Planktonic foraminifera were predominantly found at the seawater-ice interface (756 n°/l upper sea-ice vs 1140 n°/l lower sea-ice), consistent with previous Weddell Sea studies where foraminiferal numbers ranged from 87 to 1075 n°/l, mainly in the lower sea-ice core portion with sizes under 100 µm. All planktonic foraminifera identified belonged to the *Neogloboquadrina pachyderma* species. Quantitative and qualitative morphometric analyses differentiate individuals from the water column and sea ice, although with some overlap. Sea ice specimens are typically larger, always have a lip at the aperture, and exhibit more morphological variation compared to those from seawater. Linear Discriminant Analysis (LDA) using Fourier shape analysis effectively distinguishes between these groups with minimal overlap. These findings suggest the presence of a distinct type of *N. pachyderma* in sea-ice, characterized by unique shell features and adaptation to extreme temperature and salinity conditions. Further ultrastructural and genetic analyses are essential to confirm the presence of a sympagic species of planktonic foraminifera in sea-ice, providing valuable insights for paleoenvironmental reconstructions and paleoceanographic studies.

A multidisciplinary investigation into the source and impact of greenhouse gases in the Dry Valleys, Antarctica

Sciarra A.*[1], Ruggiero L.[2], Mazzini A.[3-1], Florindo F.[1], Wilson G.[4], Mazzoli C.[5], Anderson J.T.H.[6], Olivetti V.[5], Romano V.[1], Sassi R.[6], Bigi S.[7] & Ciotoli G.[8]

Keywords: permafrost, geochemical and geophysical surveys, Antarctica.

Contemporary studies conducted in northern polar regions reveal that permafrost stability plays an important role in the modern carbon cycle as it potentially stores considerable quantities of greenhouse gases. Rapid and recent warming of the Arctic permafrost is resulting in significant greenhouse gas emission, both from physical and microbiological processes. The potential impact of greenhouse gas release from Antarctica is now also being investigated. In Antarctica, the McMurdo Dry Valleys comprise 10% of the ice-free soil surface areas in Antarctica and like the northern polar regions are also warming albeit from lower mean temperatures.

The work presented herein examines a comprehensive sample suite of soil gases (e.g., CO_2, CH_4, He, 222Rn and 220Rn) concentrations and CO_2 flux measurements conducted in the Taylor Valley and Wright Valley during the Austral summer from 2019/2020 to 2022/2023. Analytical results reveal the presence of significant concentrations of soil gas at the base of the active layer. When compared with the few previously obtained measurements, we observe increasing CO_2 flux rates (estimated carbon dioxide emission in the study area of 21.6 km2 ≈ 15 tons/day; Ruggiero et al., 2023).

Moreover, a 2-D Deep Electrical Resistivity Tomography (DERT) survey in Taylor Valley was performed to visualize the distribution of permafrost, its thicknesses, lower boundaries, and watershed. Results show resistive, discontinuous domains that we interpret as permafrost units. The results indicate resistive and discontinuous domains that we interpret as permafrost units (as already referred by Mikucki et al., 2015). A multi-tiered groundwater circulation model characterizes the extensive brine system in Taylor Valley that was discovered in the obtained dataset.

The geochemical distribution of anomalous areas, compared with geophysical surveys, suggests an origin from deep brines migrating from inland (potentially from beneath the Antarctic Ice Sheet) towards the coast beneath the permafrost layer. These newly obtained data provide a baseline for future investigations aimed at monitoring the changing rate of greenhouse gas emission from Antarctic permafrost, and the potential origin of gases, as the southern polar region warms.

Corresponding author email: matteo.simonetti@isprambiente.it

Keywords: Antarctica, Victoria Land, geological map.

We supply a new geological map (1:250,000 scale) (Capponi et al., 2024) that allows to complete the coverage of Victoria Land, by filling the gap between the GIGAMAP program (Pertusati et al., 2016; a German/Italian agreement of cooperation to produce new geological maps of Victoria Land), to the north, and the maps by the New Zealand Antarctic program, to the south (Pocknall et al., 1994; Cox et al., 2012).

New mapping was performed by a three-person team in the 2017/18 and 2018/19 austral summers (XXXIII and XXXIV ItaliAntartide expeditions). The activity was heli-supported, starting from both the Italian Base Mario Zucchelli (2017/18) and from a tent camp located at Starr Ntk (2018/19).

Field activity included geological and geological-glacial field mapping, photogeological analyses, structural observations and rock sampling. Dolerite sills of the Ferrar Group are prevalent in this area, with limited outcrops of the extrusive correlative Mawson-Exposure Hill Formation. Sandstones of the Beacon Supergroup are limited to small outcrops and to 100 m-long rafts enclosed in the dolerite. Granites and granodiorites of the Granite Harbour Intrusive Complex constitute the crystalline basement underlying the Gondwanian sequence, cropping out only along the lower-lying sector close to the Ross Sea coast. Minor enclaves of Wilson Terrane gneiss are hosted in the Granite Harbour granitoid. Structural data of bedding, fault and fracture were measured. More than 250 rock samples were collected for subsequent laboratory analyses, later stored at the National Antarctic museum in Siena. Subsequent activity has included: digitization of the new cartographic data, elaboration of structural data, microstructural analyses and minero-petrographic analyses of rocks and glacial deposits.

The mapping highlighted some key features of this region, such as the scarce occurrence of rocks of the Wilson Metamorphic Complex, the occurrence of mafic rocks belonging to the Granite Harbour Intrusive Complex and the possible activity of faulting with hundreds of meters of vertical offset, linked to the post Ross Orogeny tectonics.

This new map can be used as the starting point for any future geological investigation in this region.

Keywords: crystal cargo, plumbing system, ice load.

The Pleiades Volcanic Field (PVF), located in northern Victoria Land, Antarctica, is made up of a dozen monogenetic scoria cones and two domes, with ages ranging from ca. 800 ka to present. Despite the monogenetic aspect of the edifices, the volcanic products are compositionally diverse and define a complete mildly Na-alkaline evolutionary trend. This makes the PVF a distinctive volcanic field, whose plumbing system has likely evolved under special conditions. To unravel the architecture of the PVF feeding system, we applied high-resolution petrological investigations on the crystal cargo of a set of lavas sampled in the framework of the Italy's National Antarctic Research Program - PNRA. Textural and chemical characterisation of the main mineral phases, as well as reconstruction of P-T conditions of crystallisation, have been conducted on samples representative of the whole intra-association variability. Results of this petro-chemical analysis testify to a combination of magmatic processes, including an efficient and extensive differentiation, crustal assimilation and intra-association mixing among batches of diversely evolved magma. The complexity of pre-eruptive processes suggests endogenous growth due to an incapacity of eruption, which led to a prolonged stall of the magma at crustal depths. We thus interpret a long-lived and vertically extended subvolcanic system, which has periodically fed volcanic activity for hundreds of ka. The existence of such a system, in a volcanic province where the numerous monogenetic cones are mainly mafic in composition, can be reasonably attributed to external factors. Considering the context of glaciated terrain, an efficient forcing to take into account is a variable ice load, linked to climatic fluctuations, capable of influencing the stress field conditions around crustal magmatic reservoirs. This work hence highlights the potential of a climate-controlled modulation of subvolcanic systems in Antarctica, as inferred in other glaciated regions of the world (e.g., Iceland and British Columbia).

Keywords: Norian/Rhaetian boundary, major and trace elements, Re-Os isotopes.

The Norian/Rhaetian boundary (NRB) in the Late Triassic is characterized by a faunal turnover of major pelagic groups, such as radiolarians, conodonts, and ammonoids (Rigo et al., 2020). Although catastrophic events such as the emplacement of large igneous provinces (LIPs) and extraterrestrial impacts have been proposed to account for this biotic turnover, firm evidence based on the geochemistry of sedimentary successions is still lacking. To elucidate the trigger for the environmental changes across the NRB, we performed major and trace element geochemistry in carbonate rocks for the Pignola-Abriola section in the Lagonegro Basin, southern Italy. This section is a candidate for the Global Stratigraphic Sections and Points for the Rhaetian Stage and it has been investigated in detail for high-resolution biostratigraphy, carbon isotopes, magnetostratigraphy and rock magnetism (Rigo et al., 2016; Maron et al., 2024). In addition, we analyzed the Re-Os isotopes and highly siderophile element (HSE) concentrations in the Rhaetian shales with the aim of correlating the nearby Sasso di Castalda section where the HSE-enriched layer was detected (Sato et al., 2021).

Our data demonstrate that the lower part of the section (0-36 m) is dominated by SiO_2-poor (<30 wt.%) limestone, sometimes dolomitized, whereas the upper part of the section (36-56 m) contains SiO_2-rich (>30 wt.%) marls and mudstones with variable concentrations of Al_2O_3 (0.2-7 wt.%). This variation is consistent with a progressive increase in the relative abundance of cherty and siliceous components (Rigo et al., 2016; Maron et al., 2024). Although the enrichment factors (EF) of most elements in the upper section do not show remarkable changes, the redox-sensitive elements such as VEF and CrEF show appreciable increases across the NRB (45 m). The stratigraphic profile of ReEF obtained from the corresponding shaley beds provides a consistent variation showing a gradual increase just above the NRB. Thus, VEF in carbonate and ReEF in shale record transient changes to suboxic conditions in the Lagonegro Basin across the NRB. However, it is not clear whether these environmental changes in the Lagonegro Basin were triggered by LIPs or impact events, because our 187Os/188Os and HSE data are limited to the Rhaetian shale. Thus, more comprehensive dataset including the carbonate through the entire section and the Norian shales may provide critical evidence for the causal mechanism of the environmental changes in the NRB.

Keywords: carbon isotopes, clay minerals, MECO.

The Middle Eocene Climatic Optimum (MECO, 40.5-40 Ma) is an abrupt global warming pulse identified in the deep-sea record of the main oceans (Boscolo Galazzo et al., 2014) where it is associated with biocalcification crisis. However, this event is still highly overlooked in shallow-water records, where the dynamics that link warming and carbonate production is still highly debated (Sluijs et al., 2013). In this study, we aim at identifying the impact of such a rapid and intense warming pulse on a shallow water, mixed carbonate-siliciclastic succession. With a multiproxy approach based on facies and microfacies analyses, trace element concentrations, clay mineral assemblages, C and O isotope analyses, we intend to identify the signature of the MECO in the Capo Mortola section (Ligurian Alps, Northern Italy). Age constraints are provided by Larger Benthic Foraminifera and nannofossil biostratigraphy. The Capo Mortola section consists of rudstones to packstones with nummulitids that pass upwards to marly wackestones to floatstones with solitary corals and ostreids. The latter facies is overlain by rudstones with densely packed Discocyclina tests. The peculiar texture of this facies is the result of internal waves impacting the deep portion of the middle ramp, characterized by a significant stratification of the water column. According to biostratigraphy, the onset of the warming pulse occurs within the marly floatstone deposition, while the peak is recorded within the Discocyclina dominated facies. An increase of the terrigenous input during the MECO is attested by a mild increase of continental-derived elements such as Al, Si and Fe, as well as an increase of kaolinite content in the rudstones with Discocyclina, associated to intense weathering of silicate rocks in the land masses. Carbon isotope ratios, measured on LBF tests, show a positive shift in correspondence of the MECO, attesting increased primary productivity triggered by increased nutrient contents, in turn linked to higher weathering rates, in the middle ramp. This integrated approach indicates that shallow water carbonate production itself did not suffer any crisis during the MECO, when instead the oligophotic Discocyclina-dominated factory thrived, favoured by warm temperatures, and by the balance between nutrient availability sustained by runoff and the persistence of light penetration in a wide middle ramp.

Keywords: Villaggio del Pescatore, geochemistry, palaeoenvironment.

The Adriatic Carbonate Platform (AdCP) was one of the largest carbonate platforms of the peri-mediterranean region during the Mesozoic, with deposits ranging in age from the Lower Jurassic to the latest Cretaceous. By the end of the Mesozoic, the AdCP probably appeared as several deep troughs separated by shallow marine or partially/completely emerged areas. The Villaggio del Pescatore fossil site (VdP), in Duino-Aurisina, Trieste, Italy, originated in one of these emerged areas during the lower to middle Campanian, between 81.5 and 80.5 Ma. This fossil site is probably the result of the tectonic driven uplifting of a sector of the carbonate platform above the sea level, followed by the formation of a depression inside the emerged limestones. This depression housed a water body in which finely laminated limestones – either light-coloured or black – accumulated. Such deposits host exquisitely preserved fossils remains, including fish, molluscs, crustaceans, ostracods and benthic foraminifera, as well as pterosaurs, crocodilians and dinosaurs. Here we introduce a detailed geochemical analysis of the fossil beds, which represent a unicum in the geological record of the Mesozoic Mediterranean carbonate systems. Thin sections and bulk samples were analysed through XRF, XRD, WD-XRF and LOI. Results suggest that the mineralogy of the laminated limestones is mainly composed of calcite, whilst the LOI value is probably increased by the organic matter conserved in them as a result of bottom water anoxia. In addition, several paleoenvironmental proxies suggest decreasing salinity, progressively drier climate and decreasing quantity and grain size of terrigenous input at the site during the laminated limestones' deposition. Primary productivity at the site seems to have remained relatively constant and the different amount of organic matter preserved in the two kinds of laminated limestones is probably the result of periodic bottom water oxygenation during the light brown strata's deposition. Finally, the laminae have historically been interpreted as varve, but the absence of chemical differences between the darker and lighter micro-laminae forming each lamina suggests that this difference in colour might be the result of bacterial maths being continuously covered by sediment and regrowing on it.

Seawater temperatures, pH and water mass provenance reconstructions over the last century from cold-water coral geochemistry in the North Atlantic Ocean

Keywords: cold-water corals, Northern Iceland Basin, isotopes.

The geochemical composition of the aragonite skeleton of cold-water corals (CWC) can provide unique information on the physico-chemical changes and dynamics of water masses at intermediate depths at high temporal resolution (e.g. sub-decadal). Previous studies have shown that variations in seawater temperature, water ventilation age, and water mass provenance can be inferred from measurements of skeletal Li/Mg ratios, paired U/Th and ^{14}C, and neodymium isotopes, respectively. In particular, the solitary azooxanthellate scleractinian coral species *Desmophyllum dianthus* is particularly valuable due to its widespread distribution, century long lifespan, and stratified skeletal growth, which facilitates the use of geochemical tracers at sub-decadal intervals.

Here, we investigated several *Desmophyllum dianthus* samples retrieved in 2012 from the Northern Iceland Basin at depths of 570-700 m during the ICE-CTD R/V *Thalassa* expedition, using the Remotely Operated Vehicle Victor 6000 operated by IFREMER. Sub-samples of the coral skeletons collected along the growth axis were analysed for Li/Mg, stable isotopes ($d^{11}B$, $d^{18}O$, $d^{13}C$), U/Th, 14C and Nd isotopes, with the aim to reconstruct the physico-chemical changes of the North Atlantic intermediate water masses (Iceland-Scotland Overflow Water, Sub-Arctic Intermediate Water and Western North Atlantic Central Water), and quantify how their contributions have varied over the past few decades. The Li/Mg ratios revealed sub-decadal temperature records that vary between ~2 to ~6°C, which is closely related to changes in Nd-isotopic compositions. These results can be explained by decadal fluctuations in the North Atlantic Oscillation and East Atlantic atmospheric patterns, with those atmospheric drivers causing strengthening or weakening of the Atlantic Subpolar Gyre, leading to changes in the amount of warmer Subtropical Gyre-sourced water or colder SPG-sourced water. Additionally, the prevalence of ISOW is shown to have roughly halved over the past ~70 years, suggesting an increase in northward transport of warm subtropical waters over recent decades, which may have contributed to recent warming in the Arctic region, as well as substantial multi-decadal weakening of Nordic Sea overflow currents.

The PRIN "REMEPP" project: response of Mediterranean calcareous plankton to CO_2 variability during some intervals of the Plio/Pleistocene

Keywords: Mediterranean, Pliocene, Pleistocene.

The Mediterranean is an area of particular interest as it is particularly exposed to natural risks, in terms of desertification, acidification of water masses and loss of biodiversity. The REMEPP project aims to reconstruct the effects of CO_2 on the global productivity of calcareous plankton in some key intervals of the Neogene and Quaternary, in which strong climatic variations occurred. The selected successions cover the stratigraphic intervals between 5.2-4.85 Ma (EZWP), 2.95-3.3 Ma (PWP) and 2.7-2.4 Ma (PPT), where outcrop in the land famous successions of Eraclea Minoa/Capo Bianco, Punta di Maiata, Punta Piccola and Monte S. Nicola. These sections, in which the Messinian/Zanclean, Zanclean/Piacentian and Piacenzian/Gelasian GSSPs were defined, are astro-bio-magneto-chronologically well calibrated. Particularly, these intervals are characterized by strong changes in calcareous microfossil assemblages induced by astronomical cycles. In order to understand the mechanisms controlling climate variations, a multidisciplinary approach have been used, carrying out quantitative analysis on calcareous microfossils, stable isotopes ($\delta^{18}O$, $\delta^{13}C$ and $\delta^{11}B$) and alkenones to estimate the paleotemperatures of surface waters, as well as than as a proxy for marine productivity. The great sensitivity of the Mediterranean Sea to climate variations, and the signal stored in these natural sedimentary archives, is fundamental to characterize and quantify for the first time CO_2 levels, and understand how calcareous microfossils respond to these variations.

Middle Miocene paleoclimatic phases: a Central Mediterranean perspective from the SE Sicily sedimentary succession

Catania G.*[1], Barbagallo V.[1], Brandano M.[2], Borzì L.[1], Cornacchia I.[3], Distefano S.[1], Pellegrino A.[1], Mancini A.[2], Marianelli D.[2], Maniscalco R.[1], Salerno A.[1] & Di Stefano A.[1]

Keywords: Middle Miocene, paleoclimatic phases, SE Sicily.

The Middle Miocene climate is marked by a changeover from a warm period (Miocene Climatic Optimum, ~17-14.7 Ma), to a transitional phase (Middle Miocene Climatic Transition), culminating in a cold stage (Icehouse Mode, ~13.8 Ma). This period is associated with a positive excursion of $\delta^{13}C$ ("Monterey Excursion"), showing a series of $\delta^{13}C$ maxima (CM events) highlighted by cooling peaks in the $\delta^{18}O$ values (Mi events).

In south-east Sicily (Hyblean Mountains), the Middle Miocene sedimentation is represented by the marly-calcarenitic deposits of the upper Irminio Fm followed upward by the marly clays of the Tellaro Fm. Due to their excellent exposure and rich calcareous plankton content, the Miocene Hyblean formations have often been selected for detailed integrated stratigraphic studies.

This study illustrated the preliminary results of an integrated stratigraphic study which involves high resolution plankton biostratigraphy and analysis of stable isotopes of C and O carried out on foraminifera tests.

The calcareous plankton biostratigraphy (nannofossils and foraminifers) provides a well constrained age-model for the study succession, which ranges from the basal Langhian (~16 Ma) to the basal Serravallian (~13.6 Ma) stages.

Oxygen and carbon isotope ratios were measured on separated foraminifera tests belonging to Globigerinoides and Globigerina genera. The $\delta^{18}O$ record is consistent with a warm but dynamic climate phase. Furthermore, the preliminary $\delta^{13}C$ curve shows several positive peaks that correspond to different carbon maxima of the Monterey Event. This correlation testifies for a Central Mediterranean Basin extremely sensitive to the global carbon cycle dynamics during Middle Miocene.

Quantitative reconstruction of temperature changes during the last ~13500 years in Georgia through stable isotopes (δ^2H-$\delta^{13}C$-$\delta^{18}O$) from speleothems fluid inclusions and calcite

Columbu A.*[1], Asanidze L.[2], Zanchetta G.[1], Burns S.[3], Lezhava Z.[2], Tsikarishvili K.[2], Avkopashvili I.[2], Natali S.[1], Luppichini M.[1], Isola I.[4], McGee D.[5] & Fleitmann D.[6]

Keywords: paleoclimate, stable isotopes, paleotemperatures.

The reconstruction of glacial to interglacial temperature oscillations is extremely important for understanding the full scale of climate variability from global to local scale. Concurrently, rigidly defining temperature variations during the Holocene is key to provide boundary conditions upon which model future evolution driven by the current climate crisis. Unfortunately, there are large areas where multimillennial paleoclimate timeseries are unavailable. Southern Caucasus, is such a region as currently only a few continental climate time series extend beyond the short instrumental records. Importantly, temperature-related proxies are virtually absent here, thus impeding to evaluate how global-scale rapid climate instabilities propagate and impact this area. This work provides the first paleoclimate reconstruction from Georgia (Southern Caucasus) spanning approximately the last 13500 years. Four stalagmites named Zak-1, Zak-3, Zak-4 and Zak-6, measuring 46, 50, 55 and 102 cm respectively, were collected from the Zakariasklde Cave (42°10′ N; 43°20′ E). Dated by the U-Th method, Zak-1 was deposited between 3.1+0.04/-0.03 to 0.32+0.46/-0.44 ka (ka = kiloyears before 1950 AD); Zak-3 between 13.48+0.07/-0.08 to 10.11+0.05/-0.09 ka; Zak-4 between 12.01+0.08/-0.09 to 9.73+0.53/-0.61 ka; and Zak-6 between 8.77+0.07/-0.08 to 0.71+0.16/-0.13 ka, with a possible hiatus between 4.45+0.19/-1.49 and 3.27+1.35/- 0.34 ka. Timeseries of $\delta^{18}O$-$\delta^{13}C$ from calcite show the main patterns of temperature variations during the last glacial-interglacial shift as well as throughout the Holocene, which mostly agree in pace and tempo with global records (ie. Greenland ice and Atlantic/Mediterranean sediment cores). Then, $\delta^{18}O$-δ^2H from speleothem fluid inclusions (FI) are preliminarily applied to quantitatively calculate temperatures. Conveniently, FI resulted well aligned with the modern meteoric water line in Georgia, thus indicating that isotopic fractionation occurred during the karst flow-path and calcite precipitation was negligible. FI-derived temperatures document the effects of climate oscillations in Southern Caucasus related to the last deglaciation, with: a ca. 3ºC decrease of average temperatures from ~13 to ~11.6 ka related to the shift from the Bolling-Allerod to the Younger-Dryas chronozones; a ca. 6ºC of temperature increase from ~11.6 ka to ~10 ka related to the inception of the Holocene interglacial; 3) a peak of temperature, above modern average temperatures, around ~10 ka and consequent multimillennial decreasing trend of about 3ºC shifting toward the late Holocene. This latter identify the presence of a "Holocene Thermal Maximum" in Georgia, which is still a matter of debate and acquire key importance to define a solid Holocene baseline upon which modelling the evolution of global to local temperature in the future. The interpretation of the record is refined by considering changes of rainfall (e.g., amount, provenance and seasonality) as well as soils (e.g., vegetation bioactivity) trough $\delta^{18}O$-$\delta^{13}C$ timeseries and speleothem growth rate patterns. To comprehend the climate mechanisms of South Caucasus climate during rapid global instabilities, the Zak-timeseries is compared to the others from different climate regimes to advance the current characterization of regional climate shifts. Therefore, the results of this study certainly help to further investigate possible climatic teleconnections on a regional to global scale.

Chemostratigraphy study of the Toarcian marine deposits from the Paris Basin southern margin

Khatami M.[1], Vahdati B.[1], Gasparrini M.*[1], Lasseur E.[2], Spina A.[3], Montano D.[1], Dapiaggi M.[1], Compostella C.[1], Berra F.[1], Decarlis A.[4] & Ceriani A.[4]

Keywords: chemostratigraphy, organic matter, carbonate.

During the Early Toarcian, the ocean–atmosphere system was subject to one of the largest carbon cycle perturbations in the last 250 Myr, known as the Toarcian Oceanic Anoxic Event (T-OAE, about 183 Ma). Several studies reported paleoclimatic variations during this age, primarily drawing from sedimentary facies analysis of marine carbonate rocks, oxygen isotope data (δ18Ocarb), fluctuations in the oxygen and carbon isotope data of carbonates (δ^{18}Ocarb and δ^{13}Ccarb) and organic matter (δ^{13}Corg). If the paleoclimatic crisis and the related paleo-environmental changes of the Early Toarcian are well established in the literature and recorded through chemostratigraphic correlation of different basins worldwide, little is known about the climate recovery occurring during later Toarcian times.

This research aims to study the Toarcian succession (184.2 ± 0.3 - 174.7 ± 0.8 Ma) from a well-core drilled in the southern sector of the Paris Basin (present depth 360-200 m). It consists of exceptionally well-preserved pelagic marls to shales (Hermoso et al., 2009a; 2009b) containing immature organic matter (Ro < 0.5%) that may provide a valuable archive for the investigation of the Torarcian paleoclimatic variations.

To complement the previous studies that primarily focused on T-OAE related basal record (Hermoso et al., 2009a; 2009b), this study will extend the investigation to the whole Toarcian succession, by also introducing paleo-environmental and paleo-thermometric proxies not employed so far.

Detailed facies and biostratigraphic analyses on the core samples led to the reconstruction of depositional environments and a high-resolution sequence-stratigraphy framework. In total, 90 samples were collected and analyzed for XRD to highlight mineralogical changes associated with the evolution of facies/environments. Geochemical analyses on bulk samples estimated total C and N levels. O-C stable isotopes were analyzed on the carbonate fractions, and TOC and C-N isotope compositions will be analyzed in the organic fractions. Due to the overlap between the O-C stable isotope signatures of bulk carbonates and separated biogenic particles (Hermoso et al., 2009b), a selection of bulk samples will be analyzed for clumped isotope (Δ47) thermometry, that could confidently reflect sweater thermal excursions.

Keywords: carbon and oxygen isotopes, continental carbonate deposits, MIS5.

Extensive research has been conducted on Quaternary stable isotope records derived from marine and lacustrine carbonate deposits, as well as speleothems, to reconstruct global and regional climatic evolution. This study highlights the relevance of stable isotope records of travertine deposits to provide essential insights into climate dynamics and their impact on fluctuations in groundwater levels. The deposition of the *Lapis Tiburtinus* travertine succession, concurrent with the final phase of activity of the Colli Albani volcanic complex, occurred during the Late Pleistocene period (150–30 ka). Within the Acque Albule Basin, situated 23 km east of Rome, two boreholes (Sn1 and Sn2) were performed, crossing the entire *Lapis Tiburtinus* succession. The Sn1 borehole, located in the central part of the basin, shows a 62.1 m thick travertine succession, while the Sn2 borehole in the southern part of the basin features a 36.3 m thick travertine succession. A total of 118 travertine samples (59 samples each from Sn1 and Sn2 boreholes) were analysed for carbon and oxygen stable isotope ratios. Analysis and correlation of values from both boreholes enabled the determination of the sensitivity of the travertine depositional system to glacial and interglacial cycles, highlighting the intricate dynamics of the oxygen and carbon cycles recorded in this sedimentary succession. Furthermore, the obtained results were correlated with available pollen curves from the Mediterranean area (specifically, from the Castiglione crater, located 25 km east of Rome). The correlation with regional and global oxygen isotope continental and marine curves, calibrated with the stratigraphy of the Acque Albule Basin, alongside available U/Th dating, enabled the identification of at least three phases of the last interglacial period (Marine Isotope Stage 5-MIS5). On the other hand, the carbon isotope record, compared with the reconstructed CO_2 flux associated with the volcanic activity of the Colli Albani volcanic complex, shows the control of groundwater level changes. Particularly, positive shifts observed during arid phases are linked to lower groundwater levels and increased CO_2 degassing, leading to a significant fractionation effect on carbon isotopes. Conversely, negative shifts during more humid periods indicate inhibited CO_2 degassing due to a rise in groundwater level and consequent pressure increase. Thus, travertine deposits, commonly studied for delineating tectonic settings and activity in their respective areas, serve as valuable tools for understanding climate changes and groundwater variations through their stable oxygen and carbon isotope signatures.

ECORD and IODP-Italy Project: the mediterranean deoxygenation dynamics during the Pliocene in the Mediterranean

Keywords: sapropel, clumped isotope, climate change.

The Mediterranean Sea (MS) stands out as a climate change "hot spot," since it displays a remarkable sensitivity to natural and anthropogenically-driven changes. In the last decades, the climate in the MS has been featured by warming and drying, a trend that is expected to intensify in the future. Unraveling the evolution of the biochemical properties of the MS is crucial for mitigating the impacts of climate alteration. The sedimentary record of the last 15 million years is punctuated by the periodic occurrence of organic-rich sediments (sapropels), which testify moderate to strong deoxygenation events. Sapropels featured water column oxygen starvation that led to the annihilation of aerobic life in deep-sea environments. Some deoxygenation events occurred during warmer intervals than today, reflecting the temperatures predicted for the end of this century in the Mediterranean. The timing and causes of deoxygenation in the MS have varied across different oceanographic and climatic settings. Identifying the primary drivers and ecosystemic effects of deoxygenation from the past is crucial, as it can provide valuable insights into potential future impacts on the MS.

In the frame of the ECORD and IODP-Italy project, we are investigating the IODP cores from the Eastern MS, which comprise the sapropels deposited during the 3.15 - 2.94 Ma time interval; this interval was characterized by "warmer than today" temperature. Specifically, we are studying the deep-sea sapropel corresponding to "i" cycle from 282 to 300, which has also an onshore counterpart in central Italy, allowing to reconstruct deoxygenation dynamics across different depths and settings. Micropaleontological analyses (calcareous nannofossils, planktic and benthic foraminifera) will be performed to evaluate the paleoenvironmental conditions in the upper water column and at the seafloor. We will perform paired stable oxygen ($\delta^{18}O$) and clumped isotope ($\Delta47$) analyses on hand-picked monospecific planktic foraminifera. This approach will allow the reconstruction of the temperature and seawater $\delta^{18}O$, the bottom oxygen content and the paleoproductivity, thus providing key information on the environmental conditions leading to deoxygenation. We will also perform sedimentological and petrographic analyses on sediment chips and thin sections to investigate short-lived events related to seasonal variation or multiannual cyclicity, such as stochastic heatwaves or transient-type events. These analyses will be conducted focusing on the micropaleontological content and petrographic/sedimentological features which highlight variation in the sedimentation regime associated with environmental and oceanographic changes. This approach will allow to complement the long-term reconstruction of deoxygenation with the interannual variability dynamics.

Diagenesis of karsified deposits to reconstruct the sea level drop at the Eocene-Oligocene Transition in the Apulian Platform, Southeastern Italy

Keywords: Eocene-Oligocene transition, diagenesis, carbonate cements.

The Eocene-Oligocene transition (EOT) marks a critical phase in Earth's geological history, characterized by profound changes in oceanic and climatic conditions (Katz et al., 2008). This period, marked by the Oi-1 positive oxygen isotope excursion, signifies a major shift from greenhouse to icehouse climate modes, impacting shallow marine carbonate systems and leading to extensive exposure of carbonate platforms, primarily due to sea level falls associated with the expansion of the Antarctic ice sheet (Houben et al., 2012).

The aim of this study is to reconstruct the dynamics that affected the Apulian carbonate platform during the EOT, focusing on sea level fluctuations. Adopting sedimentological and geochemical approaches, we examined a 27-meter stratigraphic section at Torre Sant'Emiliano (southeastern Italy), located in the central Mediterranean region. Our study reveals an upper Eocene (Priabonian), 18-meter carbonate succession belonging to the Torre Specchialaguardia Formation (Fm), consisting of coral boundstone and large benthic and planktonic foraminifera wackestones to packstones, transitioning to red algal bindstone. A clear unconformity marks the transition to the overlying 9 m-thick Porto Badisco Fm, Oligocene (Chattian) in age, characterized by larger benthic foraminifera rudstone and red algal floatstone (Pomar et al., 2014).

The unconformity at the Eocene-Oligocene boundary is characterized by pervasive paleokarst features, including breccia deposits and fissure networks, which suggest groundwater dissolution and collapse of carbonate layers followed by refilling. Additionally, calcite-alabaster at the boundary has been found.

Along the entire Torre Specchialaguardia Fm, the carbonate cements reveal a complex diagenetic history: the first 8.5 m feature typically marine first-generation isopachous cements, from fibrous to bladed, and second-generation pore-filling mosaics. The subsequent 9.5 m display crust-like cements forming layers up to 5 mm thick around Eocene bioclasts, consisting of fibrous, microcrystalline, and acicular syntaxial forms. These cements exhibit geometric zonations, alternating between light and dark portions, reflecting the presence or absence of inclusions within the calcite crystals. In the overlying Porto Badisco Fm, typically marine, first-generation bladed and fibrous cements have been recognized. The crust-like cements in the upper part of the Torre Specchialaguardia Fm, as well as the calcite-alabaster, testify to the emersion of the Eocene carbonate platform.

Estimations of sea level fall during the EOT are based on the vertical distribution of carbonate cements, which suggest that meteoric conditions influenced the diagenesis of the Eocene terrain up to at least 9.5 m from the platform top. Moreover, geochemical analyses of calcite-alabaster, as well as the different generations of cements, provide insights into the environmental conditions affecting EOT marine and freshwater.

Keywords: Upper Triassic, paleoclimate, rock magnetism.

The late Norian to early Rhaetian (Late Triassic) interval is characterized by an important biotic crisis that involved marine and terrestrial fauna (mainly conodonts, ammonoids, bivalves and theropods). The climate perturbation that began in the Alaunian (Norian) and persisted up to the Rhaetian seems to be linked to the biotic turnover across the Norian/Rhaetian boundary (NRB). A relevant δ^{13}Corg perturbation occurred in concomitance to the Norian-Rhaetian biotic crisis and led to a negative carbon isotope excursion at the NRB, marked by the disappearance of monotids bivalves and close to the first appearance of conodont *Misikella posthernsteini*. Both the δ^{13}Corg negative excursion and the FAD of *M. posthernsteini* have been suggested as markers of the Rhaetian base (e.g., Rigo et al., 2016). To better understand the climatic perturbations that characterized the late Norian–early Rhaetian interval, we investigated the geochemical and rock magnetic properties of the magnetostratigraphically-calibrated Pignola-Abriola section in Italy (Maron et al., 2015; 2024). We performed experiments on anhysteretic and isothermal remanence (ARM, IRM), and on magnetic susceptibility (χ), to obtain the rock magnetic parameters necessary for our paleoclimatic investigation. An episode of increase in relative quantity of hematite, suggesting enhanced subaerial oxidation of iron minerals, was identified in the Norian from ~217 Ma in the Alaunian up to ~211 Ma in the early Sevatian, followed by a decline up to 207-206 Ma at the end of the Norian (late Sevatian). The results of geochemical and multivariate statistical analyses support a long-term increase and reduction in rock weathering, confirming and extending previous 87Sr/86Sr data from the Pizzo Mondello section in Italy (Onoue et al., 2018). Possible causes of these long-term weathering trends are the multiphase uplifting of the Cimmerian orogen, occurring at mid northern latitudes along the southern margin of Asia in the Late Triassic, and/or the northward motion of Pangea across the equatorial humid belt. Rapid excursions in oxidized iron minerals have also been observed across the Norian/Rhaetian boundary, the origin of which has still to be determined.

Keywords: Late Triassic, impact ejecta, radiolarian.

The Norian/Rhaetian boundary (NRB; ~205.7 Ma) in the Late Triassic is marked by faunal turnovers of pelagic groups such as ammonoids, conodonts, and radiolarians, and negative organic carbon-isotope (δ^{13}Corg) excursions on a global scale (e.g., Rigo et al., 2020). Catastrophic events such as the large volcanism activity of the Angayucham Terrane in Alaska and the impact event related to the Rochechouart crater in France have been discussed to account for the faunal turnovers across the NRB (e.g., Rigo et al., 2020; Sato et al., 2021). Anomalously high platinum-group element (PGE) concentrations have previously been reported in the Upper Triassic hemipelagic black shales from the Sasso di Castalda section in the Lagonegro Basin, southern Italy, suggesting the impact ejecta layer (Sato et al., 2021). However, the precise depositional age of the PGE-enriched layer is unclear because the detailed biostratigraphy using radiolarians and conodonts in this section is still in progress. Here we show the high-resolution biostratigraphy of radiolarians and the result of major and trace element analysis in the Sasso di Castalda section across the PGE-enriched layer. We found a characteristic radiolarian assemblage including *Betraccium deweveri*, *Citriduma* sp. A, *Livarella valida* and *L. densiporata* across the PGE-enriched layer. This assemblage comparable to the uppermost Norian assemblage (*B. deweveri* Zone) in the Pignola-Abriola section of the Lagonegro Basin (Rigo et al., 2016). Our geochemical study revealed the presence of a siderophile elements-enriched red shale just above the PGE-enriched layer. The abundances of Fe_2O_3, Ni, and Co in the red shale are ~56 wt.%, ~300 ppm, and ~100 ppm, respectively, which is an order of magnitude higher than background levels. Furthermore, this layer contains microspherules with high concentrations of Fe and Co, ranging in size from 20 to 30 μm. Our biostratigraphy reveals that the red shale and PGE-enriched layers were formed in the uppermost Norian. Based on the biostratigraphic age of the studied section and radioisotopic ages for the NRB and the Rochechouart crater in France (206.92 ±0.32 Ma; Cohen et al., 2017), these PGE and siderophile element-enriched layers were possibly formed by the Rochechouart impact event.

Keywords: chert, radiolarians, sodium hydroxide.

Radiolarians and conodonts are important components of sedimentary rocks and are used for palaeontological, biostratigraphic, palaeoenvironmental, and palaeoclimatic investigations. Research on radiolarians and conodonts has increased markedly since the 1970s, when a method of extracting these fossils from siliceous deposits (chert) using hydrofluoric acid (HF) and the application of scanning electron microscopy techniques were established. However, since HF is a highly reactive chemical, this acid is currently strictly regulated due to environmental and human health concerns. Recently, Rigo et al. (2023) found that the solubility of sodium hydroxide (NaOH) solutions in chert increases significantly with increasing temperature. They reported the use of a 3 mol/L, 80˚C NaOH solution to extract well-preserved conodonts from chert. Here we report the successful extraction of radiolarians and conodonts from Triassic chert using a low concentration of NaOH (1 mol/L) as an alternative chemical to HF. The degree of dissolution of chert in NaOH solution is strongly temperature dependent, being less at 60 or 80°C. However, when heated to 100°C, we show that even a 1 mol/L NaOH solution is sufficient to dissolve the chert. Furthermore, this method has allowed us to obtain well preserved radiolarian and conodont fossils compared to the conventional HF method. In addition, radiolarians that could not be identified to species level due to poor preservation and had been referred to by partial character names (e.g., Skirt F: Sugiyama, 1997) could be observed in their entirety for the first time using the NaOH method. The 1 mol/L NaOH solution is not internationally classified as hazardous, is easy to handle and has very little impact on the environment or human health. This allows radiolarian and conodont fossils to be used extensively for research, education and resource prospecting, even in institutions that cannot use the HF method due to equipment and chemical limitations.

Keywords: REE, microbialite, Triassic.

The REE+Y (Rare Earth Elements and Yttrium) of marine carbonates yield insights on environmental conditions at the time of their formation. The REE+Y pattern of seawater is depleted in light REE and has a marked, positive Y anomaly. The sign of Ce anomaly yields information on the oxygenation state of the fluids from which carbonates precipitated, while Eu and middle-REE anomalies may be used to track diagenetic alteration. Marine microbialites derive from biologically induced and influenced, rather than controlled, precipitation of carbonate, hence, they should record the chemistry of seawater as inorganic carbonates do, but they are more common in the geologic record and incorporate higher amounts of trace elements (Webb & Kamber, 2000).

REE+Y in microbialites from the Dolomites (Northern Italy) were analysed with multiple techniques. In samples from the upper Anisian Latemar platform, marine cement crusts and aragonitic fossils replaced by calcite occur. In samples from the lower Carnian Cortina d'Ampezzo Basin, marine cements are scarce, aragonitic shells and skeletons were never replaced, and microbialites retained a high-Mg calcite mineralogy with up to 12 mole % $MgCO_3$.

Contrary to expectations, marine cements and microbialites from the upper Anisian Latemar platform show seawater-like REE+Y patterns, while the less diagenetically modified Carnian microbialites of Cortina d'Ampezzo mostly yielded REE+Y patterns that resemble those of burial Fe-rich cements. Petrographic observations show that an initial porosity of late Anisian microbialites was filled by marine cements, while that of early Carnian microbialites was filled by detrital material and burial Fe-rich cements. Thesehave REE+Y contents orders of magnitudes higher than that of microbialites, totally obscuring the original seawater signals. In contrast, in the Anisian Latemar platform, early diagenetic cements preserved and reinforced an original seawater signal. A major issue is that pore fillings and microbialitic carbonates could not be analysed separately. Hence, the main REE+Y signal derived, most likely, from the pore filling. It is suggested that this may be a common issue and that, without careful petrographic characterization of pore fillings, the interpretation of REE+Y (and likely, any trace element) analyses of marine microbial carbonates may be very difficult.

Keywords: GSSP, Rhaetian, carbon isotopes.

The base of the Rhaetian stage (Norian/Rhaetian boundary, NRB) is still awaiting formal designation by the International Commission on Stratigraphy. At present, two sections have been proposed as GSSP candidate for the for the base of the Rhaetian: the 4.30-m-thick Steinbergkogel section (Austria) and the Pignola-Abriola section (Italy). The 63-m-thick Pignola-Abriola section crops out in the Southern Apennines and it is represented by hemipelagic–pelagic carbonate successions belonging to the Lagonegro Basin, which matches all the requirements for a GSSP: 1) it is a continuous basinal succession, well exposed and with minimal structural deformation; 2) easy access along the SS 5 road 'la Sellata' 4 (Potenza); 3) located in the protected area of the Parco Appennino Lucano - Val d'Agri – Lagonegrese; 4) it is fossiliferous and rich in age diagnostic fossils (e.g. conodonts, radiolarians, nannofossils); 5) it has a rich palynofloral association across the Norian/Rhaetian boundary, recording the presence of trilete and cavate spores, pollen of monocolpati, Circumpollens, Crinopolles, Bisaccates, and marine elements such as dinoflagellates and acritarchs; 6) it yields a geochemical record suitable for correlation (e.g. d^{13}Corg/carb); 7) it has a robust magnetostratigraphy and is correlated with the Newark APTS for age approximation of the NRB and additional Rhaetian bioevents.

In particular, the FAD of *M. posthernsteini* s.s., which is the STS-voted biomarker for the definition of the Rhaetian base, occurs at level PIG24 at Pignola-Abriola and this occurrence is along the morphocline from its ancestor *Misikella hernsteini*. Furthermore, the base of the radiolarian *Proparvicingula moniliformis* Zone, which is a second bioevent proposed to mark the base of the Rhaetian, is well documented and calibrated with the FAD of *M. posthernsteini* s.s. Besides, the Pignola-Abriola section depicts a marked δ^{13}Corg negative shift of ca. 6‰, occurring ca. 0.5 meters below the FAD of *M. posthernsteini* s.s. and within the radiolarian *P. moniliformis* Zone. This negative carbon isotope shift has been suggested as the primary physical marker for the NRB (Rigo et al., 2016) because it is a large geochemical signal that has been documented in both the western and eastern sides of the Panthalassa Ocean and in the Northern and Suothern Hemisphere (Rigo et al., 2020). The Pignola-Abriola section is subdivided into 10 magnetozones, calibrated with conodont and radiolarian biostratigraphy and statistically correlated with the Newark APTS, allowing the dating of litho-, bio- and chemo-events. The age model developed for the Pignola-Abriola section, placed the NRB (FAD of *M. posthernsteini* s.s.) at ca. 205.7 Ma, in agreement with recent high-precision U-Pb data.

Keywords: Triassic, Jurassic, mass extinction.

The Triassic/Jurassic boundary (TJB, 201.3 Ma) is characterized by profound turnovers in both marine and terrestrial biota, known as End-Triassic mass Extinction event (ETE). During this severe event, significant and distinct negative carbon isotope excursions (CIE) have been globally observed, and they were linked to volcanogenic emissions or methane release by dissociation of clathrates. The triggering factor of the negative CIEs was attributed to the emplacement of the Central Atlantic Magmatic Province (CAMP) and the break-up of the Pangea. Specifically, three significant carbon-cycle disruptions named Precursor, Initial and Main CIE have been recorded in several stratigraphic successions deposited in terrestrial and pelagic environments. We investigated the organic carbon isotope curve from the subtidal facies of the Mount Sparagio section, which is a continuous peritidal succession representing an Upper Triassic to Lower Jurassic carbonate platform edging the south-western side of the Tethys Ocean. For the first time, we achieved a complete C organic profile (δ^{13}Corg) during the End-Triassic mass Extinction event (ETE) in a carbonate shallow water environment. The δ^{13}Corg profile highlights the 3 negative excursions that characterized the Triassic/Jurassic boundary time interval in pelagic and deep-water successions. The documented CIEs correspond to significant biotic turnovers recognized along the Mt Sparagio section, suggesting that also the Upper Triassic-Lower Jurassic carbonate platforms were affected by the onset of the Central Atlantic Magmatic Province. Furthermore, although the Mt Sparagio section has been studied in detail for microfacies associations and it is well biostratigraphically constrained with shallow marine macro- and microfossils, only the documented δ^{13}Corg negative shifts allowed to correlate peritidal environments with pelagic successions, making the organic carbon curve (δ^{13}Corg) a powerful tool for global correlations.

Post-impact marine environment within the Chicxulub impact basin inferred from Re-Os isotopes

Keywords: K-Pg boundary, Re-Os isotopes, hydrothermal activity.

The delivery of platinum group elements by the Cretaceous-Paleogene (K-Pg) asteroid impact to the ocean is recorded globally as a negative osmium isotope ($^{187}Os/^{188}Os$) excursion in distal marine sediments from the Chicxulub structure on the Yucatán Peninsula in the Gulf of Mexico (Ravizza & Peucker-Ehrenbrink, 2003; Ravizza & VonderHaar, 2012). The reconstructed marine Os isotope curves can be used for global age correlations of K-Pg sediments and as an Os isotope-based geochemical clock to trace the early Paleocene on the ~10 thousand years (kyr) scale (Ravizza & VonderHaar, 2012). However, no Os isotope records from proximal sites exist to date and it remains unclear whether the K-Pg Os isotope clock can be used within the Gulf of Mexico. Here, we present new records of $^{187}Os/^{188}Os$ in the early Paleocene limestones deposited from within the Chicxulub impact basin, obtained from the IODP-ICDP Expedition 364 at Site M0077 together with other Gulf of Mexico early Paleocene sites (Bochil, Guayal, El Mulato and La Lajilla) calibrated with recent biochronological scales for planktic foraminifera (Arenillas et al., 2021). The Os isotope data show that in the Gulf of Mexico, it took at least 700 kyr, for the $^{187}Os/^{188}Os$ of seawater to return to pre-impact level after a rapid decline following the K-Pg boundary. This is much longer than the ~200 kyr negative $^{187}Os/^{188}Os$ global excursion caused by the oceanic supply of Os from the Chicxulub impact (Ravizza & VonderHaar, 2012). During the negative Os isotope ratio excursion, excess concentrations of Os were detected in all studied sites, and those for mainly Mn, Fe, P, Pb and Os were also found in the limestones of Site M0077. Higher concentrations of these elements and the decrease in Os isotope ratios suggest that the $^{187}Os/^{188}Os$ ratios in the Gulf of Mexico may recorded a long-term supply from the hydrothermal system within the Chicxulub structure after the impact event. Our results support the estimate of the longevity of the hydrothermal system based on mineralogical evidence at Site M0077 within the Chicxulub impact basin (Kring et al., 2020).

Keywords: carnian pluvial episode, anoxia, Panthalassa.

The Carnian Pluvial Episode (CPE) was a short interval of extreme rainfall in the Late Triassic that caused significant changes in marine ecosystems. This enigmatic global event is thought to have been triggered by the eruption of the Wrangellia flood basalts in the Panthalassa Ocean, as well as the Carnian Panthalassic oceanic island basalt (OIB) volcanism recorded in the Jurassic accretionary complexes of East Asia (Tomimatsu et al., 2021; 2023). Global warming induced by Wrangellia volcanism is thought to have resulted in increased continental weathering and caused oceanic anoxia during the CPE, but the detailed redox changes in the pelagic environment remain unclear. To better understand the global extent, duration, and severity of oceanic anoxia, and its effects on major pelagic taxa during the CPE, we investigated stratigraphic variations in geochemical proxies (major and trace element compositions) of paleo-ocean redox conditions, and the conodont and radiolarian biostratigraphy in Panthalassic pelagic sequences in Japan. The synchronous increase in VEF and UEF values suggests that anoxic conditions were temporarily widespread in the pelagic deep-sea Panthalassa during the late Julian. However, the enrichment factor of Mo is consistently low during the periods of V and U enrichment, suggesting that the deep-sea environment was not euxinic. Late Julian marine anoxia has been identified based on the widespread deposition of black shales and organic-rich marls in Tethyan marginal basins. This suggests that marine anoxia may have developed from the shallow continental margin into the equatorial deep-sea Panthalassic basin.Conodont extinction occurred during the period of oceanic anoxia, whereas radiolarians were less affected and their diversity increased after the recovery from anoxia. The increased radiolarian diversity during the early Tuvalian (late Carnian) can be attributed to chemical weathering and enhanced nutrient fluxes associated with global warming and the more humid climate of Pangea.

Itria Valley limestone: a multidisciplinary study on the use of the Apulian georesources in the Cultural Heritage

Annese C.[1], Bellopede R.*[2], Intini P.C.[3], Intini P.[3], Lamanna L.M.[4], Marini P.[2], Merico A.[2], Quartulli A.[1] & Sivilli S.[4]

[1] Soprintendenza Archeologia, belle arti e paesaggio per la città metropolitana di Bari, Ministero dei Beni Culturali, Bari. [2] Dipartimento di Ingegneria dell'Ambiente, del Territorio e delle Infrastrutture, Politecnico di Torino. [3] Intiniarchitetti, Noci (BA). [4] Archeologist, Bari.

Corresponding author email: rossana.bellopede@polito.it

Keywords: Itria valley geology, architecture, archaeology.

The Apulian limestones, wholly constitute the historic building constructions of that region named Trulli and other stone buildings of the well-know Itria Valley. These stones have been utilized not only in recent times but also trace back to prehistoric periods. Their petrographic characteristics, extraction sites, and architectural applications are intricately intertwined. This research, carried out by the contribution of architects, archaeologists , geologists and engineers, aimed to elucidate the significant historical and technological aspects of limestone widely employed in the Apulian region. Furthermore, it aimed to explain the high value of this landscape recognized by UNESCO as World Heritage site . The results of this research have been widely explained in the book "Natural Stone and World Heritage - Itria Valley and Alberobello, Apulia Region, Italy" edited by Taylor and Francis.

The transdisciplinary approach can be distinguished in the following steps:

- Description of Itria Valley with its towns and landscape and the Alberobello town from geological and architectural point of view;
- Study of the different example of building constructions in local stone of the Itria Valley and their origin (ancient and contemporary quarries);
- Analysis of the petrographic and physical-mechanical characteristics of the main kind of limestones quarried;
- Presentation of the significant example of stone architecture of Itria Valley, distinguishing the historical rural building from the other historical civil ones;
- Discussion of the best practice of evaluation action, protection rules and restauration methods for Stone Heritage in Itria Valley and Alberobello.

The physical mechanical characterization has been carried out both on site and in laboratory , after the selection of the most interesting case studies of Itria Valley. On site the ultrasonic pulse velocity is the main not destructive test used to recognize the mechanical features of the limestone, taking into consideration of the decay state. In laboratory together the conventional destructive test , analysis by means Scanning Electron Microscope (SEM) were carried out to detect the conservation state of ornamental stone.

The techniques used to detect the stone durability should be strictly linked to the knowledge of land and the buildings organism in order to better finalize the effort toward the monitoring and preservation of geo-resources: in this sense the case of Itria Valley is a recent application of this approach.

Archaeometric investigations on iron slags from the metallurgical workshop of Caselle in Pittari settlement (Campania region, southern Italy): a first look

Balassone G.*[1-2-3], Serritella A.[4], Rizzo M.L.[4], De Bonis A.[1-2], Valente E.[1] & Boni P.[5]

[1] Dipartimento di Scienze della Terra, dell'Ambiente e delle Risorse, Università di Napoli "Federico II". Keywords: iron slags, archaeometallurgy, Caselle in Pittari.

During 2019, the excavation in the Lucanian settlement of Caselle in Pittari (SA) unearthed a metallurgical workshop, located in the center of the site, near the main plateia that crosses it from north to south (Serritella & Rizzo, 2021). The building is perfectly integrated into the topographical system of the site; up to now, it is not yet clear whether this workshop is part of a house or is an exclusively artisanal structure. This finding is particularly important since metallurgical workshops are generally indicated by extremely light traces, which do not allow the identification of all the spaces relating to the different phases of the processing cycle. In the Caselle in Pittari settlement, it was possible to identify the bottom of a furnace and a casting basin with two terracotta crucibles as well as many remains of iron slags (Serritella & Rizzo, 2021).

Iron slags were the byproduct of smelting iron ore to extract metallic iron (consisting in some processing steps) in the past. Its study can provide valuable insights into ancient metalworking technologies, socio-economic organization of past societies, trade networks, and help to identify the raw materials used in iron production (Giardino, 2017). Preliminary archaeometric investigations have been carried out to identify the mineralogical composition of the iron slags, also aimed at giving clues on metallurgical processes as well as on provenance of metallic raw materials. To characterize the Caselle in Pittari iron slags, optical microscopy, X-ray diffraction (XRD), scanning electron microscopy coupled with electron-dispersive spectroscopy (SEM–EDS) were used for selected samples. The first mineralogical data show that the slags have heterogeneous colors ranging from blackish to red-brown, sometimes with vesicles having in size several microns in diameter. Some parts of the samples are more compact and denser, with patinas of various colors. The slags are composed of mixtures of silicates, mainly quartz and K-feldspar, together with iron oxides (likely wüstite, magnetite, + hematite) and hydroxides (goethite). The presence of wüstite, if confirmed, points to hearth temperature between 560 °C and 1200 °C, whereas magnetite can indicate poor control of the ventilation system, with a large oxygen supply to the furnace leading to FeO oxidation (Portillo et al., 2018). Glassy matrix is quite widespread, locally containing droplets of pure iron which suggest poor production efficiency during iron processing (Portillo et al., 2018). Trace amounts of galena, as well as apatite and zircon are also found. Further analyses are ongoing to fully characterize the ferrous materials from the Caselle in Pittari site.

Reconstructing Pompeii's past: insights from fossilized archaeological remains in reused amphorae from Civic Building 3, Via dell'Abbondanza

Bruzzone L.*[1], Gaggero L.[1] & Pallecchi S.[2]

[1] Dipartimento di Scienze della Terra, dell'Ambiente e della Vita, Università di Genova.
[2] Dipartimento di Antichità, Filosofia e Storia, Università di Genova.

Corresponding author email: lisabruzzone31@gmail.com

Keywords: amphorae, phosphates, carbonates.

In this study, the contents of 8 amphorae reused to seal pit latrines in the Pompeian archaeological context of the workshop named civic 3 (Regio VII, insula 14, Via dell'Abbondanza, Pompeii) were examined using a multidisciplinary approach combining OM, XRPD and SEM-EDS data.

Insula 14 of Regio VII, discovered before 1820, has been studied by the University of Genoa since 2016 (Pallecchi, 2018) through a detailed stratigraphic analysis, which allowed us exploring stratifications between the end of the 3rd century BC and the 79 AD eruption of. The study of the stratifications made it possible to learn about the transformations of the area over time.

Initially, the area was used for vegetable gardens and courtyards, with the construction of a first atrium house at the end of the 3rd-2nd century BC. This house was flanked by two structures: i) a small building, ii) pit latrines, then sealed with three amphorae bound with mortar. During the 1st century BC, a small garbage dump was built, replaced at the end of the 1st century BC by a cesspit. Subsequently, three buildings were erected: civic buildings 1, 2 and 3. Civic 3, probably a commercial building, like many other constructions along Via dell'Abbondanza, was a structure of at least two floors. Inside a gully was set up, with two quadrangular holes, in which two amphorae were placed. A destructive event, probably an earthquake followed by a small fire, in the third quarter of the 1st century AD, damaged the buildings. Then renovations followed, including the latrines reconstruction at civic 3 (Pallecchi, 2018; Pallecchi & Santoro, 2019).

The amphorae contents consisted of heterogeneous fragments including: pyroclastic sediments, encrustations, wood and bone. In addition, the presence of fungal hyphae and mineralised pollen was observed in some samples. The XRD analysis conducted on the sampled contents, previously ground, revealed in many cases the presence of apatite, as well as calcite, quartz and phyllosilicates.

Preliminary results of SEM-EDS analysis possibly confirm previous studies (Pallecchi, 2018), highlighting the presence of two different kinds of findings preservation: i) burnt and ii) mineralised archaeological relics. This suggests a different origin of the deposits: while the burnt remains could derive from hearth waste, which could provide evidence of the ancient 'sanitisation' procedures; the mineralised ones would seem to suggest the circulation of phosphate- and carbonate- saturated solution.

The study of this typology of finds has fundamental importance to reconstruct the archaeological context and obtaining information on the lifestyle of the inhabitants of Pompeii at the turn of the 3rd century B.C. and 1st century A.D.. Indeed, it provides information on the use of amphorae and the structures in which this type of ceramic artefacts were reused, identified as pit latrines.

Evaluating erythrite as a potential source for arsenic-free cobalt blue pigment production: replication of historical recipes and thermal treatments

Bruzzone L.*[1], Gaggero L.[1], Zucchiatti A.[2] & Molera J.[3]

[1] Dipartimento di scienze della Terra, dell'Ambiente e della Vita, Università di Genova. [2] School of Physics, University of the Witwatersrand, Johannesburg, South Africa. [3] Facultat de Cìencies i Enginyeries, University of Vic, Spain.

Corresponding author email: lisabruzzone31@gmail.com

Keywords: cobalt pigments, glaze, calcium arsenates.

This study investigated the thermal behaviour of erythrite, a hydrated cobalt arsenate mineral possibly used in the production of cobalt blue pigment in historical times (Gratuze et al., 1996; Soulier et al., 1996). Indeed, several ancient recipe treaties, describe the production of cobalt blue, mentioning the use of a red mineral also called cobalt bloom, still used to identify erythrite. The mineral is also found in the Erzgebirge mines that became the largest exporters of cobalt in Europe from the 15th century onwards.

The aim is to understand whether this mineral could actually have been used to produce the pigment. For this purpose, the phases obtained from the experimental temperature runs were studied and compared with historical pigments, which have evolved compositionally over time. Specifically, the possibility of removing the arsenic in the mineral was investigated in order to obtain an As-free pigment, similar to that used in ceramic and glass production until 1520.

Erythrite, hand-picked from a Bou Azzer (Morocco) mineralogical sample, was roasted individually, to replicate the *saffron* production recipes, and with different fluxes, which were used to obtain the enamel: two cobalt by-products that began to be produced in the Erzgebirge region respectively from 1520 and 1540-60 (Meltzer, 1716).

The compositional and structural changes that occurred in the ore during heating (conducted in an oxidising atmosphere, up to a maximum temperature of 1020°C) were investigated using XRF, XRD, SR-XRD and SEM-EDS.

The experiments showed that it is possible to remove part of the arsenic from the ore: XRF analyses revealed that the arsenic quantity reduced progressively, at last corresponding to 22.4% total loss in the bulk. However, according to results conducted on skutterudite (Molera et al., 2021), some arsenic remains in the ore even after thermal treatment. Furthermore, the replication of a historical mixture with erythrite, borax and CaO, heated up to 900°C, demonstrated the possibility of obtaining separate cobalt and arsenic phases: Co-Fe-Ni oxides and Ca-Co-Na-Ni arsenates.

Surface degradation and conservation strategies in the marine environment: the case of the church of S. Salvatore, in Monopoli (Bari)

Calia A.[1], Melica D.[2], Pellegrino E.[3] & Quarta G.*[1]

[1] Istituto di Scienze del Patrimonio Culturale, CNR, Lecce. [2] Consultancy and Diagnostics for Restoration and Conservation, Copertino, Lecce. [3] Architect Specialist in the Study and Restoration of Monuments, Bari.

Keywords: porous calcarenite, marine exposure, decay.

The church of San Salvatore, one of the oldest in the city of Monopoli, is located within the ancient city walls and in a position overlooking the sea. The first foundation of the church dates backs to the early Christian age and is mentioned in the 12th century in a Papal Bull. The church was rebuilt in the 16th century, and successively underwent structural changes. The façade, which preserves the evidence of this phase, was rebuilt together with the bell tower in the first decades of the 18th century.

Before recent restoration works, a study of the constituent materials and their state of conservation was conducted, and possible conservation strategies were evaluated.

The façade was made with blocks of calcareous tuffs, covered with cement-based mortars, especially in the basement part, and by lime washes on the remaining surface. The stone was affected by surface erosion and disintegration phenomena with a strong material loss, leading to different states of conservation on adjacent ashlars.

The mineralogical-petrographic study of the façade materials highlighted the sequence of mortar layers and lime washes applied over time, as well as the presence of grouting mortars containing gypsum. It also identified two different calcarenitic materials, in terms of textural and porosimetric characteristics, which could account for the different responses of adjacent ashlars to the salt damage and consequent states of conservation observed on the façade (Calia et al., 2016).

The analyses of soluble salts by ion chromatography revealed a very high presence of chlorides, directly originating from marine aerosols and identified by XRD in the form of halite. Sulphates and nitrates were also found at lower extents. The former, as well as from the sea, could also have a source from the plasters and groutings found on the surface of the façade. Indeed, gypsum crystals within the stone were microscopically observed.

In the conditions of exposure of the church to the sea, where the salt supply is continuous and cannot be removed, the use of films based on organic products for the protection of the façade against external factors, was excluded, as they could hinder the circulation of saline solutions towards the surfaces, thus introducing a further risk of damage for stone. Instead, it was more appropriate to re-propose traditional interventions, based on the application of a lime wash with a protective and sacrificial function with respect to the action of degradation agents (Calia et al., 2011).

Ancient Roman mortars under synchrotron light: unravelling the nature of disordered phases

Calzolari L.*[1], Fernandez-Martinez A.[2], Magnin V.[2], Medeghini L.[1] & Mignardi S.[1]

[1] Dipartimento di Scienze della Terra, Sapienza Università di Roma. [2] ISTerre, Universite Grenoble Alpes, Universite Savoie Mont Blanc, CNRS, IRD, Univ. Gustave Eiffel, Grenoble, France.

Corresponding author email: laura.calzolari@uniroma1.it

Keywords: pdf analysis, ancient roman mortars, disordered phases.

The characterization of mortars of interest in the cultural heritage field generally comprises a series of well-established techniques, such as optical microscopy (OM), scanning electron microscopy with microanalysis (SEM-EDS) and X-ray powder diffraction (XRPD), which give an overall comprehension of the material under study (Cuevas et al., 2023). However, some aspects remain not well understood, such as the formation and composition of amorphous phases in the binder of hydraulic mortars.

In this study, we applied Pair Distribution Function analysis (PDF), a synchrotron-based technique, to attest the presence of amorphous phases (Cuesta et al., 2017) in some *cocciopesto* samples coming from the inner duct of Aqua Traiana, an ancient Roman aqueduct built in 109 AD and still working nowadays. The combination of well-established techniques with synchrotron-based ones allows to obtain a more complete vision on the material employed for the formulation of mortars that are resisting through millennia.

Keywords: ceramics, metals, Apennine.

The project "APENNINESCAPE: Marginal landscapes and production processes along the Reno and Bisenzio-Sieve valleys during the 1st millennium BC" (funded by MUR, PRIN 2022, 2022LE33T8) focuses on the mountainous area between the Po valley and northern Etruria and its historically anthropized landscape, characterized by the development of Etruscan settlements with their specific socio-political structure.

One of the main objectives of the project is to improve the understanding of the relationship between settlements, production processes and resource exploitation through a transdisciplinary approach. Among the various research lines of the project, particular attention is given to the archaeometric analysis of ceramics and metals to establish reference groups, locate the area of origin of raw materials, possibly highlighting the exploitation of local resources and/or links with productions from the Northern Etruria and Po valley area, and to define production technologies. In addition, to identify and collect the range of raw materials that may be exploited in the area, geological surveys of the study area are planned.

For ceramics and metals, a wide range of analyses, including petrographic and geochemical (OM, XRF, XRD) characterisation of vessels and technical ceramics associated with metal production, microchemical (XRF, SEM-EDS) and isotopic analyses of metals (mainly copper alloys) and their slags, are currently being carried out on materials from Marzabotto (Chiarantini et al., 2010; Komosek et al., 2022), Gonfienti (Poggesi, 2011) and from other areas of northern Etruria (particularly the Pisa area).

In this paper preliminary results will be presented, with particular emphasis on the characterisation of metals and copper alloys from the different study areas, highlighting the contribution of analytical studies in support of the interpretation of the dynamics of material circulation between the two mountainsides and the wider area of Northern and Po Valley Etruria.

Keywords: ceramics, archaeometry, deep learning.

Ancient ceramic artifacts represent social and human markers within archaeological contexts, playing a fundamental role for the study of trade relationships and technological development of past societies. In the recent years, the adoption of automated methodologies, such as classification algorithms applied to group ceramics, has significantly contributed to the recognition of specific compositional, technological, or stylistic patterns (Bickler, 2021; Ruschioni et al., 2023). Therefore, the objective of the present project is to develop a Deep Learning (DL) image classification model based on Convolutional Neural Networks (CNNs) to categorize ceramics from the complex of the Basilica of the Holy Sepulchre, Jerusalem. During archaeological excavations at the site (License by Israel Archaeological Antiquity no. G 20/2022), numerous ceramic sherds have been found in the filling layers of the Basilica's foundations, revealing intense and particularly complex stratigraphy. In this scenario, the application of the CNN model on these samples plays a crucial role in clarifying the archaeological context and ceramic production in Jerusalem.

The starting point for the development of the model consisted of a phase of selection and acquisition of a significant number of ceramic thin-sections images from representative archaeological contexts across the Near and Middle East, forming the training dataset.

The second phase of the project focuses on the minero-petrographic and chemical characterization of the ceramic samples to determine their composition and provenance. This analysis is carried out through a multi-analytical approach that includes Optical Microscopy (OM), X-ray Powder Diffraction (XRPD), Scanning Electron Microscopy with Energy-dispersive Spectroscopy (SEM-EDS), Fourier Transform Infrared Spectroscopy (FTIR), and Inductively Coupled Plasma Mass Spectrometry (ICP-MS).

Finally, the third step aims at comparing the results of the archaeometric analysis with those obtained from the DL model, serving as an additional tool to evaluate its effectiveness.

Geomineralogical and geoarchaeological findings in Roccia San Sebastiano cave at Mondragone, central Italy

Collina C.[1], D'Aniello M.[2-3], Izzo F.*[2-4], Langella A.[2-4], Repola L.[2] & Donadio C.[2-5]

[1] Civic Museum Biagio Greco, Mondragone. [2] Dipartimento di Scienze della Terra, dell'Ambiente e delle Risorse, Università di Napoli "Federico II". [3] INAF-OACN, Napoli. [4] CRACS, Center for Research on Archaeometry and Conservation Science, Napoli. [5] Stazione Zoologica Anton Dohrn, Napoli.

Corresponding author email: francesco.izzo4@unina.it

Keywords: geoarchaeology, mineralogy, ochre.

The Roccia San Sebastiano cave represents one of the most significant underground paleoenvironments discovered in central Italy for its findings of Neanderthal, H. sapiens, and Uluzzian transitional culture of Paleolithic, as well as bony remains of meals, traces of a fireplace with charred wood, flint tools and fossil teeth of children in the silty-sandy layers of the floor (Aiello et al., 2018; Collina et al., 2020). Since 2001, systematic archaeological excavations of the prehistoric deposit referable to the Upper Paleolithic and radiometric dating were carried out. In 2021, ten sediment samples were collected from some selected levels ranging from 40 to 20 ka BCE to identify their mineralogic composition, granulometry, and quartz and silicate morphoscopic features. The analysis highlighted the presence of many bioclasts of bones of different animals also of large dimensions, over 500 blunt-edged translucid grains, about 260 not abraded transparent granules, and 175 rounded opaque grains of genetic-depositional environments in the sandy fraction of 250 mm. Moreover, mineralogical features of some selected samples suggest the occurrence of sediments due to the reworking of trachytic pyroclastic materials (likely Campanian Ignimbrite, 40 ka BCE). Surprisingly, fragments from millimetric to centimetric size of yellowish-reddish ochre dispersed both in the emplaced and reworked deposits were identified for the first time. These pigments, extracted from rubefacient soil and mainly formed from varieties of limonite (yellow ochre) and hematite (red ochre), were likely used for artistic and ceremonial purposes, as suggested by the coloration of the whitish carbonate surface of a short and hollowed-out stalagmite, shaped like a female pubis, in the middle part of the cave and along its roof. This speleothem and the whole cave underwent to a high-resolution three-dimensional digital survey.

Keywords: black crusts, heavy metals, accelerated ageing chambers.

This study examined the development of black crusts, a significant form of degradation commonly found on exposed outdoor artworks. It is believed that heavy metals and carbon particles found in polluted environments play a role as catalysts in the sulphation process, which occurs prior to the formation of sulphuric acid through the oxidation of atmospheric sulphur dioxide (SO_2). These catalysts consist of various heavy metals adsorbed onto carbonaceous particles, but their specific functions in the process are not fully understood.

To investigate further, we conducted experiments using Carrara marble mock-ups, treated Therefore, the present experimental study involved exposing Carrara marble mock-ups, suitably treated (either through deposition on the surface of mother solutions or mixtures of metal cations with graphitic carbon, and deposition of atmospheric particulate PM 2.5 extracted from filters collected in ambient air), placed in climate simulation chambers to evaluate the catalytic action. to mimic real-world conditions, and placed them in specialized climate simulation chambers. These chambers, divided into 'corrosion' and 'xenon arc UV radiation' sections, allowed us to replicate environmental factors conducive to sulphation and outdoor solar radiation, respectively. Our research comprised two separate exposure campaigns (Comite et al., 2022; 2023), each serving as a distinct experiment. During these campaigns, we carefully controlled sulphur dioxide concentrations to observe its effect on sulphation and the catalytic activity of the metals involved.

We conducted thorough chemical and physical analyses on the mock-ups before and after exposure using a range of analytical techniques. These methods included stereomicroscope observation, SEM-EDX (Scanning Electron Microscopy with Energy Dispersive X-ray spectroscopy) analysis, colorimetric analysis, IC (Ion Chromatography) analysis, XRPD (X-ray Powder Diffraction) analysis, and OM (Optical Microscope) analysis. Our findings shed light on how certain metal cations accelerate the catalytic process, while others exhibit slower activation. We also observed synergistic effects among different metal mixtures, leading to increased gypsum formation. Additionally, the data were instrumental in calculating the growth rate of the gypsum patina on the surface over time, confirming certain hypotheses regarding predictive mathematical models.

Keywords: Early Neolithic, chert, provenance.

In the Matera area several evidences testified the prehistoric human presence. Numerous settlements, located on the eastern side of Matera, show a strong frequentation of this area since the Early Neolithic. In this contribution we focus on the knapped lithic industries from the sites of Giavarra, Murgia Timone and Trasanello as indicators of the chert supply during the Early Neolithic. The Giavarra site is located near the SP51 Matera-Gioia del Colle. The excavation context is represented by five sub-circular pits. Based on the typological characteristics of the pottery and the radiometric dating, the site can be framed in an archaic phase of the Early Neolithic Impressed Ware, between the end of the seventh millennium and the beginning of the sixth millennium BCE. All the 86 Early Neolithic knapped chert artefacts were analyzed. The settlements of Trasanello and Murgia Timone (Matera, Basilicata) is two ditched villages typical of the Early and Middle Neolithic of the Southern Italy. The Early Neolithic phase of Trasanello (first half of VI millennium cal BC) provided 100 chert artefacts consisting mainly of unretouched and common tools with a low number of cores. As for Murgia Timone only 12 chert artefacts found during the new excavation of the site (2020) were attributed to the Early Neolithic phase of settlement occupation. All the samples were investigated underwent nondestructive petrographic and chemical (pXRF) analyses to understand the provenance of raw materials according to NM-PCI protocol. The chert lithotypes identified show different chert supply patterns in three investigated sites. If at Giavarra we have the prevalent use of cherts from Gargano promontory formations, at Murgia Timone and Trasanello the main component is produced using local secondary chert sources (radiolarite, silicified calcarenites and nodular chert) originated from the outer geological units of the Southern Apennine. These evidences fits well the archaeologic hypothesis of occupation strategies for the neolithization of Matera area.

De-faience. Unveiling ancient craftsmanship: egyptian faience technique in Early Ethiopian beads

d'Aniello F.[1], Germinario C.[2], Izzo F.[1-3], Pagano S.[2-4], Scanu M.*[1], Sernicola L.[5], Verde M.[6] & De Bonis A.[1-3]

Keywords: beads, Ethiopia, faience.

The archaeological site of Seglamen has unearthed a set of beads originating from around 950 BCE thatbear profound implications for comprehending the use and diffusion of ancient glass-based materials within the region.

The primary aim of this study is to investigate whether the production technique of these artifacts can be attributed to Egyptian faience and, if so, to determine the specific type of faience involved (Nicholson & Peltenburg, 2000). Such insights could illuminate the spread of this technology into Ethiopia.

To achieve this goal, a preliminary archaeometric investigation, utilizing surface spectroscopic analysis techniques (pXRF, Raman spectroscopy) and laboratory-based methods (stereomicroscopy, ATR-FTIR, SEM-EDS), was conducted.

Stereomicroscopic observation of the bead sections reveals a distinct stratification, comprising a glazed core and a coating of varying colours and compositions.

Examination via SEM-EDS further elucidates this layered structure, highlighting a clear boundary between the core, that shows an amorphous structure with a Si-based composition, and the coating, showing chemical differences, also evidenced by pXRF. Chemical analysis performed on the external surfaces reveals a composition characterised by a ubiquitous presence of Si and Ca, alongside transition metals primarily represented by Fe, Mn, Cu, and Ti. Notably, Fe is prevalent in most samples, with lower concentrations observed in the external sides. The external (iridescent) side is characterised by high amounts of Mn, whereas higher amounts of Si, Cu and Ti are present in variable quantities.

Interesting results were also provided by vibrational spectroscopy, in particular ATR-FTIR. Infrared spectra, in fact, closely resemble those of amorphous silica, exhibiting opal-like characteristics. Moreover, on the coatings, infrared bands at ca. 2930, 2858, 1630, 1520 and 1390 cm^{-1} suggested the presence of protein-based organic compounds.

These first outcomes provided interesting insights to unveil ancient craftsmanship of the Egyptian faience technique in early Ethiopian beads. They might also help to reconstruct their origin, whether local or imported.

Corresponding author email: claudia.dibenedetto@unina.it

Keywords: etruscan necropolis, geomaterials characterization, non-destructive analysis.

The Etruscan necropolis of Sasso Pinzuto (Tuscania, Central Italy) was investigated by means of a geological multidisciplinary approach. Minero-petrographic analyses were carried out on selected samples, to deepen the knowledge about geomaterials used in the site. The aim of this preliminary study was to highlight the main types of geomaterials: building materials (natural and/or artificial) and pigments.

In the necropolis, known since the 19th century, more than 120 chamber tombs dating back to the first half of the 7th century BCE to the Hellenistic (3rd - 2nd century BCE) have been explored (Naso et al., 2024).

Experimental approach to geomaterial characterization, included analytical techniques such as: 1) in-situ (non-destructive) investigation on coloured portions by means of X-ray fluorescence spectrometry (XRF) and laboratory analyses such as X-ray powder diffraction (XRPD) and microscopic study on thin sections (PLM-Polarised Light Microscopy).

The investigation focused on eleven samples for in-situ analyses and micro-sampling of geomaterials collected from three chamber tombs named 58, 125 and 129. The points of interest chosen both for in situ analyses and micro-sampling were identified following the indications of the archaeologists working on the site.

Preliminary results allowed us to obtain information about geomaterials used in the necropolis:

a) XRF analyses did not give positive responses regarding the presence of mineral pigments but, indirectly, suggested the organic nature of the colours present on the walls.

b) XRPD results evidenced that the samples' mineralogical composition is in line with the typical mineralogy of the products from the Latium volcanic district (Cappelletti et al., 1999).

Samples collected from 125 and 129 are basically identified by an external layer and the wall reddish in color. The external layer presents ceramic fragments together with pyroclastite powder and therefore seems to be only a coating layer. The wall, however, unlike the tuff samples from 58, present a slightly different mineralogical composition (the absence of analcime) suggesting their origin from another, but similar, geological formation. The presence of hematite (iron oxide) is probably the reason for the reddish color of the sample.

Keywords: pottery technology and provenance, matt painted, north-Lucanian district.

A multidisciplinary approach to the study of the matt painted pottery involves the interaction of data and results obtained from the analysis of archaeological, anthropological, ethnographical, semiotic aspects with archaeometric and geoarchaeological data. The matt painted pottery productions from the north-Lucanian district present differences in their ceramic styles but are connected by substantial cultural similarities. The analyzed potteries come from the lucanian archeological site of Atena Lucana, Baragiano, Buccino, Oppido Lucano, Potenza, Ripacandida, Ruvo del Monte, and Serra di Vaglio sites and several potsherds were selected to understand the pottery productions and to depict the workshops.

Technological aspects have been drawn from the analysis of red and brown pigments carried out using micro-Raman spectroscopy and powder/micro X-ray diffraction. The brown pigment of the pottery contains the simultaneous presence of hematite and jacobsite ($MnFe_2O_4$) (Lubraco et al., 2024). Hematite and jacobsite reveal their presence from both Raman spectroscopy and XRD. The jacobsite formation is consequence of firing in an oxidant environment of manganese oxides (mainly MnO_2) and iron oxides (Fe_2O_3). A mixture of these two oxides were applied and the artefact was fired at temperatures ranging from 900–1000°C, where the manganese oxides react with hematite to form jacobsite [$MnFe_2O_4$] (Schweizer & Rinuy, 1982). A "before firing" application of the decoration can be hypothesized as well as the use of the well-known "manganese black technique". The manganese source for the jacobsite formation may be identified in the black sand from Mt. Vulture (PZ).

The desirable red color could be obtained by firing an iron–rich clay in an oxidizing atmosphere, which could cause the oxidation of iron (Striova et al., 2006). The higher intensity of the 297–299 cm^{-1} Raman band of hematite and its intense XRD peak on sample from Baragiano could be due to the use of a more crystalline phase of hematite when comparing to hematite from all other potsherds from other sites.

On the other hand, analysis of the ceramic body and comparison of its composition to the compositional characteristics of clay rich sediments outcropping in the Basilicata region (Schiattarella et al., 2024) - and contextualized in the geomorphological scenario - and to their firing tests has evidenced that differences raw materials were used to produce pottery from Ruvo del Monte and Oppido Lucano sites with respect to those from Baragiano. The raw material can be identified in the Pliocene-Pleistocene gray-blue clay and the clay of intrachain basin, respectively. The existence of different workshops for the matt painted pottery productions from the north-Lucanian district can thus be hypothesized, and a possible reconstruction of raw material circulation achieved. This mainly occurred through rivers as primary routes: the hydrographic right of Bradano river and the Melandro basin.

Keywords: Roman mosaics, petrography, mineralogy.

Roman mosaics are an essential part of our cultural heritage. They not only provide us with a glimpse of history but also offer invaluable insights into the past. To preserve these artefacts properly, it is essential to have a thorough understanding of the raw materials used and their properties. Successful restoration and protection require a basic knowledge of the source before applying various effective treatments in conservation science. The Roman Villa of São Simão is an archaeological site in the Penela municipality (central Portugal). The Villa, which belonged to the ancient Municipium of Conimbriga in the Lusitania Province, was built between the late second and early third centuries AD and inhabited until the mid-fifth century. It serves as a remarkable reminder of the wealthy Roman history of the area. The Villa boasts colourful and suggestive mosaic pavements, revealing an impressive occupation and providing new insights into the Roman rural rule of this territory. Archaeologists have been studying these mosaics since 2015, analysing their decorative motifs, state of conservation and in situ interventions. The main aim of this work is to examine and geologically classify the various types of stone tesserae and mortars used in the mosaic pavements of São Simão Roman Villa. The research investigates the production technologies and establishes a framework for understanding the origin of raw materials. Several stone tesserae were collected, representing the mosaics' different colour nuances. Additionally, two undisturbed and large-format mortar-tesserae pieces were also gathered. All samples were analysed using standard mineral-petrographic and geochemical techniques, including optical microscopy on thin sections, SEM-EDS spectroscopy, and colourimetry measurements. Initial findings have uncovered various carbonate lithologies and microfacies within the sampled stone tesserae. Our current understanding of the local and regional geology suggests that whitish, greyish, dark-greyish, pinkish, and yellowish fossiliferous carbonate tesserae were likely sourced from the outcrops of Lower to Middle Jurassic dolomitic-limestone, limestone, and marly limestone units. Some brownish and orange tesserae made of waste ceramic fragments were also identified. Further samples of presumed raw materials are being processed for comparison purposes. The mosaic mortars have a layering structure with siliciclastic sand as the aggregate, large ceramic particles added in the lower strata, and locally sourced limestone lime as a binder. Using natural and artificial materials can explain the mortars' excellent conservation status, high mechanical resistance, and long-term durability. By examining this information alongside similar evidence discovered at other coeval and nearby archaeological sites, such as Rabaçal and Conimbriga, it will be possible to understand better the sourcing strategies used over time and the networks involved in exchange and kinship.

The Openlit Project: a first step for an open access lithotheque of italian knappable rocks

Eramo G.*[1], Bertola S.[2], Carletti E.[3], Conati Barbaro C.[3], Conforti J.[1], Ferrero A.[2], Fioretti G.[4], Moscone D.[5], Pizziolo G.[6], Santo A.P.[7], Spalluto L.[1] & Lo Vetro D.[2-8]

Keywords: virtual lithoteque, prehistory, Italy.

A few regional projects in various European countries have recently been launched for the characterization of lithic resources including the creation of geo-referenced lithoteques that have been designed according to shared scientific protocols. Italy is still lacking such tools for systematizing research in the field and enhancing our knowledge of knappable materials.

OPENLIT project aims to build up the core of the first Italian open access lithoteque, a reference collection of knappable rocks based on a multi-parametric GIS-based database. The goal of this project is to develop a standard analytical descriptive system for defining knappable rocks, based on laboratory testing, and to make it available to the scientific community through an open access repository aimed at data sharing and dissemination.

The first step in achieving this goal consists in organizing a large set of information on knappable rocks available to prehistoric communities in Italy. Various lithoteques of knappable rocks from different Italian regions are currently stored in Italian University labs. These lithoteques have been assembled over time by several researchers with different methodological approaches and are not always accessible to scholars and students.

Starting from cherts, OPENLIT will provide the scientific community with a powerful, open and implementable research tool aimed at depicting the availability of knappable rocks in some key-territories in Italy. The open access repository will host the shared lithoteque and the geo-samples mapping as part of a WebGIS platform. For the first time data will be analysed at a national level with a shared approach combining different methodologies. Macroscopic, petrographic and compositional characterization of selected geological chert will provide target values to establish reference groups for further comparisons with prehistoric collections from both the Italian peninsula and neighbouring territories.

Archaometric study of two Hellenistic pottery kilns in Ascoli Satriano (FG): a combined minero-petrographic and archaeomagnetic approach

Eramo G.[1], Tema E.[2-3] & Muntoni I.M.*[4]

[1] Dipartimento di Scienze della Terra e Geoambientali, Università di Bari "Aldo Moro". [2] Dipartimento di Scienze della Terra, Università di Torino. [3] ALP-CIMAN Palaeomagnetic Laboratory. Corresponding author email: italomaria.muntoni@cultura.gov.it

Keywords: Apulia, firing temperatures, thermoremanent magnetization.

Multidisciplinary investigation of ancient kilns can offer very useful information about the ceramic production technology and the ancient fire control skills during the different chronological periods in the past. In this study, we present the results of combined mineralogical, petrographic and archaeomagnetic investigation of two Hellenistic pottery kilns excavated in in 2022 at Ascoli Satriano (FG), Giarnera locality, in order to analyse the raw materials used for their construction, assess the temperature reached during their use and estimate the time of their abandonment.

The two kilns (USM1 and USM2) were discovered during rescue archaeological excavation for railway infrastructures. The productive context is confirmed by the discovery of discharged level of medium and large-sized stones, tiles and ceramic fragments. Both kilns could be dated from the end of the 4th to the middle of the 3rd century BC.

Coordinated sampling for both mineralogical and archaeomagnetic study was carried out, collecting a total of 30 samples for petrographic (POM, SEM-EDS), mineralogical (XRPD), and chemical analyses (XRF), and 45 in situ oriented samples for archaeomagnetic analysis.

The analysis performed showed that in USM1 rectangular kiln, a marly clay was used to prepare unfired bricks bound with the same clay and laid to set the inner structure. Some straw was added to the bricks and to the lining clay. At least two reparations phases were identified in the wall stratigraphy. A temperature distribution throughout the kiln was reconstructed indicating temperatures as high as 1300°C for the vault. The USM2 circular kiln shows an inner lining consisting of limestone blocks and recycled bricks and tiles bound together with clay. In this case, the estimated temperatures attained during use are below 1000°C.

In both cases, the firing temperatures reached during the use of the kilns are high enough to enable the baked clay to acquire a thermoremanent magnetization, making them good recorders of the ancient geomagnetic field during their last use. Archaeomagnetic directions determined through stepwise alternating field and thermal demagnetization procedures are well defined, with Dm=348.9°, Im= 61.0° and α95= 4.4° for USM1 kiln and Dm=358.1°, Im= 60.9°, α95= 1.7° for USM2 kiln. These directions were then compared with the reference Secular Variation curves for the Italian Peninsula in order to estimate the time of the abandonment of these structures. The results obtained confirm the Hellenistic age of both kilns.

Provenance of the raw materials used in the mortars and bricks take from Hagia Sophia (Istanbul, Turkey): preliminary results

Keywords: mortars, archaeometry, provenance.

The purpose of this study is to formulate preliminary hypotheses on the provenance of the raw materials used to prepare ancient mortars and bricks take from Hagia Sophia (Istanbul, Turkey) by archaeometric analysis. Different studies were previously carried out to determine the compositional features of the mortars and bricks of Hagia Sophia (Moropoulou et al., 2002; Miriello et al., 2017; Taranto et al., 2019); however, the raw material sources of the building materials used in Hagia Sophia have not been studied before.

In previous studies (Miriello et al., 2017; Taranto et al., 2019), the compositional features of mortars and bricks have been determined by SEM-EDS, XRPD, XRF and optical microscopy (OM) analyses. As a result of this study, mortar samples were petrographically divided into seven different groups, which most likely belong to different construction phases and ancient restorations. According to Miriello et al. (2017), the aggregates in mortars generally contain “cocciopesto”, quartzite, granite and carbonate rock fragments in different ratios. Four groups of bricks are determined petrographically according to chemical and microscopic data (OM). The study of the bricks highlighted the presence of quartzite, granite and volcanic rock (basalts, andesites, dacites, rhyolites) fragments (Taranto et al., 2019).

In the present study, to determine the provenance of the raw materials used in mortars and bricks from Hagia Sophia, 45 geological samples (sands, limestones, clay and magmatic rocks) were taken from different geological formations in Istanbul and its surroundings, according to the places mentioned in Byzantine and Ottoman written sources regarding bricks and lime production. These geological samples were studied by polarized light optical microscopy (OM) on thin sections, XRF and XRPD analysis methods and the data obtained were compared with those of the ancient mortars and bricks. Although the production location of the bricks used in Hagia Sophia is unknown, it has been a matter of debate. According to some scientists, the bricks were brought from regions outside Istanbul. According to one of these views, the bricks are brought from the island of Rhodes (Moropoulou, 2002). At the end of this study, the debate on the raw material sources of bricks will be answered.

The data presented here are preliminary results. Further investigations and checks on these samples are underway. The results of this study will constitute an important database for subsequent restoration works, because it is important to identify the provenance of the original raw materials to use as compatible building materials.

Corresponding author email: matteomaria.franceschini@uniroma1.it

Keywords: terracottas, Castro, provenance.

Systematic archaeological research carried out since 2000 brought to light the ancient sanctuary of Athena in the indigenous settlement of Castro (Lecce), on the Adriatic coast of the ancient Messapia region (southern Apulia). Here native groups, the Greek inhabitants of Tarentum, and the Greeks from Macedonia, Epirus and the Corinthian colonies in the Adriatic Sea used to meet between the 7th and the 2nd century BC. Since the late 6th century BC, temples and other sacred buildings were constructed and adorned with colorful terracotta roofs. Many roof types were identified and assigned to Tarentine workshops, because of their morphological and stylistic features, while other groups cannot be clearly determined based on morphological and stylistic features alone (Ismaelli, 2023). Various sampling campaigns were performed to get analytical data on their provenance. This selection of 20 samples is representative of the different roof types from the Archaic and Classical periods identified during the archaeological study. Optical microscopy (OM), X-ray powder diffraction (XRPD), X-ray fluorescence (XRF), and SEM-EDS analyses were applied for minero-petrographic and geochemical characterization. Both crystalline and amorphous fractions were calculated using internal standard method by applying the Rietveld method. Four groups based on different content of volcanic and carbonate inclusions were identified through cluster analysis on both petrographic and mineralogical data. EDS microanalysis on clinopyroxenes, feldspars, and volcanic glass was also performed. Diopside, sanidine, and glass fragments ranging from phonolite and trachyte were recognised. Volcanic inclusions, especially clinopyroxenes, were effectively used for determining the provenance. The analytical results allowed us to have a clearer picture of the origin and transport of rough materials, as well as the technical know-how of Tarentine craftsmen.

Keywords: Hierapolis, mortars, building technologies.

Hierapolis of Phrygia is a well-known archaeological site in southwestern Turkey, protected by UNESCO since 1988. Located in one of the most geologically active areas in the world, the city has suffered from the effects of earthquakes that have repeatedly destroyed or severely damaged it. During numerous archaeological campaigns, in the framework of the "Marmora Phrygiae" project (Ismaelli & Scardozzi, 2016), mortar samples belonging to the buildings from the Julio-Claudian to the middle Byzantine period were collected. The analysed materials include 71 samples of plasters, bedding and grouting mortars coming from 9 of the most important public buildings of city (i.e Plutonium, Theatre, St. Philip Church). We examined each sample with a well-established multi-analytical approach, combining optical microscope analysis (PML) on thin sections with digital image analysis, X-ray powder diffraction analysis (XRPD) and SEM-EDS analysis. The sampling was aimed at tracing the sources of raw materials and understanding the evolution of the composition and technologies of mortar-based materials with different functions over time. During the Roman period, travertine and marble were used as raw materials in binder production, while marble was more common in the Byzantine period. The aggregates consisted mainly of sands, coming from the geological formations of Lycian Nappe and the Menderes Massif, consisting of carbonate rock fragments as travertine, marble, micritic, and fossiliferous limestones, together with silicate metamorphic rocks as meta-sandstone, schist, gneiss, and quartzite. In the Roman samples we found ophiolitic rock fragments which were not present in Byzantine samples. This difference allowed us to hypothesise different sources of raw material: Çürüksu stream or local streams as Suini Dere or Gök Dere during the Roman age, and closer waterways in the Byzantine age. Cocciopesto was mainly used in waterproof masonries from Flavian to Severian age. During the early Byzantine age, we commonly observed the use of cocciopesto in areas of the building where a hydraulic function was not required, as in the bedding and grouting mortars of St. Philip Church. Straw was a common organic additive in the Byzantine age plasters. This was a remarkable technological change compared to the Roman age mortars exclusively containing inorganic aggregates.

Keywords: obsidian, glass, medieval mosaics.

The floor mosaic of Otranto Cathedral (12th century AD) is one of the most extensive medieval lithostrotes in Europe. Commissioned by the Idruntine archbishop Ionathas, it was created by the presbyter Pantaleon between 1163 and 1165 AD. The mosaic occupies the entire floor surface of the nave, the presbytery, the transept and the apse of the Cathedral and show a complex and articulated iconographic programme, on which the previous studies have focused (Settis Frugoni, 1970; Ungruh, 2000). No attention has so far been paid to techniques and materials. This paper discusses the preliminary results obtained on natural and artificial glass tesserae. The mosaic's tesserae measure one centimetre on each side, and they were cut largely from polychrome limestones or marbles. However, in some areas of higher liturgical relevance and in several scenes with high symbolic value, tesserae of natural black and coloured artificial glass are present; the natural glass, mainly black obsidian, is particularly used in zoomorphic and anthropomorphic figures to represent the eyes. We conducted a chemical analytical study on few samples of natural and artificial glass tesserae through portable X-ray fluorescence (pXRF) and through scanning electron microscopy coupled with energy dispersive microanalysis (SEM-EDS). The aim is differentiate natural and artificial glass, define their provenance and calibrate the pXRF to extend the in-situ analysis to numerous other tesserae, in order to correctly discriminate the provenance of the obsidian (Frahm et al., 2014). The pXRF allow to detect only heavy elements (Z>16) but enough to measure different amounts of K, Ca, Mn, Fe and Pb. These data allow to distinguish natural from artificial glass. The latter are opaque sodic calcic glasses, excepting someone opacified with stannate or antimoniate. Medieval glass was primarily composed of silica, alkali like potash or soda and lime, so the composition results very different from natural glasses (Raynaud et al., 2023); the obsidian composition, instead, can vary depending on the source magma and the conditions under which it formed. Differences in chemical composition or presence of microphenocrystals can lead to variations in colour, texture, and overall characteristics of the obsidian glass and different geological sources of obsidian can be detected using both techniques. In this way the analysis can extended on a large number of sample, using in situ not-destructive methods.

Keywords: limestone, lavas, south-eastern Sicily.

In the historical buildings of the Val di Noto UNESCO World Heritage Site (including Syracuse, Catania, Ragusa, Noto, Modica, Scicli, Palazzolo Acreide and Avola) there is a close relationship between the building materials and the geological context, testifying the intense reconstruction activity that followed the 1693 CE earthquake. Indeed, the cities chromatic features reflect those of the locally available stone materials, often quarried in the surroundings of the urban centre (Occhipinti et al., 2021). A very common feature in late 17th century Baroque architecture is therefore the bichromy due to the combined use of black magmatic rocks or bituminous limestone (Pitchstone) with whitish sedimentary rocks (Punturo et al., 2023 and references therein).

Unfortunately, stone materials employed in buildings are exposed to time and atmospheric agents (e.g. rain, wind, solar radiation, aggressive atmospheric pollutants, freeze-thaw cycles, crystallisation of saline solutions, growth of organisms) and can therefore show signs of deterioration (Occhipinti et al., 2021; Punturo et al., 2023). Therefore, as fabric-related petrophysical properties (e.g. petrography, porosity and seismic behaviour) play a key role on the durability and ageing of such rocks, a comprehensive multi-analytical investigation is essential for both new construction and for the conservation and restoration of cultural heritage monuments.

In this contribution, we focused on three main lithotypes employed in historical buildings in the Val di Noto: Noto Stone, bituminous limestone (Pitchstone) and Etnean lavas. The results highlighted the close relationship between microstructural features and damage and allowed us to relate them to the environmental context.

In conclusion, our multi-analytical study has succeeded in providing a useful basic tool for both the conservation of cultural heritage monuments and their restoration. Furthermore, in the context of the European policy of circular economy and resource efficiency, the stone materials of south-eastern Sicily can play a strategic role not only in the local economy as available raw materials, but also in the progress of society in terms of sustainable building and geomaterials for construction.

Kras-Carso II Interreg European project. Multidisciplinary research towards promoting the geological heritage of the Classical Karst

Krizova B.*[1], Zini L.[1], Calligaris C.[1], Busetti A.[1], Corradetti A.[1], Černok A.[1], Consorti L.[2], Bensi S.[3], Piano C.[3] & Franceschi M.[1]

[1] Dipartimento di Matematica, Informatica e Geoscienze, Università di Trieste. [2] Istituto di Scienze Marine, CNR, Trieste. [3] Servizio Geologico, Regione Friuli-Venezia Giulia.

Corresponding author email: barbora.krizova@units.it

Keywords: classical Karst region, geopark.

The Classical Karst cross-border area represents a "Gateway to the East," connecting the Mediterranean region to Europe. Spanning over ~800 km^2, it is the cradle of karst studies. The first systematic studies of the karst phenomena worldwide started in the mid-18th century, in this area, and were driven by researchers looking for drinking water to supply the growing town of Trieste.

Thanks to the EU Interreg Italy-Slovenia Program, researchers from both countries have the opportunity to join their efforts and contribute to the sustainable valorization of the unique geoheritage of the Classical Karst region. In this context, the Kras-Carso II Project of strategic importance was established. It involves many partner institutions from Slovenia and Italy, including the University of Trieste (MIGe – UNITS) and the Geological Survey of the Regione Autonoma Friuli Venezia Giulia.

The main goal of the project is to promote sustainable development in the Classical Karst region, including establishing the cross-border geopark. Researchers of the MIGe and the Geological Survey of the Regione Autonoma Friuli Venezia Giulia target the geosites of significant geological and geomorphological value to raise public interest and knowledge of this exceptional region. These efforts involve creating 3D models and virtual outcrop representations to make geosites more accessible, conducting dye-tracing experiments to better understand the hydrogeological processes of the karst, and drilling a core across the Cretaceous-Paleogene boundary (K-Pg) to assess the local sedimentary evidence of the Chicxulub meteorite impact; an event marking the end of the dinosaur era. The scientific findings of these studies are translated into popular language for the professional training of geopark guides, who will subsequently lead guided tours along routes that both highlight the geological heritage and encourage eco-friendly tourism in the region. Dedicated paths and cycling routes are being designed to guide visitors through fascinating geological storytelling, raising environmental awareness among the public. Furthermore, workshops, traveling exhibitions, interactive games, and similar initiatives are being arranged to engage school children and families, fostering awareness of the geological richness present in their local environment. Collectively, the joint effort of the partners of this project converges toward the establishment of the Kras-Carso Geopark that will help valorize the unique geological features of the Classical Karst, an area that deserves preservation along with responsible and sustainable development.

Bridging gaps in blue expertise through a triple transition training model for the UCH field: new challenges in uBlueTec project

Keywords: underwater technologies, blue economy, blue/green/digital skills.

The evolving landscape of the Blue Economy highlights critical gaps in blue skills and expertise (directorate-General for Maritime Affairs and Fisheries. Skills and career development. Available: https://oceans-and-fisheries.ec.europa.eu/ocean/blue-economy/skills-and-career-development_en), particularly in the context of achieving sustainability and embracing zero-carbon, technology-driven solutions. Key to addressing these gaps are advancements in underwater (UW) technologies, pivotal across several sectors such as marine biodiversity and cultural heritage conservation. However, a pervasive challenge persists: the lack of qualified professionals skilled in implementing UW technologies in the context of the green and digital transition, also related to the Underwater Cultural Heritage (UCH) field.

Motivated by these challenges, the project uBlueTec - Training framework on Underwater Tecs as key enabler for blue careers development - (uBlueTec project website. Available: http://www.ubluetec.eu) proposes a comprehensive triple transition training and skills development model (green, blue, digital skills) that promotes long-lasting partnerships between universities, vocational education and training (VET) providers, industrial clusters and small and medium-sized enterprises (SMEs) within blue economy value networks.

In particular, the uBlueTec model aims to: a) develop educational materials and curricula to facilitate skills enhancement in state-of-the-art UW technologies with a green and digital focus; b) pilot the developed assets within higher education (HE) and VET institutions to validate effectiveness and relevance; c) establish a Hub on UW technologies, serving as a permanent capacity-building structure to sustain collaboration among stakeholders; d) deploy a recruitment platform for blue jobs, offering online courses and facilitating seamless matching of labor force skills with industry demands. Additionally, the platform will serve to identify and address skills gaps at regional, national, and EU levels, and also to attract and nurture young talents through initiatives like Career Days and Entrepreneurial Bootcamps, in order to fostering a vibrant ecosystem of skilled professionals in the blue economy. By addressing the skills shortage and aligning training with the evolving needs of the blue economy, uBlueTec endeavors to propel sustainable growth and innovation in underwater technology sectors worldwide, such as in UCH field.

Multianalytical study of lithic materials from the prehistorical site of Pirro Nord: preliminary results

Lepore A.*[1-3], Arzarello M.[2], Germinario C.[3], Mercurio M.[3-4] & Grifa C.[3-4]

[1] Dipartimento di Scienze dell'Antichità, Sapienza Università di Roma. [2] Dipartimento di Studi Umanistici, Università di Ferrara. [3] Dipartimento di Scienze e Tecnologie, Università del Sannio, Benevento. [4] Center of Research on Archaeometry and Conservation Science.

Corresponding author email: andrea.lepore@uniroma1.it

Keywords: chert, lithic tools, non-destructive analyses.

Pirro Nord is a prehistoric site dated 1.6 - 1.3 Mya in Southern Italy (Apricena, Puglia) testifying the oldest presence of hominins on the Italian peninsula. Inside a quarry for the exploitation of limestone (Apricena Stone), paleontological remains (Pirro Nord Faunal Unit) associated with the lithic industries were found inside Pleistocene paleokarst formation at the top of the Mesozoic limestone formation (Arzarello & Peretto, 2010). The archaeological evidence suggested that raw materials, selected based on their morphology, were probably collected in secondary deposits (river beds or slope deposits). However, the distances are unknown and the opportunistic behaviour in lithotypes selection has not been supported by scientific data so far.

The aim of this research deals with the identification of the raw material's supply areas by investigating both archaeological and geological samples using an interdisciplinary and combined analytical approach encompassing non-invasive spectroscopic, minero-petrographic and geochemical techniques, which will be supported by territorial mapping analyses, to create an integrated geological, geo-archaeological and environmental web-GIS system to infer the sourcing, the technology and the mobility patterns in a referenced space.

In this study, we present preliminary results obtained on 70 lithic samples by using Digital Microscopy (DM), Fourier Transform Infrared Spectroscopy using an External Reflectance module (ER-FTIR), and Fiber Optical Reflectance Spectroscopy (FORS) in a visible range, providing the preliminary identification of the specific lithic types used for the lithic industry, to select representative samples to analyse by in-lab techniques.

The main lithic types consist of cherts and rare limestones. Microscopic observation in DM and colorimetric measurement via FORS permitted the identification of main groups, featured by different textures and colours. Cherts with brown-yellow colour (av. L*=53.3; a*=6.3; b*=24.9) have hyaline or granular with inclusions like oolites, the grey cherts (av. L*=53.7; a*=11.3; b*=11.9) are featured by small inclusions and microfossils whereas the reddish samples (av. L*= 39.8; a*=13.1; b*= 18.1) are homogeneous, occasionally containing microfossils.

Interesting features were also revealed by ER-FTIR; spectra, in fact, show the characteristic Reststrahlen band of chert between 1300 and 1000 cm^{-1} (Si-O stretching) along with the doublet at ca. 800 and 780 cm^{-1} (Si-O bending and Si-O-Si stretching). However, the shape of Reststrahlen band, which can change in function of the surface treatment and grain size of the chert, appears different on samples with knapped or polished surface, and shows more intense in lithic types with coarser grain size. Moreover, statistical analysis carried out on the FTIR spectra highlighted similarities between the geological and archaeological samples, further confirming the similarities in microscopic description.

Arzarello M. & Peretto C. (2010) - Out of Africa: The first evidence of Italian peninsula occupation. Quatern. Int., 223-224, 65-70, https://doi.org/10.1016/j.quaint.2010.01.006.

Lime mortar production: the case of Panchina calcarenite from Tyrrhenian coast

Lezzerini M.*[1], Aquino A.[2] & Pagnotta S.[1]

[1] Dipartimento di Scienze della Terra, Università di Pisa.
[2] Department of Geosciences, Universität Tübingen, Germany.

Corresponding author email: marco.lezzerini@unipi.it

Keywords: limestone, lime, geomaterials.

Since ancient times, lime has been utilized in the production of mortars and plasters. Generally, the process of lime production commences with the quarrying and crushing of limestone, a material comprised primarily of carbonates and occasionally containing minor impurities. Limestone is transformed into lime through heating in a kiln, a process known as calcination. When pure limestone is subjected to high temperatures, it undergoes chemical decomposition, yielding lime (CaO) and emitting carbon dioxide gas (CO_2). To achieve complete thermal decomposition of limestone into lime, the stone must be heated to the dissociation temperature of the carbonates and maintained at that temperature for a certain duration. The dissociation temperature varies depending on the type of limestone being burned. Less commonly known is that in the past, lime mortars were also obtained by burning suitable calcarenites without the addition of anything other than water.

The objective of this study is to investigate the physical and mechanical characteristics of lime mortars obtained using the Panchina calcarenite from the Tyrrhenian coast, burned at 900°C. The mortar's carbonation rate was evaluated using TG/DSC, while its primary physical properties were assessed through measurements of apparent density and water absorptions. Mortar shrinkage and uniaxial compressive strength were also measured directly, as well as indirectly through ultrasonic techniques. The results obtained indicate that lime mortars produced from burned Panchina calcarenite exhibit a high carbonation rate and relatively high values of compressive strength, capillary rise coefficient, and porosity accessible to water compared to conventional lime putty mortars. Additionally, the conducted tests demonstrate that the Panchina calcarenite is a beneficial material for producing lime mortar from a natural source, requiring minimal to no additional sand to mitigate shrinkage.

Preliminary results of the petrographic and mineralogical study of the Oenotria ceramic artifact (Southern Italy)

Lo Riso M., Buccione R., Rizzo G.*, De Bonis A. & Teghil R.

Dipartimento di Scienze, Università della Basilicata, Potenza.

Corresponding author email: giovanna.rizzo@unibas.it

Keywords: ceramic artifacts, archeometry, Southern Italy.

The archeometric study of ceramic archaeological finds has, since the second half of the 20th century, an increasing importance. The objective of the present work is the compositional characterization, based on mineralogical and petrographic study, of Oenotrian ceramic finds from the Archaic Age (6th - 5th centuries B.C.) from archaeological excavation campaigns conducted in the necropolis of the Oenotrian communities of Anzi, Garaguso and Brindisi di Montagna (PZ). The Anzi-Calvello basin (hereafter ACB) is a small Plio-Pleistocene basin extending in the ENE-WSW direction for about 10 km. The deposits of this basin unconformably overlie a substrate composed of the Sicilide Units, the Lagonegro Units, and flysch deposits of the Gorgoglione Miocene Basin. Marine-derived deposits of Plio-Pleistocene age of ACB are widely distributed in this area and have a predominantly marine feature. The outcropping successions are dominated by pelitic facies, consisting mainly of clays, silty clays, and sands, which are followed by fluvial conglomerates that close the marine successions of the basin. Petrographic and mineralogical characterization of manufact fragments from Anzi and Garaguso were assessed by using polarized light microscopy, scanning electron microscopy (SEM-EDS), and X-ray Powder Diffraction (XRPD), allowed to define the compositional difference between the matrices of the Anzi and Garaguso artifacts. To define the natural materials used for the studied artifacts, several samples of natural clayey-marly sediments were collected in the nearby the center of Anzi and Calvello villages, which is part of the ACB. The mineralogical composition of the collected clay sediments is dominated by quartz and calcite with discrete amounts of feldspar and varying amounts of clay minerals. The comparison between the studied artifacts and the natural sediments revealed a difference regarding the mineralogical abundances of clay minerals which are more enriched in the analyzed artifacts. This finding suggests that the raw materials used in the Oenotrian ceramics come from an area which not fall in the ACB. In addition, the results of the compositional analysis allowed the characterization of the manufacturing process, and particularly to provide a preliminary characterization of the black pigments, with a maximum temperature of 850-900°C for firing the artifacts, and a more controlled firing atmosphere in the case of the manufacture of the Brindisi di Montagna and Garaguso artifacts. These results show that knowledge of the composition of materials used in artifacts can give information not only about their origin but also about production methods.

Artificial weathering and surficial consolidation techniques applied to the 'Peperino' from the Alban Hills volcano (Latium, Italy)

Luconi I.*[1], Ercoli R.[2] & Paris E.[1]

[1] Scuola di Scienze e Tecnologie, Sezione Geologia, Università di Camerino.
[2] Department of Material Science, Faculty of Mechanical Engineering, Università di Urbino "Carlo Bo".

Corresponding author email: irene.luconi@unicam.it

Keywords: Peperino, consolidation, restoration.

Degradation affects all stone monuments and artifacts, although the effects vary with the lithotype involved, as well as with the exposure to atmospheric agents, the climatic conditions, the urban/industrial pollution and the natural hazards. In the future, also climatic change will contribute negatively to increasing degradation problems in the cultural heritage, calling for actions to restore or prevent damages.

Peperino, from the Latin piper (i.e. pepper) derives from phreatomagmatic eruptions of Alban Hills related to the potassic and ultrapotassic magmatism of the Roman province (Middle to Upper Pleistocene), with mafic (K-foidites) to differentiated (trachites and phonolites) compositions. Peperino has been employed since the antiquity in the construction of buildings and ornamental elements (Marra et al., 2022), although it is subjected with time to degradation phenomena.

Peperino samples have been preliminarily evaluated by optical microscopy, Scanning Electron Microscopy (SEM), X-ray Diffraction, X-ray micro-tomography aimed at determining mineral composition and texture, but also by physical tests to determine porosity, absorption by total immersion and by capillarity. All samples have been artificially weathered by heating them at 400°C for an hour (Franzoni et al., 2013), then the tests have been repeated to evaluate the effects of the artificial weathering on the samples. The results have demonstrated how the artificial weathering allows to simulate in the laboratory an accelerated alteration, useful to investigate how strongly alteration affects mineralogy, porosity and permeability.

Two inorganic consolidants (i.e. ethyl silicate and nanosilica) have been chosen and tested by treating the sample surface with the aim to verify the effects of the consolidation treatments. The effects of the consolidation, evaluated by observations under the optical microscope and SEM, have been compared. The capillarity absorption tests have been carried out to enlighten the possible permeability variations after the consolidation, to be compared to the heated and to the natural samples. Micro-tomography has been used to assess the variations in volume porosity, pores distribution and micro-fractures after the artificial weathering and the consolidation treatment. Surficial colour changes occurred and alterations were measured by a spectrophotometer.

The results showed that consolidation treatments have contributed to:

– an increase of the surficial grains cohesion;
– a decrease of the surface permeability, especially using ethyl silicate;
– porosity and micro-fractures variations;
– slight colour alterations.

This preliminary data will be useful to determine the problems related to the degradation of Peperino, as well as evaluate the most efficient consolidants for the protection from alteration.

Evaluating biosurfactants as eco-friendly biocides (TEch4YOU Project)

Macchia A. [1], Diliberto Cascio C.[1], Zicarelli M.A.[1], Alisi C.[2], Catania V.[3], Schillaci D.[4], La Russa M.F.[1] & Ruffolo S.A. *[1]

[1] Dipartimento di Biologia, Ecologia e Scienze della Terra, Università della Calabria, Rende (CS). [2] ENEA, Department of Environment, Global Change and Sustainable Development, CR-Casaccia. [3] Dipartimento di Scienze e Tecnologie Biologiche Chimiche e Farmaceutiche, Università di Palermo. [4] Dipartimento di Scienze della Terra e del Mare, Università di Palermo.

Corresponding author email: andrea.macchia@unical.it

Keywords: biosurfactant, stone materials, biocides.

The colonization of stone substrates by biological organisms is instigated by photoautotrophic pioneers like cyanobacteria, algae, and lichens, along with chemolithotrophic and chemioorganotrophic bacteria. These organisms harness the limited energy resources available on the stone surface and adapt to challenging environmental conditions, including variations in solar radiation and exposure to precipitation, as well as fluctuating nutrient availability. This process often leads to the establishment of a distinct ecological niche characterized by specific micro and macroflora. Operators typically remove this colonization through a combination of mechanical and chemical methods, primarily utilizing Quaternary Ammonium Compounds (QACs). However, QACs have been detected in wastewater, surface waters, and sediments, with documented effects on antibiotic resistance, necessitating the development of new biocides with enhanced biodegradability.

The TECH4You project under the PNRR is founded on the integration of established technologies with emerging ones such as biosurfactants (Walter et al., 2010). This study presents the selection of potential biosurfactants for use as inhibitors of microbial growth. Biosurfactants derived from strains including *Pseudomonas aeruginosa*, *Rhodococcus qingshengi*, *Pseudomonas glycinis*, *Microbacterium hydrocarbonoxydans*, and *Acinetobacter sp*. were extracted to develop marketable products. Extraction trials were conducted to achieve consistent percentages of cationic, anionic, and non-ionic surfactants, with preservation tests assessing the durability of the products over time. The biocidal efficacy of the products was evaluated both in laboratory settings and in situ.

In laboratory tests, the antimicrobial activity was evaluated against pathogenic strains P. aeruginosa ATCC 15692 and S. aureus ATCC 9144 (Ceresa et al., 2019). The minimum inhibitory concentration (MIC) and minimum bactericidal concentration (MBC) of both filtered and unfiltered samples, were determined 30 days post-biosurfactant production.

In situ, biosurfactants were applied to artificial stone materials, and their biocidal efficacy was evaluated through macroscopic and microscopic observations under visible light, as well as ATP analysis using a bioluminometer. The strains *Rhodococcus qingshengi* (OSS 19) and *Pseudomonas glycinis* (A2-5) exhibited the highest biocidal efficacy.

The Mg/Ca ratio in mortars used in ancient rural buildings in the north-Eastern Piedmont plain: a methodology to support archaeological studies

Mancini S.*, Dino G.A., Tazzini A. & Gambino F.

Dipartimento di Scienze della Terra, Università di Torino.

Keywords: ancient mortars, cultural heritage, archaeometry.

Rural architecture deserves to be considered a cultural heritage because it bears witness to the development of territories over the centuries. Rural settlements in the Piedmont Po Valley present a wide range of structures dating back to Roman and early medieval times. These structures are characterised by considerable irregularity in texture and height, and consist of wooden walls with cobblestone bases or brick fragments, parts of older and more recent walls, and reused older elements. Therefore, these types of structures do not allow for an architectural dating and chronological classification. The only material coeval with the construction and with specific characteristics are mortars.

Mortars are made up of a mixture made up of an inert material (usually sand), a binder (lime) and water. Lime, obtained by cooking carbonate rocks (limestone, dolomitic limestone, dolomite), is one of the most popular building materials in the world and has been used since ancient times.

This study presents a low-cost and efficient diagnostic method based on the geochemical characterization of two oxides present in the lime of mortars and in carbonate rocks of the area: MgO and CaO.

The Mg/Ca ratio of the carbonate fractions of the limestones quarries remains almost constant within the same depositional environment, and is therefore characteristic at the outcrop scale.

The Mg/Ca ratios of the mortar samples taken from three rural settlements, Brusasco, Trino and Ticineto, of Roman and medieval origin, located in the plain area along the alluvial belt of the Po river, were analysed and compared with those of the mortar samples carbonate rocks taken from ancient limestone quarries in the nearby hilly area of Monferrato, in the Piedmont region (Italy).

Through the analysis of the MgO/CaO ratio in the limestone rocks of the ancient quarries and in the lime present in the mortars of the sampled rural buildings, it was possible to carry out spatial and temporal correlations with the historical phases identified in the various archaeological sites.

Furthermore, it was possible to identify the original quarries used for the production of limestone and, in some cases, establish the period of exploitation.

In this context, mortar has proved to be an important diagnostic tool to identify the original limestone quarries and the period of exploitation, and to provide interesting information on the network of trade routes and their changes over time.

Finally, the study showed that quarries exploited in an earlier period (e.g. Roman times) were often no longer exploited in more recent periods (e.g. medieval or late medieval times). The reasons may not only be related to the impossibility of quarrying or need of different characteristics of limestones, but also to political and road changes.

Influence of clay processing on bulk chemistry signature in ancient pottery productions

Maritan L.*[1], Filippou V.[1], Renson V.[2], Pasqual D.[1], Cattò S.[1], Koutovaki E.[1], Nodarou E.[3], Cantisani E.[4], Dikomitou Eliadou M.[5] & Zomeni Z.[6]

Keywords: clay depuration, chemistry, mineralogy.

The production of many ceramic materials in ancient times required the base clay (the clayey material collected from primary or secondary deposits) to be processed according to various methods. Among others, the depuration by sedimentation (in clam water or in water flow) was probably one of the most used one. It allowed to obtain a clayey material finer in terms of grain-size than the base clay due to the removal of the coarser fraction, and therefore more plastic and suitable to produce fine pottery. But, the removal of the coarser fraction, even with different degree of depuration, determined important changes on both the mineralogy and chemistry of the depurated clay with respect to the originally exploited one. It is important to remark that the provenance especially of fine ceramic is normally based on their chemical composition and the comparison with reference groups (ceramic materials of known provenance, often linked to attested production centres/workshop) and/or clayey materials available in the possible production regions. Therefore, clay processing affected the composition of the clay paste and the relative fired products (ceramics). Despite many archaeometric studies remark that possible differences between the ancient productions and the possible used base clays are ascribable to depuration processes, not systematic works as been done coupling the grain-size analysis and workability (plasticity, Atterberg limits) of the original and depurated clays with their mineralogical and chemical composition, as well as microscopic features. This research therefore report the results of the depuration of different types of clays in terms of their grain size, mineralogy and geochemistry with respect to the sampled clays . In particular 4 different types of raw material, representing “clays systems” widely exploited in the past to produce ancient pottery, were selected: i) illitic-chloritic clays rich in calcite; ii) illitic-chloritic clays poor in calcite; iii) illitic-kaolinitic clays rich in acidic-rocks sand; iv) chloritic-smectitic clays rich in iron. These clays were collected from well-known exploited deposits used in antiquity (Cyprus, Crete, Nile Valley, Arezzo, Veneto region) and then depurated, separating the coarser fraction for sieving and sedimentation in water, in order to obtain a depurated clay from each raw material. Each of these products, as well as the original base clays and of the separated coarse fractions, were characterized under a granulometric, mineralogical, microscopic (optical and electronic microscopy) and chemical point of view.

Investigating post-depositional alterations in underwater ceramics. The case of the archaeological site of Torre Santa Sabina (south-eastern italy)

Mascaro M.E.*[1], Auriemma R.[2], Mazzoli C.[1] & Maritan L.[1]

[1] Dipartimento di Geoscienze, Università di Padova. [2] Dipartimento di Beni Culturali, Università del Salento, Lecce.

Corresponding author email: mariaemanuela.mascaro@phd.unipd.it

Keywords: archaeometry, underwater ceramics, post-depositional alterations.

An archaeometric investigation is currently in progress on a series of amphora fragments from the underwater archaeological site of Torre Santa Sabina (Apulia, south-eastern Italy), dating back to the Republican period (late 2nd century BC) (Auriemma et al., 2022). The main aim is to analyse the post-depositional alterations occurring in ceramics in the underwater environment by studying the systematic physical, chemical and mineralogical transformations. All the results obtained contribute to discriminate which chemical element changed in terms of concentration due to interactions with the underwater environment from those that are indicators of provenance, allowing the archaeometric data to be properly tuned. This will also help provide important evidence of cultural and technological identity and deepen knowledge of the site's ancient maritime history. Geochemical, mineralogical and micro-stratigraphic characteristics of 40 amphora samples from the underwater site of Torre Santa Sabina and 13 from the terrestrial production areas of Apani and Giancola, have being analysed combining optical and spectroscopic techniques. A comparison between marine and terrestrial samples was considered to verify the nature of the main transformations in objects exposed to different burial environments and to detect compositional similarities that may be indicative of the provenance of underwater ceramics. In order to identify the factors determining the precipitation of specific secondary phases in the pores and the enrichment or depletion of certain chemical elements (Maritan, 2020), and to verify their systematic nature, sherds of similar production but recovered from other submerged and terrestrial sites were also considered. The preliminary results show that the underwater ceramic bodies are characterised by a chromatic stratigraphy linked to post-depositional processes that is not detected in terrestrial samples. Some chemical elements, such as sulphur, show great variability as they are related to the precipitation of secondary phases during burial (e.g. pyrite) the presence of which is confirmed by XRPD data. The preliminary SEM-EDS analysis verified the frequent presence of pyrite microcrystals and highlighted the occurrence of lamellar structure of hydrotalcite-like layered double hydroxides (LDH) in underwater fragments. These phases are absent in terrestrial samples. Statistical treatment of chemical data is carried out by selecting the elements least susceptible to alteration in order to use them for the comparison of samples from different burial environments and to properly assess the provenance of ceramics found on the seabed. All the outcomes will provide useful information for the Underwatermuse project, of which Torre Santa Sabina is the reference site, aiming to create an underwater archaeological park through experimental methodologies, encouraging the conservation of the submerged heritage and promoting cultural activities.

Keywords: archeometry, contemporary archaeology, petrography.

Located in close proximity to Altamura (Puglia, Italy), the site, commonly referred to as PG65, spans an area of 31 hectares. It held the distinction of being the largest concentration camp for prisoners within fascist Italy during World War II. Following the armistice in 1943, it underwent a transformation into a training facility for Yugoslav partisans and, subsequently, in the 1950s, evolved into a center for gathering refugees. Later on, it served as a military training ground before being almost completely burned to the ground in the late 1980s (De Felice, 2021).

The site's history is intricate and so its materials. Archaeological investigations, conducted by the Universities of Bari and Foggia since 2021, have been aimed to research material traces in order to reconstruct the history of the site and understand the material transformations associated with those phases. A total of 65 samples, primarily extracted from the remaining elements such as floors within two kitchens, a lavatory, and a dormitory, were collected and analyzed. The particular military building context raises questions about the binder and aggregate provisioning during and after World War II and provides evidence of lime and cementitious binders technology in the mid-20th century. Mineralogical and petrographic analyses (SEM-EDS, POM, XRD, etc.) have been fundamental to answer these questions and understand the chronological succession and the materials employed, particularly focusing on mortars.

Reproduction of ancient lime mortars from the Baroque built heritage of Catania (Sicily): an experimental study

Menta S.*, Stroscio A., Mazzoleni P. & Belfiore C.M.

Dipartimento di Scienze Biologiche, Geologiche e Ambientali, Università di Catania.

Corresponding author email: salvatore.menta@unict.it

Keywords: lime, cultural heritage, Catania.

The Baroque built heritage of the historic center of Catania (Eastern Sicily) is the result of the city reconstruction after two devasting natural events occurred during the second half of 17th century, i.e. the eruption of 1669 and the earthquake of 1693. Volcanic stones from Mount Etna have been used in combination with limestones from the Hyblean area giving the buildings a peculiar bichromatic appearance. Basalt blocks were mainly used for the base of building facades and for church columns due to their strong physical-mechanical properties (Barone et al., 2021). In addition, volcanic materials have been also used in the formulation of both bedding and rendering lime mortars. Specifically, two different volcanic aggregates were used, locally known as azolo and ghiara. Azolo, now obtained from the fine grinding of basalts, in its ancient meaning was an incoherent pyroclastic rock, while ghiara is a peculiar reddish material deriving from the transformation of palaeo-soils due to lava flows (Belfiore et al., 2022; 2023). These two aggregates peculiar of the Etna territory were used as the main source of aluminosilicates to be mixed in variable proportions with lime to produce the ancient mortars.

In this contribution, an experimental approach is used, based on the reproduction in laboratory of historic mortars for conservation and restoration purposes. Specifically, different formulations were prepared by using a binder/aggregate ratio of 3:1 and 4:1 for the ghiara-based mortars, while 3:1 and 2:1 for the azolo-based ones, according to the ancient recipes known from literature (Battiato, 1988). In addition, further specimens have been prepared by adding specific quantities of pozzolana to the above mixtures to enhance the hydraulic behavior of mortars. The specimens were left curing for 28 days at room temperature in laboratory and then underwent the following investigations to assess their physical-mechanical features as well as their behavior to decay processes: i) mineralogical analysis through X-ray diffraction (XRD) of both binder and aggregate fractions to identify the constituent phases; ii) thin section analysis by polarized optical microscopy; iii) SEM-EDS investigations along with a semi-automated image processing procedure based on the multivariate statistical analysis of X-ray maps to highlight and quantify the hydraulicity index of the mortars as a function the binder/aggregate ratio; iv) water absorption by capillarity; v) water absorption at atmospheric pressure; vi) accelerated aging test by salt crystallization and salt mist; vii) uniaxial compressive test; and viii) perforation resistance test.

Keywords: archaeological ceramics, multi-analytical characterization.

The information provided by the study of ancient archaeological materials often allow the reconstruction of cultural and technological contexts of the artifact's production. The archaeological excavations recently carried out in the Sulci's region are bringing to light data of remarkable implications, as they provide evidence of Phoenician populations settlement in this area of the Sardinian region, at the site of Pani Loriga (Santadi), an area of strategic relevance and, thus, inhabited since the ancient times.

In the present work, we provide a multi-analytical characterization of a set of 46 samples of different use and shape from the Pani Loriga site, dated back to the end of the 6th and 5th BCE. In order to fully characterize the sherds, we performed chemical, mineralogical, and petrographic characterizations (on thin sections) using analytical techniques such as X-ray powder diffraction (applying the Rietveld full-profile fit to the diffraction patterns for phase quantification), portable X-ray fluorescence and scanning electron microscopy (SEM-EDS).

Coupling different techniques lead to have an in-depth knowledge of this class of materials and a complete picture of their trademark, for the reconstruction of the raw materials assemblages and their firing conditions, making it possible to trace-back the history of products and trades of an important civilization for the Mediterranean history.

Sand slaking in the lime mortars of Tertiveri (Foggia, 12th-15th century)

Muntoni I. M.*[1], Eramo G.[2], Ruggiero G.[2] & Clemens L.[3]

[1] Soprintendenza Archeologia, Belle Arti e Paesaggio per le province di Barletta - Andria - Trani e Foggia. [2] Dipartimento di Scienze della Terra e Geoambientali, Università di Bari "Aldo Moro". [3] Universität Trier, Germany.

Corresponding author email: italomaria.muntoni@cultura.gov.it

Keywords: Apulia, medieval mortar, aggregate.

Tertiveri, the ancient Tortiboli, was a small medieval Episcopal see that probably dates back to as early as the 10th century in the Byzantine period and reach a maximum extension of some 7 hectares. The medieval settlement was in a strategic position for the defence and control of the territory in intervisibility with the coeval settlements of Castel Fiorentino and Montecorvino, along the border between Capitanata and the Beneventan territories.

The site was given in fief to the Muslim nobleman Abd al-Aziz and his family – the clan consisted of 60 women and 40 men- by Hong Charles II in 1296, after having been temporally abandoned. In 1300, the rights over Tertiveri were again conferred on a Christian, the knight Johannes Pipinus de Barolo. The only upright leftovers of its medieval constructions are the distinctive remains of a residential tower built only quite late, i.e. around 1340. The bishopric of Tertiveri was present until 1450, but in the 15th century, was formally united with that of Lucera. In 1456 Tertiveri was destroyed by an earthquake.

Archaeological excavation from 2011 to 2023 revealed the outlines of some major building, including two churches, and its fortifications. The bigger church was the former cathedral in which a family tombs of the local elites, including the tomb of a bishop dated around 1250-1260 BC, were excavated.

In this work, the lime mortars of the excavated area are considered. Thirty samples were analyzed by POM, XRPD, SEM-EDS and XRF, in order to identify the type of lime and the technological aspects.

Petrographical and chemical evidence of the use of siliceous limestone for calcination. The presence of charcoal in the mortars suggests mobile calcination structure, where the bottom ash is more easily mixed up with the quicklime blocks. Although all the mortars were obtained by mixing feebly hydraulic lime and fluvial sand as aggregate, some compositional and microstructural differences were detected between the bedding mortars of the tower and those from the cathedral area. In the residential tower, the siliciclatic component is prevalent on the carbonate one. In particular, clasts of chert and marls show a reaction rim with the lime, formed during the pozzolanic reaction, which imparted greater mechanical strength to the mortar. The mortars from the cathedral area are less uniform with each other, show nodular structure and a more calcareous aggregate. The results obtained point to sand slaking for all the analyzed mortars, with differences related to the aggregate composition and texture and water/lime/aggregate ratios.

The mortars as a marker of the evolution over time of materials and construction techniques in the Benedictine Monastery of Catania

Occhipinti R.*, Belfiore C. M., Fugazzotto M., Barone G. & Mazzoleni P.

Keywords: cultural heritage, mortars, multylayer context.

The present contribution falls within the research activities of the PNRR project CHANGES – Spoke 6 – History, Conservation and Restoration of Cultural Heritage. The main focus of the spoke is to develop and apply integrated methodologies, strategies and approaches to support the processes of historical understanding, conservation, restoration, monitoring, sustainable and participatory planning in multi-layered contexts of cultural heritage. In this framework, the Benedictine Monastery of Catania has been selected as first case-study. The Benedictine Monastery of Catania is a late Sicilian Baroque masterpiece founded by a Cassinese congregation in 1558. Afterwards, it underwent significant transformations due to natural disastrous events, namely the 1669 lava eruption and the 1693 earthquake, which led to its partial destruction (Branciforti & La Rosa, 2007; Pafumi, 2015). The following reconstruction interventions resulted in a unique combination of different historical periods. In 2002, UNESCO included the monastery, along with other late Baroque sites in South-Eastern Sicily, to the World Heritage List. A thirty-year restoration project uncovered the town's history from the Roman period to the present day, revealing an entire Roman neighborhood (including the Cardo and Decumanus Maximus), as well as Hellenistic and imperial-era houses beneath the monastery. Some remains can be seen in the main courtyard and under the former stables, where a Roman domus with its peristyle seamlessly integrates with the 16th-century monastery structure and the contemporary "hanging" structures in the university library.

The present contribution focuses on the analysis of historical mortars covering a broad time span, from the Roman era to the late Baroque period. This research is of great importance because it allows for an examination of how the materials and manufacturing methods of mortars have changed and developed over the centuries. Furthermore, mortars play an essential role in the stability and structural integrity of historical buildings, and comprehending their behavior over time can provide valuable insights for conservation and restoration efforts. A multianalytical diagnostic approach has been used for the complete characterization of the selected materials. The chemical and mineralogical-petrographic composition of mortars has been assessed through both non-destructive in-situ investigations and conventional laboratory techniques. The manufacturing processes and construction techniques used in different periods together with the impact of technological and cultural evolution on the quality and durability of mortars have been also evaluated.

This research can be considered pioneering since no study to date had ever concerned the construction materials of a such valuable site of the Catania built heritage.

Keywords: plaster, pigment, archaeometry.

Located on the Tuscan coast near the ancient Via Aurelia, the archaeological site of Vignale was an important crossroads linking the inland areas with the maritime routes. Its strategic position gave it great economic importance and justifies the long history from the 2nd century BC to the 11th century CE. Archaeological research unearthed a prominent villa maritima overlooking the Falesia lagoon, which underwent various developments and transformations in its southern part at the beginning of the 1st century CE; moreover, in the 4th century CE, the atrium and the adjoining rooms constituted a great hall, decorated with an impressive polychrome mosaic, located in the immediate vicinity of the lagoon (Giorgi, 2016).

A total of twenty-three samples of painted plaster were collected from the different spaces using a sampling strategy based on their colours and stratigraphy, in order to study the differences in plaster materials and painting techniques during the phases of occupation.

A preliminary study was carried out on the pictorial surfaces by means of digital microscopy (DM), fiber optic reflectance spectroscopy in the visible range (FORS-VIS), portable X-ray fluorescence spectroscopy (pXRF), Fourier Transform Infrared Spectroscopy in attenuated total reflectance mode (ATR-FTIR) and μ-Raman spectroscopy (RS). Multi-layered mortar-based supports, instead, were investigated by minero-petrographic analyses performed via polarized light microscopy (PLM).

The archaeometric analysis of the pictorial surfaces reveals the extensive use of natural and synthetic pigments, i.e. yellow and red ochres, green earths, and Egyptian blue, used both in their pure form and in mixtures; different shades, in fact, were achieved by mixing pigments of different hues, as, for example, observed for vivid greens obtained by mixing Egyptian blue with green earths.

While the typology of pigments appears to be consistent, there are significant differences in the composition of the plasters among the different areas. These differences indicate different preparation techniques, possibly associated with different phases of construction. A first group of samples shows two layers: the stratigraphy is given by an internal layer composed by lime-based binder mixed to carbonate and silicate aggregate covered by a marmorino layer. Conversely, the second group shows only one thick layer composed of lime-based binder with frequent lumps, mixed to the aggregate composed of limestone fragments, quartz and chamotte; the same mix-design was also found in a group of samples preserving incannucciata imprints. Only in one sample, the support is constituted by cocciopesto, covered by a thin layer containing angular calcite grains.

Keywords: climate change, cultural heritage, reaction path modelling.

Nowadays climate change is an additional potential threat for the Cultural Heritage, as it exacerbates the expected rates of decay phenomena by affecting the structure and composition of the stone materials and leading to a greater need for preventive interventions (Sesana et al., 2021). Therefore, the application of innovative methods, able to monitoring and predicting the effects of climate change on Cultural Heritage, becomes essential. For this purpose, Reaction Path Modelling represents a high-potential geochemical tool, based on the use of software packages to study different geochemical processes, including materials weathering. A geochemical process can be represented by a series of chemical reactions describing mass transfer from reacting minerals to other phases in the system, that include the aqueous solution as well as minerals precipitated as reactions products (Helgeson et al.,1970).

This work aims to apply Reaction Path Modelling in order to study the weathering processes occurring on cultural heritage sites in two environmental conditions, coastal environments versus urban ones, both particularly exposed, albeit in different ways, to pollutants and meteorological agents. In this research, the rock-water interaction process, which is the basis of geochemical modelling will be applied to the study of the interaction of water with stone materials used in Cultural Heritage. Water, in fact, is among the most aggressive mediums of deterioration of building materials. The preliminary phase of the research involves the collection of data necessary for the geochemical modelling setup. In particular, the research will involve the following steps: a) selection of case studies of cultural interest made of stone material (pilot sites), in urban and coastal contexts; b) recovery of samples of stone material (altered and unaltered) at the pilot sites, to investigate the minero-petrographic and geochemical properties and compare the data according to the recognized alterations; c) collection and comparative study of environmental data (i.e., temperature, rainfall and rainwater composition) in the vicinity of the selected pilot sites in order to model current weathering processes and hypothesize future degradation scenarios on heritage materials; d) simulation of the weathering processes through software. Specifically, such simulation will be performed using EQ3/6 software package (Wolery et al., 2003) and the code PhreeqC Interactive (Charlton et al., 2002), adopting the kinetic mode approach; e) data comparison and future predictions on the alteration processes of stone materials. The expected results of this research should provide an understanding of the processes involved in the weathering of stones belonging to Cultural Heritage, predicting their evolution and dependence on current and future environmental factors exacerbated by the effects of climate change.

Keywords: minero-petrographic analysis, roman mortars, imperial economic investments.

This paper is part of the ongoing Economy of Roman Imperial Architecture project, which aims to assess the nature and extent of imperial investment in Rome's construction industry during the 2nd to 4th centuries CE through qualitative and quantitative evaluations of masonry and mortars from imperially sponsored, functionally and chronologically compatible buildings. The research was funded by the Rome Transformed project (ERC grant agreement No. 835271) and by Newcastle University PGRAs research funds (Haynes et al., 2023; 2024).

The masonry data capture process involved visual inspection, structural analysis, and 3D laser scanning of the structures to assess their structural function, chronology, and state of conservation. Additionally, we conducted a comprehensive evaluation of the technical, qualitative, and dimensional qualities of the masonry, including assessing the size, type and quality of bricks, the presence of pointing or surface reworking, and determining the height of modules.

Mortars were then sampled from structurally compatible and chronologically coeval walls and analysed. Information regarding the textural and mineralogical characteristics of the samples, including the identification of the main minerals constituting the aggregate, its grain size and shape, and the evaluation of the binder/aggregate ratio, was obtained through Optical Microscopy (OM) observations followed by SEM/EDS analysis, enabling data acquisition concerning the chemical composition of the samples.

Preliminary results from the analysis indicate that all types of mortars are characterized by a lime-based binder with a cryptocrystalline and micritic texture in varying proportions. The binder fraction also contains lime lumps, ranging from common to rare. The aggregate fraction mainly consists of volcanic fragments (red and black scoriae) ranging in size from mm to cm, exhibition reaction rim and secondary carbonation evidence. This volcanic component of the aggregate is consistent with ultrapotassic products of the Roman Magmatic Province, likely originating from the volcanic district of the Alban Hills (Peccerillo, 2005), providing insight into the main area of procurement of aggregate situated in the immediate proximity of the buildings.

The results we have obtained thus far have provided us with interesting preliminary insights into the composition of the mortars, as well as their likely production techniques. This information is crucial for our final assessment of the economic investment required for the procurement of raw materials, including binding materials and aggregates, necessary for the construction of the imperial buildings.

Keywords: provenance, holy sepulchre, white marbles.

Archaeological excavations have been conducted inside the Church of the Holy Sepulchre in Jerusalem by Sapienza University of Rome as part of a project to restore the floor of the religious complex (IAA license G-20-2022). In the north-western part of the Rotunda the rock level emerged after removing the current flooring and close to the base of Aedicula cleaning operations revealed the presence of lithic and marble slabs. They are placed in direct contact with the rocky bank to create thickness, as well as remains of marble cladding from an earlier phase of the same Aedicula (Stasolla, 2022). For the present study, an archaeometric investigation has been carried out on the building materials used as basement of the Aedicula by applying a multi-analytical approach using Optical Microscopy (OM), Infrared Spectroscopy (FTIR), X-ray powder diffraction (XRPD) and isotope-ratio mass spectrometry (IRMS) to reach information about the minero-petrographic composition and the provenance of the samples. The results allowed to divide the lithotypes used into four groups based on their micro and macro characteristics: white marbles, limestones, bitumen rocks and red rocks. Regarding the provenance, the lithic materials are compatible with local geology, except for the white marbles for which hypothesis have been proposed basing on the microscopic features and the isotopic results.

Stasolla F. R. (2022) - Archaeological excavations in Jerusalem, Holy Sepulchre: a preliminary report. Liber Annuus, 72, 449-486, https://doi.org/10.1484/J.LA.5.134546.

Statistical analysis of IR spectra of mortar for studying the relationship between building phases

Rea C.[1], Bastida Armesto M.[1], Calzolari L.[1], Di Fazio M.[1], Capriotti S.[1], Mignardi S.[1], Stasolla F.R.[2] & Medeghini L.*[1]

Keywords: IR spectroscopy, mortars, geomaterials.

Typical applications of diagnostic methodologies focus on the characterization of constituent materials, their origin, degradation products, and the causes that led to degradation. Among the widely applied methodologies in cultural heritage analysis, FTIR spectroscopy is one of the most applied for the characterization of artworks. However, the heterogeneous nature of geomaterials in cultural heritage usually negatively affects the interpretation of spectroscopic data. Indeed, this heterogeneity results in numerous peaks (often overlapping) and shoulders, which are challenging to resolve.

Statistical treatments of experimental results are, therefore, a useful complementary analysis to improve the interpretation and highlight analytical data relationships among different samples. In particular, multivariate statistical techniques are the most commonly applied methodologies to correlate a large number of variables, allowing the identification of groups based on spectral profile similarities and differences. The most common statistical analysis applied to define "pattern recognition" in spectra is principal component analysis (PCA).

This project (funded by PNRR PE05 – CHANGES_SPOKE-5-DST - CUP B53C22003780006 - Medeghini) aims at exploring the potential of the PCA treatments of attenuated total reflectance Fourier transform infrared spectra (FTIR-ATR) as a tool to compare and correlate different building phases in archaeological sites. In particular, FTIR-ATR spectra of mortars have been considered, being the material which are mainly related to the timing availability and building construction knowledge of skilled workers.

The proposed procedure has been applied to mortars from the archaeological site of the Holy Sepulchre in Jerusalem (IAA license G-20-2022) to correlate different building phases identified below the floor of the Holy Sepulchre. The results have been compared with data obtained by an usual multi-analytical approach using Optical Microscopy (OM), X-ray powder diffraction (XRPD) and Scanning Electron Microscopy with micro-analysis (SEM-EDS) to validate the procedure.

Advancing in underwater cultural heritage monitoring: the case of NERITES Project

Keywords: underwater technologies, cultural heritage, decay.

The EU HORIZON EUROPE NERITES project (Systematic Autonomous Remote Surveying of Underwater Cultural Heritage Monuments and Artefacts, using non-destructive, cost-effective, and transportable digital solutions) employs innovative monitoring solutions tailored for underwater cultural heritage (UCH) sites that will allow autonomous site's condition inspection. These advancements offer enhanced cost-effectiveness and precision compared to traditional methods, with a particular emphasis on addressing stone and ceramic degradation caused by biological agents and environmental pollutants prevalent in marine ecosystems, in a cost-effective manner of the overall system at design and operational (mission execution) phase.

Leveraging interdisciplinary scientific approaches, NERITES stands out for its integration of state-of-the-art technologies, offering a unique and innovative solution for in-situ monitoring of UCH assets. Its novel framework facilitates systematic autonomous (self-managed) remote assessment of the preservation status of various UCH elements, including materials, artifacts, and monuments.

The project core lies in the development of a digital infrastructure centered around an Autonomous Underwater Vehicle (AUV) piloted by elaborate deep AI for mission planning and motion control; while equipped with cutting-edge, non-destructive sensing devices and techniques. These include 1DoF LIBS for metal mapping, innovative QCL-based IR sensor system for detecting hydrocarbons and minerals, and advanced Artificial Intelligence models for detailed visual analysis. An integral component of this system is the subsea docking station, accompanied by a surface buoy. The buoy serves as a communication bridge between the autonomous underwater vehicle (AUV) and external monitoring systems. It is equipped with renewable solar collectors to meet the energy requirements of the mission. Together, these technologies promise comprehensive autonomous monitoring and assessment of UCH site conditions.

The NERITES monitoring scheme will be tested in two UCH sites, one Italian, Pozzuoli Bay, the offshore counterpart of the Campi Flegrei caldera and one Greek, Fournoi Archipelago, where 58 shipwrecks have been surveyed so far.

NERITES seeks to transform UCH preservation and degradation assessment protocols by minimizing operational costs, improving assessment accuracy, and reducing human risks. Through rigorous comparison with validated results from laboratory and in-situ tests, alongside new experiments and samplings, NERITES aims to establish a new standard for efficient and reliable UCH monitoring methodologies using high-end autonomous underwater multi-torpedo-shaped vehicles.

The technologies developed in NERITES will provide a new approach in monitoring UCH sites from an environmental and conservative point of view in order to preserve the submerged heritage and make it accessible and usable for present and future generations.

Acknowledgments: The project receives funding from the European Union through the Horizon Europe Programme, Call: HORIZON-CL2-2023-HERITAGE-01 (GA – 101132575).

SOUTH - Safeguard Of sUbmerged culTural Heritage: project presentation

Ricca M.[1], La Russa M.F.[1], Sfravara F.[2], Catania V.[3], Montana G.[1] & Randazzo L.*[3]

[1] Dipartimento di Biologia, Ecologia e Scienze della Terra, Università della Calabria, Rende (CS).

Corresponding author email: luciana.randazzo@unipa.it

Keywords: underwater cultural heritage, antifouling, machine learning.

In the present SOUTH project, a comparative study of the degradation forms that occur on different types of stone materials typically present in submerged historical/archaeological sites will be proposed. The study focuses on the experimentation of innovative formulations to protect materials from biofouling by monitoring the growth of colonization and decay processes over time. The monitoring process will be automatic and it will take advantage of the application of new methods of image acquisition, image processing and machine learning algorithms for the reduction of noise of the images captured under-water and the study of the growth of microorganism by means in situ data collection. This automated process will allow to avoid to extract the manufacts from the under-water position at interval defined of time. The main objective is understanding the main characteristics of the phenomena in a long period of time with a continuous monitoring of the stones and manufacts. Furthermore, the new protective formulations and the monitoring of biofouling on stones will be carried out both in the laboratory and in situ. The pilot activities will be implemented in southern Italy by selecting an ideal submerged site in the Mediterranean area to carry out all the experimentation. Solutions adopted, tested and validated by the SOUTH system, could be then applied to other Mediterranean historical/archaeological sites suffering the same conservative problems. For this reason, the partnership will disseminate the project results and outcomes to all relevant stakeholders and sector operators who deal with the maintenance and protection of underwater sites, at the local, regional and national level.

Inside the stone: new elements for targeted conservation of Sicilian Baroque Monuments

Rovella N.*[1-2], Cirone M.[1-2], Belfiore C.M.[3], Török Á.[4], Figoli A.[1] & La Russa M.F.[2]

Keywords: calcarenites, conservation, stone degradation.

The Sicilian Baroque Architectonic style represents an "unicum" significantly modifying the aspect of cities and towns in South-Eastern Sicily such as Catania, Noto, Ragusa, and Siracusa since XVII cent. such that UNESCO included this area in the World Heritage List since 2002. Baroque monuments owe mainly the refinement of the architectural forms and decorations and the variability of the colours to the different local calcarenites used as building materials. Despite their wide diffusion in the construction field, they are subject to different degradation processes (Belfiore et al., 2010) evolving with heterogeneous rates and forms. In this regard, Comiso, Modica and Ragusa stones have been selected and analysed because, on one hand, they are very similar macroscopically (e.g. colour), on the other hand, their responses to degradation phenomena differ visibly. These differences depend on mainly the petrographic and physical features of the materials (Anania et al., 2012; La Russa et al., 2015). Factors such as mineralogical composition, pore size, and differential mechanical properties are determining the type of degradation observed (Belfiore et al., 2021). Thus, minero-petrographic and physico-mechanical analyses will be carried out on representative samples of each stone (Belfiore et al., 2021). Specifically, the analyses consist of optical microscopy, x-ray diffraction (XRD), mercury intrusion porosimetry (MIP), salt crystallization test, determination of ultrasound speed, uniaxial compressive strength, flexural strength, and elastic modulus. Samples of Comiso Stone were directly extracted from quarries, while those of Modica and Ragusa stone come from natural outcrops. Finally, the definition of the intrinsic properties and the related criticalities of these stones will provide crucial information useful for the planning of conservation strategies adapted to the different materials and able to preserve the Baroque monuments over time.

The "Cantine di Sant'Angelo Le Fratte" geosite and the historical-cultural heritage used as a growth driver for an inland area of Basilicata

Santarsiere C.*[1], Palladino G.[2] & Bentivenga M.[1]

[1] Dipartimento di Scienze, Università della Basilicata. [2] University of Aberdeen, UK.

Corresponding author email: chiarasantarsiere@gmail.com

Keywords: cultural heritage, geosite, geodiversity.

The work addresses on the geological and geomorphological geodiversity of a portion of Sant'Angelo Le Fratte municipality area, approximately 30 km SW of Potenza.

The investigated zone falls in the axial part of the Apennine Chain, whose evolution has given rise to a differentiation of geological environments, clearly visible in the area, each of them characterized by their own geodiversity.

The greatest peculiarity is represented by cavities, utilized as cellars, which are the result of the accumulation of collapsed tens of metre-sized limestone blocks.

To characterize the geosite of the "Cantine di Sant'Angelo Le Fratte" a detailed geological and geomorphological survey and an extrapolation of the landslide map has been carried out. This allowed us to highlight the peculiarities of the site and to learn about the origins of the cellars themselves.

These are natural caves originating from the collapse of large blocks from the carbonate wall of the mesozoic formations of the Apennine Platform Unit (Upper Triassic-Jurassic). This outcrop appears as an intensely fractured sub-vertical wall, in tectonic contact with the arenaceous-clayey-marly succession of the Monte Siero Formation (Miocene), on which much of the town develops. The Monte Siero Formation area extends from the town towards the valley until it connects with the terraced alluvial deposits of the Melandro River (Holocene).

The study highlighted the numerous landslides affecting the town, in particular the landslides involving the limestone wall to the NW of the town. Landslides due to rotational sliding, flows and complex mechanism, that develop in the medium-lower part of the slopes, also occur.

The large blocks, collapsing, were arranged in such a way as to create caves which over time were used by man, first as homes and then for food conservation. The spaces between the blocks were closed in the front part by building a wall with the entrance to the cellar.

The combination of geological-geomorphological evolution and man's capacity for exploitation and adaptation allows the site of the "Cantine di Sant'Angelo Le Fratte" to be defined as a "geosite" and therefore a place to be geopreserved and enhanced, as required by the R.L. 32/2015 "Conservation and enhancement of the geological heritage" of the Basilicata Region.

The geosite must be associated with aspects of historical and cultural interest of the place to ensure that it becomes a sustainable tourism destination.

The geosite welcomes many visitors during the "Open cellars" event which is held every year in August. Attractive place, with more than 100 cellars set in the rock, over 50 full-sized and life-size statues representing the history of this ancient village, museums, multimedia itineraries and the open-air museum of around 170 murals.

In this work we want to give suggestions on how to preserve this geosite and attract more and more tourists throughout the year to make its geological and cultural heritage known.

African amphorae from Cumae: archaeometric study for provenance and technological features

Scanu M.*[1], Capaldi C.[2], Ciotola A.[2], D'Uva F.[1], Morra V.[1], Verde M.[4] & De Bonis A.[1-3]

[3] CRACS, Center for Research on Archaeometry and Conservation Science, Napoli. [4] Dipartimento di Architettura, Università di Napoli "Federico II".

Corresponding author email: michela.scanu@unina.it

Keywords: mineralogical, petrographic roman, amphorae cumae.

The aim of this research is to define the technological characteristics and the provenance of African amphorae found in Cumae (Southern Italy), an ancient settlement known for the presence of some of the most powerful families of the rising Roman aristocracy.

Representative fragments of African amphorae, covering a chronological arc from the 1st century CE to the 6th century CE, were selected among all of the archaeological types found in Cumae in order to better represent the variety of amphoric products.

This research fits into the body of the much wider context of the ancient trade definition between the Campania's coasts and North African areas involved in the production of amphoras, which include Zeugitania and Byzacena in the south-central Tunisia, Tripolitania between southern Tunisia and western Libya, and Mauretania Caesarensis located between Marocco and Algeria.

After a first morpho-typological study of the materials, archaeometric analyses were performed via mineralogical-petrographic analytical techniques.

Polarised light microscopy (PLM) allowed the samples to be divided into two petrographic groups, which show affinities with the geological features of the lithologies of the supposed production areas and with archaeological materials used for comparison.

X-ray powder diffraction (XRPD) reported quartz as the predominant mineralogical phase followed by calcite, feldspar, and sporadic mica, along with calcium silicates formed during firing.

Highly relevant information for estimating the temperatures to which the amphorae were exposed during firing is provided by the mineral phases detected via XRPD and by microstructural features observed on fresh fractured samples at the scanning electron microscope (SEM) to investigate the vitrification degree.

Chemical analysis via X-ray fluorescence spectrometry (XRF) revealed a high concentration of CaO (> 6%) in the majority of the samples. Again, through comparison with other chemical elements, the samples turned out to be divided into two groups, which show affinities with the petrographic ones.

The initial paleontologic study of the microfossils observed in thin section promises an interesting output. The identification of the microfossils that were still recognisable in the ceramic paste upon the firing process provided a more accurate recognition of the raw materials exploited for making the amphorae.

Combining literature data on local geology with compositional data of archaeological materials (kiln rejects, locally found ceramic finds belonging to the same ceramic class, mainly from the Tunisian coast) used as a comparison, it was possible to associate each group of samples to a specific atelier of production.

Mineralogical and technological characterization of pozzolan mortars from the Brick Amphitheater in Nola (NA)

Spadavecchia S.*[1], Cappelletti P.[2-3-4], Rispoli C.[2-3], Montesano G.[2] & Cesarano M.[5]

Corresponding author email: serena.spadavecchia@uniroma1.it

Keywords: roman mortars, hydraulic mortars, cocciopesto.

The 'Brick' Amphitheater is an archaeological site located in Nola (NA), at Masseria d'Angerio, dating back to the 1st century BC. Part of this structure was excavated during essays conducted in 1992 by the Superintendency, revealing an elliptical plan, dimensions of 138 m on the major axis and 108 m on the minor axis, with a total capacity of about 20,000 spectators. Since the extended use and the several architectural interventions over time, the archaeological area is of particular interest. The present preliminary study is aimed at: i) characterize the different types of the used mortars (Miriello et al., 2015); ii) investigate the origin of the raw materials used for mortars production (Columbu et al., 2022); iii) identify similarities and/or differences between the various samples analyzed, in order to make hypotheses about the different construction stages (Lezzerini et al., 2018). Furthermore, this study will try to evaluate, with the help of historical sources, whether and how much the analyzed samples might be related to different socio-economic situations. Eighteen mortar samples, 12 taken from different areas of the amphitheater and 6 from ancient walls, were investigated (Rispoli et al., 2021). An initial macroscopic observation was conducted, followed by a more detailed thin-section examination through Polarized Optical Microscopy (POM), which enlightened the type and distribution of elements constituting the mortar and the background matrix. X-Ray Powder Diffraction (XRPD) technique was used for qualitative mineralogical characterization. The obtained results allowed to assess that the raw materials used for mortars production were locally sourced, as they were compatible with the geological features of the Vesuvian Area. In particular, preliminary results confirmed the occurrence of lime-based mortar, in which the binder shows a prevailing cryptocrystalline texture and subordinately micritic, with a volcanic aggregate fraction around 40-50% mainly composed by pumice, leucite slag, amphibole, biotite and garnet. The analyzed mortars, especially those related to the amphitheater structure, are hydraulic, as they show reaction rims at the volcanic aggregate-binder interface. Comparison between different mortar samples shows three different groups, which differ in the production technology and are presumably attributable to three different construction phases of the archaeological site. The first group (samples A1-A9) stands out for the accuracy of preparation and choice of aggregates, the second group (samples A11-A13) and the third group (M2-M6) have a higher binder fraction and more lime lumps at with respect to the aggregate fraction. Moreover, the aggregate fraction of groups 2 and 3 appear to be coarser in the samples taken from the walls. These preliminary data represent a good starting point for further investigation in order to develop a suitable pozzolan mortar for future conservative interventions of the monument, and for the re-using of waste geomaterials in a view of a more sustainable restoration.

Air pollution related deterioration of limestone heritage: an overview

Torok A.*

Department of Engineering Geology and Geotechnics, Budapest University of Technology and Economics, Hungary.

Corresponding author email: torok.akos@emk.bme.hu

Keywords: air pollution, limestone, deterioration.

Air pollution-related stone deterioration has been investigated since the beginning of the 20th century (Grün, 1931), and it has been noticed that the most sensitive lithologies are carbonates. Limestone, mainly porous limestone, shows various forms of deterioration. The main stone decay processes are gypsum formation and carbonate dissolution. The process differs from the region and is influenced by local climatic factors, exposure, pollution level and the substrate's lithology, micro-fabric and mineralogical composition. The presentation gives an overview of the deterioration process of carbonates using examples of heritage structures located in different parts of Europe. The studied buildings are exposed to industrial, urban, and rural pollution fluxes representing limestone monuments of seven countries (Belgium, Czech Republic, France, Germany, Hungary, Italy, and Poland). Weathering crusts and host rocks were sampled, and environmental conditions and pollution fluxes were documented. Mineralogical analyses (XRD, polarizing microscopy, SEM) and elemental composition (XRF, LA-ICP-MS), as well as organic compounds (GC-MS), were detected. The concentration of compounds was compared, and correlations were found between water-soluble calcium and gypsum content and between sulphate and gypsum content of weathering crusts and the limestone substrate. PAH and Pb content of selected samples was also measured. A trend was identified regarding the Pb and PAH content of samples collected from different environmental settings. The study suggests that despite decreasing trends in SOx levels and the use of unleaded petrol, large amounts of air pollution-related elements (Pb), minerals, and organic pollutants are still found on the facade of buildings and in the black weathering crusts of European limestone heritage structures.

Finishes in architectural elements: "Domus Pasolini" of Faenza

Valdrè G.*[1], Grillini G.C.[2-3], Moro D.[1] & Ulian G.[1]

[1] Dipartimento di Scienze Biologiche, Geologiche e Ambientali, Università di Bologna. [2] Dipartimento di Architettura, Università di Ferrara. [3] Accademia di Belle Arti, Bologna.

Corresponding author email: giovanni.valdre@unibo.it

Keywords: cultural heritage, architectural finishes, analytical characterization techniques.

This work presents a case study of analytical micro-characterization applied to architectural finishes. In the historic centre of Faenza (Italy), at Palazzo Pasolini, between 1994 and '95 the Superintendence for Archaeological Heritage of Emilia Romagna brought to light a rich Domus of the Augustan age. The Domus was inhabited for a very long period, at least until the end of the 4th century CE (Grillini, 1998; Guarnieri et al., 1998). The finds of the architectural decoration of the Domus Pasolini ("stucco" plasters and "marmorino" plasters) have today been taken up again for in-depth analytical micro-characterization studies, with a new analytical approach, within the Department of Biological, Geological and Environmental Sciences (BiGeA) of the University of Bologna (Valdrè & Grillini, 2021). Polarized optical microscopy, X-ray Diffraction, Scanning Electron Microscopy, specific ultrasound sample treatment to separate binder from aggregate, and granulometric analysis, have been employed for the characterization of the materials.

The analytical results of the multi-layered plasters have highlighted a particular construction technology, especially as regards the surface finishing layer, used to imitate noble materials such as "marble". They are aerial lime plasters, as a binder, while the aggregate used for the finishing layer is not the classic "marble dust", but heterogranular spathic calcite with a tabular and rhombohedral appearance. The spathic calcite comes from the crushing of macrocrystalline calcite veins present in the carbonate geological formations of the Alberese area in the Bolognese Apennines (Monte Canda, Piancaldoli, etc.) and in the Forlì and Rimini Apennines (San Marino, San Leo, etc.). The choice of this particular technology, in architectural elements in ancient times, by Hellenistic, Phoenician-Punic to Roman workers to cover poor, porous and not pleasing-to-the-eye materials, leads back to two properties: high toughness of the plasters and reflective power of the surface ("mirror effect"), due to the crushing and orientation of the spathic calcite following surface smoothing and polishing, obtained with particular tools or, perhaps, even with hot iron (Grillini et al., 2004).

Keywords: pigments, non-invasive methods, multi-analytical approach.

The House of Arianna represents, with its 1700 square meters of floor space, one of the most majestic examples of a residence within the Pompeii archaeological site.

The domus also known as the House of Colored Capitals due to the decorations that have been found, included about 70 different units on the ground floor alone, organized around three distribution areas: the atrium, the central peristyle, and the North peristyle.

The research developed within Cultural Heritage Active Innovation for Sustainable Society CHANGES - Spoke 6 - History, Conservation and Restoration of Cultural Heritage, reports the first outcomes of the archaeometric study of polychrome wall paintings which decorate the room number 6 of the House of Arianna. This room was chosen for the richness and variety of the palette used.

To achieve this goal, non-invasive on-site techniques were employed, including digital microscopy (DM), colorimetry, Raman spectroscopy, X-ray fluorescence (pXRF), Fourier Transform Infrared Spectroscopy (FT-IR). In addition, laboratory-based IR method (Attenuated Total Reflection mode) was performed on micro-samples to reach our characterization scope. This approach was applied to wall paintings, allowing the composition of the pigments used to decorate the rooms to be defined, revealing the use of a characteristic Roman palette (Germinario et al., 2018).

The results show that different colors were obtained by using pure, natural, and synthetic pigments including calcite, red and yellow ochre, red lead, cinnabar, green earth, Egyptian blue, and carbon black. These pigments were also combined to obtain specific shades, such as a mixture of green earth and Egyptian blue for green shades, addition of Egyptian blue to red pigments brightened with calcite for pink, a mixture of red ochre and red lead for red and brownish tones. Lastly, signals of incipient alteration have been highlighted by spectroscopic analyses Raman and FT-IR.

Germinario C. et al. (2018) - Multi-analytical and non-invasive characterization of the polychromy of wall paintings at the Domus of Octavius Quartio in Pompeii. Eur. Phys. J. Plus, 133, 1-12.

Geosciences on display: the role of Natural History Museums in the future of our planet

CONVENERS & CHAIRPERSONS

Rosarosa Manca (Università di Firenze)

Maura Fugazzotto (Università di Catania)

Luca Bellucci (Università di Firenze)

Daniela Mauro (Università di Pisa)

What is the role of Natural History Museums in the future of our planet?

Barbagli F.*

Presidente Associazione Nazionale Musei Scientifici, Sistema Museale di Ateneo dell'Università di Firenze.

Corresponding author email: fausto.barbagli@unifi.it

Keywords: natural history museums, collections, society.

In recent decades, the role of museums has been extensively examined, prompted by debates on the concepts and societal value of cultural heritage. The strengthening of the social and educational use of heritage has also fueled discussions on its income-generating potential and the development of related economic strategies.

Traditionally considered as places for the preservation of material evidence, museums have increasingly developed into venues for cultural initiatives and educational activities, becoming hubs for diverse audiences that engage with them in continuous historical, political, and moral relations. Alongside their educational and cultural enrichment functions, museums have also embraced roles in entertainment and amusement, activities found in other institutions but distinguished in our case by the presence of collections.

On the front of collections, museums are tending to evolve the sense of ownership towards the value of accessibility, through sharing policies on digital platforms that facilitate the circulation of images and data related to artifacts. This facilitates connections and linkages between objects, disciplines, stories, places, and people, emphasizing the material evidence that holds extraordinary value in terms of shared knowledge.

Nevertheless, it is advisable not to overlook that Natural history museums, within the aforementioned changes, preserve collections of extraordinary importance and vast dimensions that have been the basis of scientific research for centuries. In recent decades, they have acquired a fundamental role, thanks to their increasingly close ties with contemporary society, which they can influence the future through education about nature and its conservation.

This intervention aims to reflect on how natural history museums can contribute to the understanding and conservation of the planet and the sustainable management of its resources.

The SIMP Commission on Museums: a network for sharing and promoting museum activities

Barone G.[1-2], Carbone C.[1-3], Fugazzotto M.[1-2], Mauro D.[1-4], Merlini M.[1-5], Nazzareni S.*[1-6] & Pratesi G.[1-7]

Keywords: mineralogical and lithological museums, collection preservation and conservation, dissemination.

The Italian Society of Mineralogy and Petrology (SIMP) established the "Commissione Musei" (SIMP-MuseiCom) in 2019 with the aim of networking the mineralogical component of the Italian Natural History Museums and Universities and other public mineralogical collections. SIMP-MuseiCom aims to be a place for discussions and promotion of joint initiatives for the valorisation of the public mineralogical and lithological collections. Up to now, the SIMP-MuseiCom network has about 40 members. SIMP-MuseiCom's activities started with on-line meetings to present the situation of the public mineralogical collections from the network members and discuss problems and opportunities.

SIMP-MuseiCom is also acting to improve the accessibility, fruition and promotion of the mineralogical and lithological collections preserved in Italian museums through traditional and innovative means. Some examples are multi-sensory experimental geological laboratory @Museo dei Saperi e delle Mirabilia Siciliane, (UniCatania), production of a comics volume ("The Colors Issue" - Comics&Science) for the Exhibition "Il mondo a colori: uno sguardo su Arte, Pigmenti e Minerali" @MANU (Pg), photo exhibitions with guided tours for educational workshop @Andora(Ge), preparation of multimedial and 3D photogrammetric models of minerals @Milano. As part of the celebration for the International Year of Mineralogy, 2022, a national event "Gli zolfi italiani" was organised by SIMP-MuseiCom. The events took place in June 2022 with exhibitions, guided visits and videos by 15 Museums around Italy.

Among its many activities, SIMP-MuseiCom also promotes the accreditation of individual university museums to the National System of University Museums, with the aim of creating a structured network to manage collections according to common criteria. A focus on the catalogue activity following the ICCD (Istituto Centrale per il Catalogo e la Documentazione, Ministero della Cultura) catalographic standards is ongoing, and an online short course on the ICCD national standard for the cataloging of the geo-mineralogical heritage has been done.

In the future, new activities regarding curatorial aspects (e.g., collection preservation and conservation, digitalization and cataloguing, as well as dissemination activities) will be organised. Moreover, a second event involving Italian museum will be planned. Upcoming activities will be publicised by the SIMP mailing list and if someone working in the mineralogical collections is interesting to be part of the network, please send an email to simpmusei@gmail.com.

Development and valorization of the historical and modern mineral collections of the Department of Earth, Environment and Life Sciences (DISTAV), University of Genova

Belmonte D.* & Carbone C.

Dipartimento di Scienze della Terra, dell'Ambiente e della Vita, Università di Genova.

Corresponding author email: donato.belmonte@unige.it

Keywords: ligurian minerals, type locality, museum.

Liguria displays an outstanding mineral diversity despite its limited area (less than 5500 km^2), since currently 35 mineral species have their type locality (TL) in this region. Two thirds of them have been found in the renowned manganese deposits of Val Graveglia and Cerchiara mine, often representing unique findings. Such a valuable heritage has been preserved in the historical and modern mineral collections of the Department of Earth, Environment and Life Sciences (DISTAV) of the University of Genoa, whose first nucleus dates back to the beginning of the XIX century thanks to the effort of the naturalist Domenico Viviani (1772-1840). The historical collections then increased significantly during the XX century mostly due to the monumental work of Arturo Issel (1842-1922), who became the Director of the Museum of Mineralogy and Geology of the University of Genoa and fostered a dense network of scientific and didactical interactions. After that, a number of eminent mineralogists, such as Gabriele Lincio (1874-1938) and Alberto Pelloux (1868-1948), continued the development of the mineral collections by enhancing its quality and diversity. The modern part of the DISTAV mineral collections was built during the 1960s and 1970s by virtue of the fruitful collaboration between the academic community and keen-eyed amateur mineralogists, like Paolo Onofrio Tiragallo (1905-1987), to whom was dedicated a new mineral species found in the Mn ores of Val Graveglia (tiragalloite, IMA1979-061). The recent acquisition of important local mineral collections generously donated by both private citizens and eminent scholars, like Angelo Stagnaro (1940-2018) and prof. Andrea Palenzona (b. 1935), further increased the scientific value of the collections due to the rarity and quality of some specimens. The historical and modern collections of the University of Genova academic museums will get a renovation and full digitalization in the framework of the project "Università degli Studi di Genova per la Cultura Scientifica (Unige-CS) – ricognizione sistematica, digitalizzazione e diffusione dei Beni Culturali dell'Ateneo genovese", Bando Diffusione della Cultura Scientifica (Cod. ACPR20_00227), funded by the Ministero dell'Università e della Ricerca (MUR).

An "enlightened" museum of Nature, Art and Science. Rediscovering Specola 250 years after its foundation

Benvenuti M.*[1], Barbagli F.[2], Fabrizi L.[2], Manca R.[1] & Moggi Cecchi V.[2]

[1] Dipartimento Scienze della Terra, Università di Firenze. [2] Sistema Museale di Ateneo, Università di Firenze.

Corresponding author email: m.benvenuti@unifi.it

Keywords: La Specola museum, 250 years, new museological project.

On February 21, 1775, Grand Duke Peter Leopold of Lorraine inaugurated, in the ancient Bini-Torrigiani palace in Via Romana in Florence, the Imperial and Royal Museum of Physics and Natural History, probably the first scientific-naturalistic museum open to the public.

The Grand Duke of Lorraine did not limit himself to welcoming the heritage of art, science and culture collected by the Medici over three centuries. As a convinced Enlightenment thinker, he immediately understood the importance that these collections, especially those of a scientific nature, could have for the education of his people, It was an unprecedented operation: his museum was literally the "Museum of Nature" because, as its first director Felice Fontana wrote, nature was represented in it as a whole, "from earth to sky", with the establishment of the first Florentine astronomical observatory, (i.e., the Specola), on the top of the Palace. The purpose was "to enlighten his people and make them happy by making them more cultured", and in fact the museum was open to everyone "as long as they were cleanly dressed". Thus, at the end of the eighteenth century, a museum was born for the cultural growth of the people, thus anticipating by almost 250 years the Faro Convention of the Council of Europe on the value of cultural heritage for society and the contemporary concept of "museum" as an institution at the service of society, open to the public, accessible and inclusive.

After more than four years of structural work and refurbishment, the Specola Museum reopened its doors to the public on February 22, 2024. After almost a century and a half away, the mineralogical collections return to the Specola with a new exhibition itinerary that develops in four large monumental rooms. The museological project and the museographic arrangement of the collections intended to ideally reconnect with the conceptual framework of Peter Leopold's museum. A special section of the exhibition is dedicated to illustrating some of the infinite applications of minerals for the satisfaction of the needs of our society, with particular emphasis on the indispensable need for ethically and socially sustainable exploitation.

The specimens exhibited here are only a very modest fraction (about 1200) of the more than 50,000 specimens that the Museum preserves, a priceless heritage that the Florentine mineralogical tradition has been able to put together and preserve for over five centuries.

On the preservation and the availability of holotype minerals

Bosi F.[1], Lapaire J.[2], Meisser N.[3], Pasero M.*[4] & Rumsey M.[5]

[1] Dipartimento di Scienze della Terra, Sapienza Università di Roma. [2] CTMS Editor, La Chaux-de-Fonds, Switzerland. [3] Naturéum, Department of Geology, University of Lausanne, Switzerland. Keywords: holotypes, IMA-CM, IMA-CNMNC.

Since its foundation in 1958, the International Mineralogical Association (IMA) takes care about the preservation of holotype minerals, namely the sample on which the first description of a given species has been carried out. Among the guidelines for the approval of new mineral species set up by the IMA Commission on New Minerals, Nomenclature and Classification (CNMNC), it is explicitly stated that the holotype must be deposited in a public institution, typically a museum, with a catalogue number assigned, and made forever available upon request for possible later re-examination.

This is a relevant piece of information concerning new mineral species: for this reason the name and address of the public institution, as well as the catalogue number, are mentioned in the CNMNC Newsletters, which are the first public testimony of all new minerals approved each month.

The good practice of conservation in public collections of mineralogical samples which were the subject of analytical studies by far precedes the birth of IMA. Nowadays mineralogical museums are plenty of historical samples, dating back to the 19th Century and even older.

The IMA Commission on Museums (CM) maintains the Catalogue of Type Mineral Specimens (CTMS). More precisely, this is a joint effort by the CNMNC, which manages the official IMA List of Minerals, and the CM, through a dedicated Subcommittee. For recent minerals the designation of type material is straight, as it occurs at the time of the approval. For those mineral species which have been known since before the IMA era, the so-called grandfathered minerals, the recognition of the holotype material is made by searching literature data and based upon time priority. In some rare cases, holotype material may be no longer available, therefore a neotype may be defined. Neotypes should be sampled whenever possible at the same locality of the original material.

Statistics on the designed type material for all valid species and on the museums in which they are preserved will be provided.

For the years 2023 and 2024, updating the CTMS, which is largely carried out on a voluntary basis, will receive partial funding from the Swiss Academy of Sciences as part of the SwissCollNet project SCN201-VD, a national initiative for digitisation of natural history collections. The CTMS is available online: www.ctms-jack.ch

Interactive exhibits, gamification and digital storytelling in Scientific Museums: the case of MUGEPA in Rotonda

Bruno F.*[1-2], Mollo F.[3], Di Cuia P.[2], Cozza M.[2], Sardella R., Iurino D.A., Strani F., Franzese F. & Bellucci L.[4]

Keywords: storytelling, virtual reality, serious games.

Through digital transformation, museums can evolve from traditional repositories of artefacts to dynamic environments where individuals can actively engage and enhance their knowledge through discovery and self-challenge. In this regard, leveraging digital technologies and storytelling serves as an effective means to communicate ideas and beliefs, allowing visitors to immerse themselves in history and science through narratives that facilitate the creation of meaningful memories (Barbieri et al., 2017). Furthermore, digital technologies can help to enhance museum accessibility, embracing a wider audience.

With this goal in mind, the Geo-Paleontological and Archaeological Museum (MUGEPA) in Rotonda has undergone a complete revamp in its educational, cultural, and scientific offerings. This entailed a redesign of the exhibition display in terms of architectural layout and scientific content, as well as the implementation of several multimedia installations involving computer graphics, virtual reality (VR), digital storytelling, and serious games. The overarching aim was to seamlessly merge physical and digital content into a unique exhibition that guides visitors through the scientific, geological, paleontological, and archaeological richness of the Mercure's valley. The paleoenvironment is a perfect example, as it has been created from scientific content using the photobashing technique. It was then printed on a physical support and installed near to the remains of the animals.

The multimedia exhibits have been designed and developed using a multidisciplinary approach, combining scientific, creative, and artistic visions into interactive and educational experiences.

One of the most challenging tasks was to design and implement interactive experiences that catered to the needs of younger audiences, both in terms of content and languages used. In particular, two different multimedia applications were developed. The first is a VR experience wherein participants are immersed in a futuristic lab, tasked with solving a 3D puzzle to reconstruct the skeletons of the straight-tusked elephant (*Palaeoloxodon antiquus*), the Hundsheim rhinoceros (*Stephanorhinus hundsheimensis*), and the hippopotamus (*Hippopotamus antiquus*) (Palombo et al., 2024). The second application consists of a collection of 3 mini-games (namely a visual quiz, a puzzle game, and a simulation of a paleontological excavation) that can be accessed via tablets at the end of the museum visit.

Moreover, interactive experiences were designed and developed for the general audience, including a VR application that provides visitors with a virtual walkthrough of the Middle Pleistocene landscape of the valley, completed with reconstructed and animated 3D animals. Additionally, a touch-screen table offers users access to 3D models of animal remains, additional content, and insights. Lastly, a mobile application will assist all users during their visit by providing a multimedia audio guide.

Enhancing the accessibility of the Herbaria of the University of Florence by reducing mercury contamination due to historical conservation treatments

Ciani F.[1], Manca R.*[1-2], Lastrucci L.[3], Costagliola P.[1], Benvenuti M.[1-2-4] & Rimondi V.[1-2]

[1] Dipartimento di Scienze della Terra, Università di Firenze. [2] National Biodiversity Future Center NBFC, Palermo. [3] Museo di Storia Naturale, Sistema Museale di Ateneo, Università di Firenze. [4] Istituto Geoscienze e Georisorse, CNR, Firenze.

Corresponding author email: rosarosa.manca@unifi.it

Keywords: natural history museums, mercury pollution, biodiversity.

The Herbaria of Natural History Museums preserve exsiccated plant specimens gathered from different parts of the world over the centuries and act as a source of invaluable importance for biodiversity studies. However, access to these repositories of dried plants is partially hindered by the past use of the corrosive sublimate, a highly toxic solution of mercury dichloride (HgCl2HgCl_2) employed worldwide as a pesticide to preserve the collections. The reduction of the Hg2+Hg^{2+}of HgCl2HgCl_2 to Hg0Hg^0 has led to the contamination of the herbaria halls (e.g. Briggs et al., 1983). In the Herbarium of the University of Florence (Italy), both gaseous elemental mercury (GEM) and particulate Hg are present in the halls and in the historical wooden cabinets where the plant samples are stored (Ciani et al., 2024). The present project aims to reduce the Hg contamination at the Herbaria of the University of Florence, which are among the largest and most ancient worldwide, to favour the fruition of the collections for both research and dissemination purposes. In this framework, a purpose-made steady-state flux chamber was set up and connected with a Lumex RA-915M analyzer to determine the GEM degassing rate from both a herbarium sample (dry plant + paper support sheet) and a wooden support. GEM fluxes (ng m-2h-1ng m^{-2}h^{-1}) were calculated following Floreani et al. (2023) and measurements were repeated at different relative humidity (RH) conditions to check the influence of this parameter on GEM emissions. RH was varied by inserting water-filled containers (wet conditions) or silica gel (dry conditions) in the flux chamber and monitored with a datalogger in continuum during the experiment. GEM fluxes at the RH typically detected in the herbarium (c. 60% RH) showed average values of 18±4 n gh-2h-1ng h^{-2} h^{-1} for the herbarium sample and of 17±1 n gh-2h-1ng h^{-2} h^{-1}for the wooden tablet. The RH increase (to c. 80% RH), led to a strong increase in the GEM fluxes (to c. 100 ng h-2h-1ng h^{-2} h^{-1} for the wood support and c. 1000 ng h-2h-1ng h^{-2} h^{-1} for the herbarium sample). On the contrary, drying the sample (to c. 30-40% RH) the GEM emissions dropped significantly down (herbarium sample: 8±2 ng h-2h-1ng h^{-2} h^{-1}; wood support: 1±0.3 ng h-2h-1ng h^{-2} h^{-1}). The present work confirmed that both herbarium samples and museum wooden cabinets are currently releasing GEM in the museum halls and allowed us to quantify the contribution of both sources. Moreover, a prominent role of relative humidity in the release of GEM was highlighted by these tests. These results suggest that both a decontamination treatment of the cabinets and the optimization of the indoor climatic conditions can help in minimizing the Hg pollution of the University of Florence Herbaria and, thus, favouring the fruition of their remarkable collections.

Keywords: historical museum, digitization, virtual reality.

The Geological Collection "Giovanni Capellini Museum" officially opened to the public in 1881 during the Second International Geological Congress hosted in Bologna, and at the time was the major geological museum in Italy. The geological and paleontological specimens currently on exhibition have been collected since the XVI century and represent one of the oldest and richest geological collections in Europe. Wood cabinets date back to the mid XIX century and are still on display today, making the collection fascinating, but very difficult to read for a modern audience.

In 2023, the Collection was identified as a case study for the PNRR Spoke 4 "Virtual technologies for museums and art collections". Among other targets, the project aims to investigate how a digitalized cultural heritage can improve the comprehension and narrative of museums. Although outcomes are expected by mid-2025, here we want to share our ideas on how technology can aid a geological museum narrative and how virtual reality, augmented reality, gamification, 3D models and video storytelling can expand the current space-time perception of geology among general audience and people with disabilities. Our main goal is to expand the knowledge and narratives by recreating objects and even localities that no longer exist, fostering citizens participation and social inclusion and bringing inside the museum people that usually do not attend such institution, with a particular focus on teenagers and young adults, an audience familiar with technology, but not so interested in museums.

The Arab-Norman itinerary stones: where geological history meets the local artistic heritage

D'Arpa C.*[1], Di Patti C.[1], Surdi G. [2] & Incarbona A.[2]

[1] Museo Geologico "G.G. Gemmellaro", Università di Palermo.
[2] Dipartimento di Scienze della Terra e del Mare, Università di Palermo.

Corresponding author email: carolina.darpa@unipa.it

Keywords: scientific collection, exhibition, education.

The role of scientific museums in disseminating Earth Sciences is a basic requirement for enhancing public awareness on natural conservation and protection. Especially natural history museums educate visitors by showing the wonders of ancient organisms, ecosystems and environments. The link between the geological history of an area and its urban monumental and artistic heritage is largely overlooked, though it should be well within its educational mission. The Geological G.G. Gemmellaro Museum has recently acquired the "Sicilian Marbles" and the "Sicilian Petrographic Collection". These are historical rock collections, the second one coming from G.G. Gemmellaro's research, aimed at the production of the first Sicily Geological Map. The "marbles" are exhibited following their own compositional and chromatic differences, with the blatant indication to their use in the Arab-Norman itinerary architecture (two palaces, three churches, a cathedral and a bridge in Palermo and the Cathedral Churches of Cefalú and Monreale), which is UNESCO World Heritage. The monumental and artistic heritage of a territory mirrors the geological history itself, through the use of materials they are built with. Architecture, geology and history are merged, as starting point for a multidisciplinary approach to citizen science, scholastic and touristic activities, especially for high schools (PCTO).

A dual approach to enhance the Targioni Tozzetti collection, a little-known mineralogical heritage: digital and analytical methods

Fabrizi L.*[1-2], Moggi Cecchi V.[1], Barbagli F.[1] & Benvenuti M.[1-2-3]

[1] Museo di Storia Naturale, Sistema Museale dell'Università di Firenze. [2] Dipartimento di Scienze della Terra, Università di Firenze. [3] Istituto Geoscienze e Georisorse, CNR, Firenze.

Corresponding author email: lucilla.fabrizi@unifi.it

Keywords: museum collection, mineralogical analysis, digitalization.

After approximately 20 years since the project that digitized 4500 documents and estimated 2687 surviving specimens (Cipriani & Scarpellini, 2007), the litho-mineralogical collection of Giovanni Targioni Tozzetti (1712-1798) has once again become the subject of study.

The collection is not solely composed of what we would consider minerals today, but it illustrates lithic materials in various manifestations. The collection follows the Linnaean logic that distinguishes nature among Animal, Vegetable and Mineral (Lapideum) Kingdom, placing itself in the latter. Giovanni not only gathers minerals and rocks, which constitute the most abundant specimens, but also shells and fossils. Furthermore, embodying the spirit of the experimental scientist in service of the nation, he collects samples during his territorial research aimed at discovering raw materials useful for the technological development of the Grand Duchy of Tuscany and provides information on origins, suppliers, and uses of different materials. The samples are document of the exploitation of ore deposits, lithic samples for construction, along with objects that testify the use of different materials (e.g., an armed magnet, made of magnetite), etc. Moreover, although the concept of a collection as a gathering for wonder and aesthetic contemplation had been surpassed, the separation between scientific and artistic value was not yet fully accomplished, hence there are also valuable artifacts such as worked stones or a lithic head of Etruscan manufacture.

To preserve, enhance, and transmit to future generations the values and the data contained in this 18th century document of scientific and technological relevance, a dual approach has been taken.

Firstly, 287 artifacts were inventoried (~11% of the total), among which 154 were catalogued following ICCD criteria. Consequently, 109 BNM (Beni Naturalistici-Mineralogia), 39 BNPE (Beni Naturalistici–Petrologia), 1 BNZ (Beni Naturalistici–Zoologia), and 5 PST (Patrimonio scientifico e tecnologico) cards were produced, accompanied by high-resolution images. The project is part of the Tuscany Region's program which has led to the creation of an online portal dedicated to the digital fruition of Tuscan heritage.

Simultaneously, an analytical campaign aimed at the correct mineralogical attribution of various specimens and a survey of their places of origin is underway. Specifically, 67 gems, both rough and cut, were analysed with optical microscope and μ-Raman to identify their mineral species (Fabrizi et al., 2023). In addition, 8 massive samples containing metallic minerals catalogued as "Stannum" and 11 as "Plumbum" underwent to optical microscope and SEM-EDS analysis for identifying the paragenesis and compare it with the deposits of origin.

Some noteworthy pieces have been identified during these studies and exhibited for the first time in the new exhibition dedicated to mineralogy, at the "La Specola" museum of the University of Florence Museum System.

Stories for the future. The cataloging of the Italian geo-mineralogical heritage

Franza A.* & Pratesi G.

Dipartimento di Scienze della Terra, Università di Firenze.

Corresponding author email: annarita.franza@unifi.it

Keywords: cataloging, museum collection, astromaterial curation.

The Italian geo-mineralogical heritage, a treasure trove of our national geological history and geoscientific cultural knowledge, is primarily housed in natural history museums. The preservation, study, and valorization of this unique resource, which stands as irreplaceable evidence of our past, is a shared responsibility of scientists and museologists. It is imperative that they unite under common standards and practices to ensure its preservation and accessibility for scholars and the general public for the years to come.

This research is designed to present the current state of Italian geo-mineralogical heritage cataloging according to the ministerial catalographic standards issued by the Istituto Centrale per il Catalogo e la Documentazione (ICCD). The data for this study are sourced from the Catalogo Generale dei Beni Culturali website (Veninata, 2020), a database managed by the Ministry of Culture that provides open access to cataloging records on the entire Italian cultural heritage. The analysis focuses on mineralogical and petrographic specimens cataloged according to the BN-M and BN-PE national standards (Pratesi & Franza, 2021), as well as meteorite collections cataloged using the BN-PL standard (Franza et al., 2022). This review will demonstrate the active involvement of natural history museums in the national cataloging system and the implications for advancing museum studies and scientific knowledge. Specifically, it will delve into the role of cataloging meteorite specimens according to the BN-PL national standard in the advanced curation of astromaterials, an interdisciplinary and cutting-edge field of research to improve curation practices (e.g., sample handling, cataloging, characterization, distribution, and valorization) in the existing collections and for future sample return activities (e.g., McCubbin et al., 2019).

In conclusion, this work will highlight how cataloging the Italian geo-mineralogical heritage according to the ICCD national standards represents an effective strategy for correctly preserving and valorizing the Italian geo-mineralogical heritage kept in natural history museums from a scientific, juridical, and managerial perspective. These cataloging procedures also enable diverse audiences to improve their awareness and understanding of the Italian geo-mineralogical heritage along with past, present, and future challenges and opportunities for geoscience research.

Taxonomic diversity of fossil vertebrates from the quaternary deposits of the Karst Pit of Cà Negra (Croatia)

Furlan A.*[1], Contessi M.[2] & Fanti F.[3]

[1] Dipartimento di Scienze Biologiche, Geologiche e Ambientali, Università di Bologna. [2] Collezione di Geologia "Museo Giovanni Capellini", Università di Bologna. [3] Dipartimento di Scienze Biologiche, Geologiche e Ambientali, Università di Bologna.

Corresponding author email: alessia.furlan.1998@gmail.com

Keywords: Cà Negra, paleofauna, paleoenvironment.

In 1932, quarrying operations in an chalk quarry named Cà Negra (in the Gulf of Piran, Croazia), revealed a karst sinkhole containing countless fossil specimens of macro- and micromammals. About 20,000 fossil specimens were collected and initially classified by Franco Anelli, a speleologist who was working on Italian Cave Registry. His studies were interrupted in 1939 due to the outbreak of World War II. Carefully packed in newspapers, the specimens were sent to Bologna, where they remained unstudied to these days. Along with these specimens, also their packaging made of newspaper sheets and the correspondence of letters between Professor Michele Gortani and Franco Anelli provided a significant amount of historical information that enriched the museum's collection. As the site is no longer accessible due to massive quarrying activities, data housed in Bologna represent a pivotal tool to infer palaeobiological data from this unique Quaternary site.

The Cà Negra sinkhole was 15 meters deep, an horizontal stratification revealing five distinct levels based on filling type could be distinguished, two of which bearing the majority of fossil remains. In addition to typical carnivores, large herbivores, and micromammals, non-mammalian microvertebrates such as amphibians (Bufonidae), reptiles (Lacertidae), fish (Esocidae), and birds (Corvidae) have also been identified. A comparison of the fauna identified at Cà Negra with other karst fossil deposits in the Istrian peninsula has revealed some fundamental differences, thus adding an unusual dimension to the site biodiversity. These differences consist in the absence of proboscideans, the presence of non-mammalian microvertebrates and the presence of the gastropod Pomatias elegans, a good palaeoenvironment indicator.

Furthermore, of particular interest is the discovery of human remains, along with signs of manipulation such as cutmarks and fractured or burnt bones. These fossil specimens suggest direct involvement of Homo in the Quaternary ecosystem, opening new perspectives on his relationship with local fauna and evolutionary dynamics of the period.

The cataloguing of the scientific instruments of the University of Catania: research and prospects

Keywords: cataloguing, university museums, scientific heritage.

Long mistreated, the scientific and technological heritage in Italy has obtained the recognition of 'cultural heritage' only since 1999 with the Testo Unico on the legislative provisions on cultural and environmental heritage and then, officially, with the Code of Cultural Heritage and Landscape since 2004 (Canadelli, 2019). Thanks to its qualities, this heritage is transversal and allows multiple stories to be told, not only the one of the individual artefact, but also that of the collection that hosts it, of the scientists who used it and more generally of the evolution of science. In order to adequately protect and enhance scientific heritage, it is necessary to start from a solid knowledge of it; therefore, it was necessary to adapt the regulations on cataloguing for it too, through a specific standard sheet drawn up by the Central Institute for Catalogue and Documentation (Vannozzi, 2014; Ferrante, 2018).

Aware of the importance of cataloguing as the first and fundamental step for a correct enhancement of the heritage, in recent years the University Museum System of the University of Catania has launched an impressive cataloguing campaign of the movable heritage kept in its various locations. Among these, within the PhD research project entitled "Cataloguing and enhancement of scientific instruments of historical interest of the University of Catania", financed by Sicilian region, more than 520 scientific instruments were registered, of which 93 pertaining to the Collection of minero-petrographic, geophysical, and geochemical measuring instruments (scientific responsible: professor Rosolino Cirrincione) present within the Museum of Mineralogy, Petrography and Volcanology, 309 to the Collection of ancient physics instruments (scientific responsible: professor Elena Geraci), 34 to the Museo dei Saperi e delle Mirabilia siciliane (scientific responsible: professor Germana Barone), 18 to the Museo della Fabbrica (scientific responsible: professor Federica Santagati), 26 to the science centre Città della Scienza (scientific responsible: professor Alessia Tricomi) and 40 to the Museo di Anatomia (scientific responsible: professor Velia D'Agata). This intervention therefore aims to illustrate the work carried out during the compilation of these technical data sheets, highlighting the methodology used, the conservation issues and the results obtained. Starting from this work, a reflection will also be conducted on how this activity can help improve the use of the instruments, seen both in their nature as museum items and as tools especially in relation to the geological and mineralogical samples present therein.

The Angelo Da Costa mineral collection: a new acquisition of the Natural History Museum of the University of Pisa

Mauro D.*[1-2], Biagioni C.[1] & Bonaccorsi E.[1-2]

[1] Dipartimento di Scienze della Terra, Università di Pisa. [2] Museo di Storia Naturale, Università di Pisa.

Corresponding author email: daniela.mauro@unipi.it

Keywords: Angelo Da Costa collection, mineral acquisition, mineralogical museum.

The mineralogical collections of the Natural History Museum of the University of Pisa consist of more than 25,000 specimens. Among them, mineral specimens from Tuscany are well represented, owing to the long-lasting interest of mineralogists of the Pisa University in sampling and studying mineral occurrences from this region. Over the last thirty years, the improvement of the Tuscan collection has continued thanks to the acquisition of specimens belonging to some renowned collections (e.g., Cerpelli Collection, 1999; Del Taglia Collection, 2015). Recently, a suite of mineral specimens belonging to the Angelo Da Costa collection were acquired (Mauro et al., 2023).

Angelo Da Costa (1940–2022) was one of the most important Tuscan mineral collectors. He was a curious explorer and an excellent mineral digger. He began to collect minerals in 1973. During his 50 years of collecting activity in several Tuscan localities (i.e., Apuan Alps, Monte Pisano, Campigliese, etc.), he discovered some new mineralogical localities and found outstanding specimens of minerals. A peculiar feature of the Angelo Da Costa mineral collection, composed by more than 600 samples, was that most of his specimens were self-collected (Lorenzoni & Dini, 2023). The Natural History Museum of the University of Pisa acquired a selection of 33 specimens. Among them, some aesthetic samples of quartz from some classic Tuscan localities, i.e., Apuan Alps, Monte Pisano, Campiglia Marittima, Val Castrucci, and Gavorrano. It is worth noting that, among them, there is also the sample of smoky quartz with baryte from the Pollone mine (Apuan Alps) exposed during the XVI General Meeting of the International Mineralogical Association which took place in Pisa in September 1994. Other interesting samples were representative of his findings of hematite crystals from Gorfigliano (Apuan Alps) and of goethite after iron carbonates from the Monte Pisano, as well as other classic findings, such as arsenopyrite, allanite-(Ce), and fluorite from the Botro ai Marmi area (Campiglia Marittima) and aurichalcite from the Buche al Ferro, still in the Campigliese region. This suite of the Da Costa specimens is a further addition to the mineral collection of the Natural History Museum, but it also honours the memory of Angelo Da Costa and his passion for mineralogy, hoping that his life and his specimens may be a source of inspiration for the future generation of geoscientists.

The mineralogical collections at the Earth's Science Department, University of Milano: history, conservation, digitization, and valorization

Merlini M.* & Mangano C.

Dipartimento di Scienze della Terra "A. Desio", Università di Milano.

Corresponding author email: marco.merlini@unimi.it

Keywords: minerals, collection, history.

The Museo delle collezioni mineralogiche, gemmologiche, petrografiche e giacimentologiche at the University of Milano has a rich history dating back to 1939 when Professor Emanuele Grill acquired the prestigious collection of Ing. Eugenio Bazzi. Over the years, under the direction of Professor Giuseppe Schiavinato, the collections expanded significantly through donations, acquisitions, and contributions from the Institute's personnel. Noteworthy additions include the Sala dei Minerali delle Alpi, dedicated to Ing. Magistretti, and a collection of mineral deposits curated by Professor Dino di Colbertaldo.

Currently, the museum houses over 30,000 specimens, including minerals, gemstones, and rocks, displayed across showcases and corridors. Notable exhibitions include the prestigious demantoide samples from Luigi Magistretti collections, as well as notable hystorical specimens from Baveno and other alpine localities. The museum also preserves historical analytical instruments, archival material, and educational resources.

Ongoing efforts focus on updating and digitizing the inventory, alongside the creation of multimedia materials. Conservation activities involve assessing the overall condition of specimens, with some undergoing restoration processes to enhance their display quality. The collections serve educational, scientific, and public engagement purposes, including teacher training and outreach activities with primary and secondary schools. Recognized as a Museal Collection by the University in 2004, the museum plays a vital role in preserving and disseminating scientific and cultural heritage.

Museums for the development of inclusive education practices: a case study in the Earth Sciences Museum - University of Bari Aldo Moro

Keywords: museum, accessibility, inclusion.

The social role that museums play in the global community constitutes a distinctive element of contemporaneity, assuming the relevant role of intermediary between culture, well-being and inclusion. The need therefore emerges for heritage mediation paths in a multi-dimensional key (physical, but also social, cognitive, sensorial-perceptive, emotional etc.) to encourage participation and awareness of its value by all citizens, through the widest accessibility to its contents. Accessibility to cultural heritage has long been a topic of great interest for the Università degli Studi di Bari (UniBa), implemented in particular thanks to SIMA (Sistema Museale di Ateneo). This following the indications of the Convention for rights for Persons with Disability (ONU, 2006, art. 30) which recognizes their right to participate to cultural life, by enjoying access to places for cultural performances or services, such as the museums.This research work starts from the synergy created between different professional figures within the scope of the UniBa transversal skills course "NO ONE EXCLUDED: from university classrooms to inclusive cultural and museum fruition" held at Earth Science and Geo-environmental Dep. and at the Earth Sciences Museum at the beginning of the current year. A new collaboration between some geologist and naturalist researchers and experts in scientific museology already engaged for years on this front with psychologists and pedagogists has been started in order to propose a holistic approach to museum fruition of indoors and outdoors itineraries. The educational activities through frontal teaching and laboratory group works were aimed at: i) provide an overview of the main SLD (Specific Learning Disorders) and forms of disability; ii) deal with the topic of inclusion with an operational approach; iii) enhance the adaptive capabilities of people with SLD/disabilities by enhancing their individual resources; iiii) raise awareness among all participants of a broader concept of "active citizenship". The laboratory activities carried out at the UniBa Earth Sciences Museum, allowed the participants to benefit from inclusive museum itineraries, such as "Museums in the Dark" in the Geological-Paleontological Section (through the use of 3D technologies for the prototyping of fossil samples made fully accessible to video impaired people; Francescangeli & Monno, 2010; 2011; Montenegro, 2024) and "Aural Structures" in the Mineralogical-Petrographic Section (through two sonification cabins in which it will be possible to "listen" to the symmetries of the crystals; Monno et al., 2024).The active involvement of young people and adults with sensory disabilities (blindness and hearing loss) and autism spectrum disorders coupled with the attention to their specific needs allowed participants to gain real experience of good practices for accessibility and inclusion.

From the past to the future: the new exhibition of the Mineralogical collection of the Florence University Natural History Museum and its relocation to the "La Specola"

Moggi Cecchi V.*[1], Fabrizi L.[1], Barbagli F.[1] & Benvenuti M.[2]

[1] Museo di Storia Naturale "La Specola", Sistema Museale dell'Università di Firenze.
[2] Sistema Museale dell'Università di Firenze.

Corresponding author email: vanni.moggicecchi@unifi.it

Keywords: mineralogy, Medici collection, "La Specola" museum.

The Mineralogy and Lithology Collection of the Florence University Natural History Museum represents, in terms of origin, quantity and quality of the specimens owned, one the most important mineralogical collections in Italy. (Pratesi, 2012). It is enough to remember how the "Imperiale e Regio Museo di Fisica e Storia Naturale di Firenze", inaugurated in 1775 and from which the present Museum originates was the first naturalistic museum open to the public in Europe. In the museum, a central role was assigned to the mineralogical collections which reflected not only the scientific interests of the Grand Duke itself, but also the ever-increasing importance assigned to the study of minerals (Cipriani, 2011). Its relocation within the La Specola Museum represented therefore a considerable challenge from a museologic and museographic point of view, that was overcome through an approach respectful of the characteristics of the other parts of the Specola complex (Moggi Cecchi et al., 2022). The exhibition itinerary starts with a fascinating environment in which the visitor is totally projected into a "spatial" context in which specimens of meteorites are exhibited, to remember the origins of the Earth. It continues with showcases dedicated to the development of our planet - observed from a geological point of view - during its 4.5 billion years of life. A connecting room illustrates some old instruments and the scientific figures that have characterizing the history of mineralogy at the "La Specola" museum. In the next room the fundamental concepts of the general mineralogy are presented, starting from the evolution and differentiation of terrestrial rocks and going on with the concepts of crystal growth, habit, polymorphism and isomorphism, the basic principles of crystallography and the physical properties of minerals. The systematic collection is also exhibited in the same room. Another connecting room displays the exceptional tourmaline specimens from Minas Gerais, Brasil, belonging to the former Ponis Collection and the unique pink morganite crystals, flagships of this collection. In this room are also exhibited the huge beryl and topaz specimens, well known as amazing masterpieces of the Museum. The path continues with the exhibition of the carved stones belonging to the Medici Collection and of the precious stones, with a showroom that presents many references to the historicity of the samples on display. The next room is dedicated to the exhibition of the mineralogical regional collections, first of all the worldwide famous Elban collection, with its extraordinary polychromatic tourmaline specimens and the huge ilvaite aggregate of crystals, considered one of the largest in the world. A corner of this room is dedicated to fluorescent minerals glowing in the dark. The final part of the itinerary is dedicated to the exploitation of mineral resources and the consequences of this human activity from a social and environmental point of view.

Corresponding author email: marcello.tropeano@uniba.it

Keywords: late Cenomanian Aigialosaur, Apulia platform limestones, Earth Science Museum of Bari university.

Remains of an upper Cenomanian reptile were found during 1995 on a limestone slab collected in the "Ruvo di Puglia" quarry district (Murge, SE Italy), and stored in the Earth Science Museum of Bari University (Italy). These remains correspond to the anterior half of a partially articulated skeleton of a squamate, and represent one of the few Mesozoic reptiles coming from the Apulia Carbonate Platform, part of the tethyan periadriatic domain. A multidisciplinary research, based on paleontological, stratigraphic, geochemical, and 3D methods, was performed on these remains. Geochemical components of bones, such as apatite, phosphate, and organic material residues, recognized through the use of UV contrast light, micro Raman spectrometry, and XPS laser ablation mass spectrometry, indicate that bone material is excellently preserved. Stratigraphy, microfacies analysis, and taphonomy suggest that the reptile body was non promptly buried when it was in a warm and protected shallow-marine environment. This datum agrees with data coming from several bones features, ascribable to a marine reptile living in a shallow sea. The 3D reconstruction highlighted the presence of both bones and natural casts profiles, and led us to obtain a virtual fossil. This helped to attribute the studied squamate remains to Aigialosauridae on the basis of : i) the cranium base structure, ii) the cervical and ventral vertebras shape, iii) the humerus and rib morphologies, and iv) the total body size.

The mineralogical and petrographic collections of the Regional Museum of Natural Sciences in Turin, Italy: a dazzling journey through the wonders of nature

Senesi M.* & Fino M.

Museo Regionale di Scienze Naturali di Torino.

Corresponding author email: massimiliano.senesi@regione.piemonte.it

Keywords: historical, wonders, explorations.

The MRSN reopened to the public on January 12, 2024 after over a decade of closure due to an accident in the summer of 2013. Three halls in the newly designed layout: - the Historical Museum of Zoology, where naturalised specimens from historical collections of the the University of Turin are displayed; - the Ark of Explorations, an ideal route through past and present naturalistic journeys; - the Hall of Wonders, a careful selection of specimens and samples held in the museum's collections. The MRSN was established in 1978. Pursuant to a specific agreement, the museum acquired the zoological, mineralogical, petrographic and palaeontological collections of the University of Turin, being committed with preserving, studying and enhancing them. To mark the reopening to the public, the Department of Mineralogy and Petrography contributed to the setting up of the Hall of Wonders and the Ark of Exploration by selecting unique samples of aesthetic, scientific and historical value. The historical core of the collections comes from the Museum of Mineralogy and Petrography and the Museum of Geology and Palaeontology of the University of Turin. From 1980 to the present day, the Museum has developed its own collection to complement the university ones (which had not been enriched since the first half of the 20th century). More than 20000 aesthetically appealing minerals and rocks from the latest mineralogical discoveries worldwide have been acquired. The Hall of Wonders was set up by selecting samples with high visual impact, and emphasising the size, colour and morphology of the crystals. The history of the collections is recalled by the display of samples from the Traversella mines and the mineralogical sites of the Val d'Ala. The Ark of Explorations houses specimens and samples from scientific explorations carried out from the first half of the 1800s to the early 1900s. The 1836 exploration of Egypt of the engineer Carlo Boreani, who had been sent out in search of precious metals by the Italian Royal Household. General La Marmora's journeys to Sardinia. He donated three copies of its own collection of rocks to the Turin, Cagliari and Paris Museums. The Ruwenzori expedition carried out by the Duke of the Abruzzi in 1906. The 1899-1900 'Polar Star' expedition to the North Pole made it possible for the crew to reach a record latitude and for the Museum to acquire another 300 mineral and rock samples of outstanding scientific and historical value. The study of these samples made it possible to trace the geological structure of the remote regions reached by the expedition. An old granulite bears testimony to an orogenesis that occurred in those areas around 1.3 billion years ago.

A multi-sensory experimental laboratory for Earth Sciences at the Museum of Sicilian Knowledge and Mirabilia of the University of Catania

Spironello M.Y.*[1], Majorana S.[1], Barone G.[2] & Fugazzotto M.[2]

[1] Dipartimento di Scienze Umanistiche, Università di Catania.
[2] Dipartimento di Scienze Biologiche, Geologiche e Ambientali, Università di Catania.

Corresponding author email: marilisa.spironello@phd.unict.it

Keywords: university museums, accessibility, Earth sciences.

The University of Catania, through the Sistema Museale d'Ateneo (SiMuA), is significantly committed to promoting initiatives that - by combining audience development and audience engagement strategies - favour not only an enhancement of its rich heritage, but also a greater involvement of different audiences in its cultural offer (Barone et al., 2023). The multisensory workshop to discover geology and mineralogy recounted in this abstract had a dual purpose: on the one hand, to bring young students in Catania closer to STEM subjects, towards which there is a growing disaffection, through an experimental approach (Scippo et al., 2020); on the other, to sensitise them to the theme of inclusivity by placing them on the side of less fortunate visitors, blind or visually impaired, who are used to enjoying collections through all the senses (Bollo et al., 2017; Da Milano & Gariboldi, 2019). Sicily, after all, is a geological laboratory in continuous evolution and with which the territory is in constant dialogue: the Museum of Sicilian Knowledge and Mirabilia's repertoire of samples is very extensive and consists mainly of minerals from Sicilian solfares, systematic mineralogy, Sicilian rocks, volcanology, with samples from Etna, the Aeolian Islands and the Vesuvian area, rocks used in construction and precious rocks, gems and ambers, all samples coming from the Museum of Mineralogy, Petrography and Volcanology at the same university. This vast repertoire also made it possible to explain historical events, settlements, economies, offering the possibility of a direct and highly educational experience. For the participants (students aged 9-11) this represented a new environment, never seen before, but also for those who had already experienced it, the museum was perceived as a place of growth and discovery. A stimulating process was therefore set in motion that involved obscuring the sense of sight and at the same time stimulating the sense of touch, thanks to the possibility of touching the specimens on display, as well as the sense of smell and taste for some specimens with specific peculiarities, following a common narrative line, born from the union of all the stories created by the working groups, specifically homologated from a lexical, syntactic and content point of view. These stimuli were then taken up, discussed, evaluated and used at school and included in an elaboration work that allowed knowledge and skills to be refined in order to connect them to other contexts and uses.

Mèmora: a showcase for the cultural heritage of Piemonte Region

Storta E.*[1], Senesi M. [2] & Borghi A.[1]

[1] Dipartimento di Scienze della Terra, Università di Torino. [2] Museo Regionale di Scienze Naturali, Torino.

Corresponding author email: elena.storta@unito.it

Keywords: ornamental stones, Piemonte region, digital archive.

The Regional Museum of Natural Sciences of Turin (NW Italy) has created, since the end of the 20th century, a collection of stone materials of particular importance; the collection is represented by a petrotheque of natural materials, both raw and in slabs with various processes (polished, smoothed, bush-hammered, split, chiselled), coming from all over the world, but with the prevailing objective of representing the materials in the best possible way, of Italian or foreign origin, marketed on the national trade. This nucleus is also accompanied by a series of specimens of "extinct" rocks, materials whose quarries have been closed or have long been abandoned. The objective of the collection is to be able to provide specialized users (architects, engineers, researchers, historians, quarrymen and other operators in the sector) with a consultation, study and research tool for current lithotypes and, at the same time, to have a comparison for rocks no longer commercialized, but often still present in architectural works. Based on a collaboration developed over twenty years, the entire collection is available for consultation by the Department of Earth Sciences (DST) of the University of Turin for the mineralogical and petrographic study of stone materials. Recently, some historical stone materials from the Piemonte region have been selected and studied by the DST for an in-depth petrographic characterization and for their enhancement in the field of cultural heritage. The results of these studies are progressively included in the Mèmora catalogue. Mèmora is the tool used by the Piemonte Region for cataloging the cultural heritage, including naturalistic heritage. Mèmora consists of two components, Memora Back End which allows operators to catalogue and describe the heritage, and Memora Front End for the publication, consultation, fruition and use of data on the web. It describes the objects being catalogued in an integrated way using national descriptive standards (ICCD). Textual content can be accompanied by images, digital documents, audio and video and offers the possibility of geolocating and viewing resources on maps. The data can be exported in the most popular formats (XML, Excel, PDF etc.) guaranteeing high interoperability. The Mineralogy, Petrography and Geology section completed the data migration into the new application and began using it during 2021, also cataloguing the samples selected for the research project with the Department of Earth Sciences. Through Mèmora, by means of thematic insights, cultural heritage can also be read by a wide audience and not just specialists.

"Fauglia... un mare di anni fa": a new palaeontological exhibition and an example of valorization of the palaeontological heritage in the Fauglia Municipality (Pisa Province, Italy)

The Lower Pleistocene sediments exposed at Montalto, near Fauglia (Pisa Province), have yielded a remarkable fossil assemblage, including an exquisitely preserved seagrass (*Posidonia oceanica*) meadow and an extensive coral (*Cladocora caespitosa*) bank, which on the whole provides valuable insights into the paleoenvironmental conditions and palaeodiversity of the Mediterranean Sea during the Calabrian age. The high diversity of the fossil assemblage (which includes pinnipeds, sharks, rays, bivalves, gastropods, barnacles, echinoids, corals, foraminifera and ostracods) and the many different fossilization styles observed at Montalto (which witnesses to a complex and peculiar diagenetic history) makes this locality much remarkable as well as worthy of conservation and valorization (Bosio et al., 2021). What is relevant here is that the main palaeontological outcrops at Montalto occur within a large quarried area that is not subject to any special protection measures, which means that the locality is bound to undergo progressive destruction due to quarrying activity. With the aim to showcase and give a platform to this threatened palaeontological heritage, a new palaeontological exhibition – "Fauglia... un mare di anni fa" – was established thanks to the collaboration between professional paleontologists of the University of Pisa, avocational paleontologists of the Gruppo AVIS Mineralogia e Paleontologia Scandicci (GAMPS) and the local Municipality. The long-term goal of this exhibition is to establish a site museum to provide a permanent home for many valuable fossils. By curating and exhibiting a good deal of representative specimens from the various different facies and taphofacies observed at Montalto, we hope to raise awareness on the natural heritage of the Fauglia area as well as on the urgent need for sustainable practices to safeguard these and other remarkable localities.

Earth Science Collections, housed within European institutions, represent invaluable data repositories encompassing the Earth's formation, physical attributes, geosphere, atmosphere, and the evolution of all life. These collections offer profound insights into past extinction events and climate fluctuations that are key for comparing and predicting forthcoming environmental challenges as well as for deciphering their underlying causes. They are also essential to the development of sustainable resources. However, many of these resources remain untapped by researchers across diverse disciplines grappling with present-day sustainability, climate change, and biodiversity loss. The Earth Science Group (ESG) within the Consortium of European Taxonomic Facilities (CETAF) aims to promote the significance of these collections in enhancing our comprehension and prediction of the present environmental and biodiversity crisis. This talk showcases a selection of examples from CETAF member institutions where Earth Science Collections have played a pivotal role in advancing our understanding of hazards, resource management, climate shifts, and biodiversity decline. Moreover, it addresses the challenges inherent in integrating these collections into modern scientific frameworks and facilitating interdisciplinary collaboration. Efforts to enhance the accessibility and interoperability of Earth Science Collection data are underway through initiatives such as the Geoscience Collections Access Service (GeoCASe) portal, developed to promote universal online access to mineral, rock (including borehole cores), meteorite, and fossil specimens. Programmes such as DiSSCo will increase the level of specimen digitisation (MIDS level) and collaborative endeavors with organizations like the Biodiversity Information Standards (TDWG) aim to refine metadata standards for digitization and publication, fostering harmonized understanding and facilitating scientific research and collaboration on a global scale. Through these endeavors, Earth Science Collections emerge as reservoirs of invaluable data and as catalysts for multidisciplinary scientific advancement and international cooperation.

Falsification techniques and materials in Geoheritage

Veronese M.* & Artioli G.

Keywords: geological forgeries, μ-Raman, UV luminescence macro photography.

Natural geological samples have always exerted a deep fascination on human mind. The symmetry and optical properties of minerals and gemstones quickly attracted the attention of humans, inducing Homo Sapiens to transform these into amulets as well as pigments in wall paintings.

Hence, natural specimens should be considered as part of humankind cultural heritage because of their intrinsic aesthetic value as well as their contribution to expand hominids technical skills as well as their abstract thinking.

Such a geoheritage maieutic role needs to be strengthened nowadays, especially in light of the rapid environmental change we are experiencing now. In this context, one of the most important goals that the scientific community must fulfil is in promoting society's increased awareness of and comprehension of natural processes (Artioli, 2022).

Geological forgeries identification play a crucial role in educating people because they might incorrect information upon geological processes. Indeed, manufactured minerals are created as a way to be aesthetically attractive although they frequently haven't any geological consistency as for natural forming minerals remounted on incompatible matrices and crystals dyed with the aid of unnatural dyestuff (Calik et al., 2019).

For such a reason, we'll discuss some case studies involving dyed samples and original specimens that have been remounted on matrix from both contemporary and historical collections. We propose to combine the macroscopic investigation with microscopic and spectroscopic methods in order to positively identify counterfeiting and materials involved in the forgery. First of all, digital photos are taken exciting specimens at UV frequencies, in order to highlight potential inhomogeneity in the chemical composition. Subsequently, an exhaustive characterization by means of μ-Raman vibrational spectroscopy is conducted to thoroughly identify incompatible phases (Bernardino, 2016).

μ-Raman are favoured over alternative analytical methods because to its non-invasiveness, high specificity and versatility that allows to clearly detect both organic and inorganic, amorphous and crystalline compounds.

This macro-micro incorporated method allows us to undoubtedly discover the compounds utilized in counterfeiting the analysed samples. Moreover, it may be implemented domestically in Natural History Museums because of transportability capabilities and in situ appearing of those techniques, training people in faking minerals detection and in familiarizing with scientific methods.

The MuSTe (Museo di Scienze della Terra) of the University of Bari Aldo Moro houses a rich paleontological heritage which tells the history of our territory over geological time and testifies to the changes in biodiversity in relation to climate changes and natural processes . To enhance the exhibitions and involve a wider public in the natural history of the region, the University of Bari Aldo Moro, in collaboration with CETMA (European Research Center for Design Technologies and Materials), has carried out a project supported by the Apulia Region (POC Puglia FESR ESF 2014-2020-action 10.4), based on the use of digital technologies. In particular, the project was aimed at the digitization of two of the most important Pleistocene vertebrate fossils from Apulia housed at MuSTe: an almost complete fossil skeleton of Balaenoptera sp. and a Coelodonta antiquitatis partial skull. The two specimens were digitalized through photogrammetry and laser scanner, the missing parts of the skeletons were digitally reconstructed and then a scientifically accurate life-reconstruction was created through 3D graphic softwares. The models thus obtained were animated and inserted into digital dioramas, which include palaeoenvironmental reconstructions. Final digital diorams are aimed to be played or projected in a permanent exhibition. The present project represents the first step towards a progressive digitalization of the museum collections and updating of the MuSTe exhibitions which will hopefully be able to integrate other specimens from the museum collections in the future.

Keywords: micro-Raman spectroscopy, X-ray microscopy, corrosion.

Raman spectroscopy is a non-destructive technique which can provide a unique fingerprint of the corrosion products embedded within the patina of archaeological artifacts, leveraging molecular vibrational modes analysis. Its sensitivity and capability for discriminating between corrosion products make it a valuable tool, particularly due to its ability to delve into structural characterization at the microscale and produce qualitative phase distribution maps.

In this research, we employed micro-Raman spectroscopy in combination with correlative imaging techniques and imaging tomography to investigate corrosion phenomena in nails from the Phoenician-Punic site of Motya (Sicily, Italy). To accomplish this, we used correlative light and electron microscopy, micro-Raman spectroscopy, and X-ray microscopy. This approach involves the integration of complementary investigation techniques to perform multiscale and multimodal experiments, all focused on the same area of interest.

The aim of this study is to investigate the stratification of corrosion layers and the mechanism of transformation of Fe products formed under specific conditions that occurred in lagoon-like environment. Recognizing the spatial distribution and interconnectivity of mineral phases and cracks within corrosion layers was crucial for comprehending the corrosion process's evolution. The results showed remarkable differences in the condition of the nails and provided 3D imaging of the internal structures, revealing cracks and the original shape of the nails.

Archaeological mortars under IR light: application of IR spectroscopic techniques for the study of hydraulic Roman mortars

Calzolari L.*[1], Fernandez-Martinez A.[2], Capriotti S.[1], Di Fazio M.[1] & Mignardi S.[1]

Keywords: IR spectroscopy, ancient hydraulic mortars, geomaterials in cultural heritage.

The aim of this work is to apply different IR-based spectroscopic techniques for the study of mortars (Jordan et al., 2018), to evaluate pros and cons of each analytical procedure and the possibility to obtain an effective grouping of samples. The object of the study are ancient Roman mortars coming from hydric structures (mainly aqueducts and cisterns), which have been analyzed with thermogravimetric analysis (TGA) to assess their hydraulic nature. Thanks to the use of a multi-analytical approach which comprises optical microscopy (OM) scanning electron microscopy with microanalysis (SEM-EDS) and X-ray powder diffraction (XRPD), the characteristics of the aggregate (predominantly pozzolanic) and the binder have been inferred (Botticelli et al., 2021; Calzolari et al, 2023a; Calzolari et al., 2023b). Fourier-transform infrared spectroscopy (a) in attenuated total reflectance (ATR) and reflectance mode have been applied to evaluate the possibility of grouping mortars samples by PCA, checking the results by the comparison with the characterization obtained with OM, SEM-EDS, XRPD and TGA.

An Archaeometric Investigation to analyze some medieval rings from Cencelle (Tarquinia, VT)

Capriotti S.*[1], Di Fazio M.[1], Miele F.[2], Mattia V.[2] & Annoscia G.M.[2]

[1] Dipartimento di Scienze della Terra, Sapienza Università di Roma.
[2] Dipartimento di Scienze dell'Antichità, Sapienza Università di Roma.

Keywords: spectroscopy, gems, archaeometry.

The city of Leopoli-Cencelle, founded by Pope Leo IV in 854 A.D., is located in the Tolfa Mountains in the territory of Tarquinia (Viterbo, Italy). Between the 12th and 13th centuries the city underwent a radical restructuring with an overall redesign of the "forma urbis" according to the dictates of the time. Cencelle represents a unique opportunity for the archaeological study of a medieval urban centre since, having its development stopped at that time without any other reuse during centuries, it can be investigated in its entirety (Stasolla et al., 2011; Somma, 2014).

The present research focuses on the analysis of 3 gem-set rings, which can be dated between the 13th and 15th centuries, and a cameo, dating from the Etruscan period with a subsequent reuse during the Middle Age. All these samples have been recovered from funerary contexts. Rings found as part of grave goods often serve as significant indicators of social status and personal identity. Indeed, items buried with the deceased frequently reflected their status and/or their role in society (Marshall, 1907; Pollio, 2018). In particular, the inclusion of precious materials, elaborate designs, or engraved symbols on the rings provides useful insights that offer important information about the social position of their owners. The aim of this study was to determinate the nature of the gems through a non-invasive and non-destructive multi-analytical approach that involved the use of Fourier Transform Infrared Spectroscopy (FTIR), Raman Spectroscopy and Scanning Electron Microscopy with Energy Dispersive Spectroscopy (SEM-EDS). The results of the archaeometric investigations have made it possible both to delineate some traits of their production processes, which is still poorly understood, and to obtain useful information to understand the social and gender differences that may have existed among the inhabitants of Cencelle.

The Deposition by Raffaello: a rediscovery of old cross-sections through vibrational spectroscopies

Ciccola A.*[1], Ioele M.[2] & Postorino P.[3]

[1] Dipartimento di Biologia Ambientale, Sapienza Università di Roma. [2] Istituto Centrale per il Restauro, Roma.
[3] Dipartimento di Fisica, Sapienza Università di Roma.

Corresponding author email: alessandro.ciccola@uniroma1.it

Keywords: Raffaello Sanzio, Raman, FTIR.

The Deposition, dated 1507 and located at the Borghese Gallery of Roma, represents one of the masterpieces by Raffaello Sanzio. This painting was subjected to a remarkable series of non-invasive diagnostic campaigns over the years (Miliani et al., 2007; Alberti et al., 2023), exploiting X-Ray Fluorescence, both in standard and mapping modes, UV-Visible Light Reflectance and mid-InfraRed Reflectance spectroscopies . The analytical results provided by these techniques allowed characterizing the palette of the Urbino Master in a totally non-invasive way, but some uncertainties about the compositions of the pigments remained unsolved. In 2020, the year celebrating the 500th anniversary of Raffaello Sanzio death, the altarpiece has been subjected to conservative revision and preventive conservation project: on this occasion, an in-depth study was conducted on cross sections prepared between 1966 and 1972, during an older restoration intervention conducted by the Istituto Centrale per il Restauro (ICR) (Ferrara et al., 1972). The ethical and sustainable choice of investigating stratigraphic sections from the 1960s was adopted because these represent a powerful documenting evidence of the original pictorial film and restoration repaintings before intervention of 1966-1972, in order to both reconstruct the conservation history of the painting and to achieve new information on the materials composition.

For the characterization of materials, with reference to the complexity of species hypothesized on the base of previous non-invasive analyses, a combination of vibrational techniques was applied, taking into account of the versatility and the informative power of these analytical methods for the identification of chemical species belonging to different classes. Fourier-Transformed InfraRed and Raman spectroscopies were exploited in different setups and methodologies, in order to provide a complete characterization of inorganic, organic and "hybrid" pigments. The presence of very fine-grained particles in the film and the low concentration of some species represented a challenge to respond through the coupling with microscopies and with the support of Scanning Electron Microscope with Energy Dispersive X-Ray analysis. The adopted multi-technical diagnostic approach has made it possible to recognize the pigments employed in the different pictorial layers, including those in traces and those based on organic materials, responding to open questions from previous investigations and deepening further aspects of Raffaello's palette and painting technique.

Raman spectroscopy reveals pigments on ancient Sicilian inscriptions

Coccato A.*[1], Barone G.[2], Mazzoleni P.[2] & Prag J.[1]

[1] Faculty of Classics, University of Oxford, United Kingdom.
[2] Dipartimento di Scienze Biologiche, Geologiche e Ambientali, Università di Catania.

Corresponding author email: alessia.coccato@classics.ox.ac.uk

Keywords: Raman spectroscopy, pigments, ancient epigraphy.

Within the interdisciplinary project "Crossreads: Text, materiality, and multiculturalism at the crossroads of the ancient Mediterranean" (https://crossreads.web.ox.ac.uk/), a full work package is dedicated to materials of ancient Sicilian inscriptions, alongside palaeography and linguistics, for the study of the epigraphic culture of the island (c. 5000 inscriptions). Within the project, detailed knowledge of the pigments used in epigraphy complements the ongoing characterization of the stone supports (including marble provenance), which will provide the first systematic account of the material aspects of epigraphic culture. Pioneering results are being obtained on polychromy through a multi-analytical approach, where Raman spectroscopy plays a dominant role.

The poor preservation of so-called rubrication is due to both the action of environmental factors and to human intervention, as inscriptions have been thoroughly cleaned to increase their readability and subjected to squeezing (i.e. applying pressure to damp paper applied to the surface to obtain a 3D reproduction of the text). This means that often the only traces of pigments are in the deepest part of the grooves, which makes focussing directly on the paint particularly challenging during in situ analyses. On the other hand, collection of minute samples by rubbing cotton swabs in the grooves of ancient inscriptions, or by gentle scraping with a scalpel has been allowed by museums and conservators. These samples are then brough to the laboratory for micro-spectroscopic analyses. X-rays fluorescence analyses are also being applied in situ to areas showing traces of colours, and the elemental information is considered for a full characterization of the pigments.

The most widely used colour in Greco-Roman epigraphy appears to be red, followed by blue and others, seemingly corresponding to the ancient palette used in sculpture and architecture. Pliny suggests the use of expensive minium (the mineral cinnabar, HgS) for painting letters, on walls, tombs and monuments. However, its occurrence is exceptional and related to specific contexts. The other reds used in antiquity (ochres and red lead Pb_3O_4) are also identified, with further details on iron oxides and oxyhydroxides (e.g. Fe_2O_3, FeOOH, Fe_3O_4) present in the mixture coming from Raman spectroscopy.

Although the identification of pigments, especially the red ones, is a straightforward task for Raman spectroscopy, it appears that the topic has not been explored in a systematic way. The possibility of obtaining precise mineralogical information on pigments provides interesting information on many aspects of manufacturing of ancient inscriptions, such as the choice of expensive vs. readily available pigments and the use of mixtures, chronological or local patterns both for pigments use and for specific pigment – support combinations.

Advanced deep Raman Spectroscopy methods for the non-invasive investigation of materials subsurface: impact on Heritage Science

Conti C.*

Istituto di Scienze del Patrimonio Culturale, CNR, Milano.

Corresponding author email: claudia.conti@cnr.it

Keywords: deep Raman, heritage science, inorganic scattering materials.

One of major outstanding and only partially addressed needs in conservation and material sciences is the non-destructive and non-invasive analysis of subsurface components with molecular specificity at micrometre scales. This capability is just in part fulfilled by confocal Raman microscopy, since its depth–resolving power is restricted to depths at which sample is transparent or semi–transparent. In case of highly diffusely scattering materials, i.e. pigments, powders, tissues, and many inorganic compounds, the restriction can be very severe and, although it is highly undesirable and, in many cases, impossible as in the case of precious objects of art, cross section sampling becomes the only available recourse.

This presentation will focus on recent technological and methodological developments of advanced Deep Raman Spectroscopy methods at the Raman Spectroscopy Laboratory of ISPC-CNR for the non-invasive investigation of deep portions of highly diffusely scattering materials in Cultural Heritage. Micro Spatially Offset Raman Spectroscopy (micro-SORS) is the proposed approach developed in 2014 for non–destructive probing in turbid media (Conti et al., 2014; Mosca et al., 2021). The method involves separating the laser illumination and Raman collection zones from each other on sample surface to facilitate deeper recovery of sublayer signals than with confocal Raman microscopy and identify their chemical makeup. First, the principles of micro-SORS and the existing instrumental modalities will be presented; then, the analytical capabilities of two benchtop and portable micro-SORS prototypes (Lux et al., 2024), recently developed at ISPC laboratory, will be demonstrated on mock-ups mimicking situations encountered in art field with the aim of identifying non-invasively the molecular composition of the compounds and their mutual position. The coupling of micro-SORS with imaging/mapping modalities will be also presented for studies of high-resolution molecular distribution of compounds hidden by external opaque layers in art objects (Botteon et al., 2024). Finally, limitations as well as case studies will be depicted through case studies within the network of the European research infrastructure for heritage science (E-RIHS).

Characterization of chert raw material using a non-invasive approch: the case of Hyblean foreland (South-Eastern Sicily)

Corrente G.*[1], Caggiani M.C.[2], Eramo G.[3], Lanzafame G.[2], Mazzoleni P.[2], Militello P.M.[1] & Barone G.[2]

Keywords: chert, hyblean foreland, Raman spectroscopy.

During Prehistory, chert was the most used lithic material to produce stone industry. Chert is a sedimentary rock composed of mostly microcrystalline silica (about 95%) in addition to minor oxides and trace elements. The petrographic, micropaleontological and geochemical features are related to the depositional environment and the diagenetic evolution and represent an essential database to determine artifacts' provenance.

The Hyblean foreland (South-Eastern Sicily) has been known for its abundance of chert outcrops. Regarding the primary deposition, raw material occurs as nodules and lists in limestones of Amerillo Formation and Ragusa Formation (in the Leonardo Member). During the Prehistory, this resource played an important role in the economy of Hyblean area, indeed some researchers hypothesize about the presence of a "chert network" ("network della selce"- Scerra S., 2023). In fact, the strategy of the mining activity is not yet clear and the area is currently investigated by different research groups. In the Comiso town the discovering of a mining complex (e.g. Monte Tabuto and Contrada Coste mines) attests to the systematic exploitation of the raw material in this district.

In this work, we present preliminary data about the characterization of the Hyblean chert, through the use of non-invasive investigation analyses. While there have been preliminary studies on source catchment areas (Barone et al., 2018; Chatyimpaloglou et al., 2020), the current study aims to collect and analyse geological samples from a large area, with the aim to create a related lithotheque.

For this study we follow a non-destructive and multi-parametric protocol involving macroscopic observation, microscopic description and chemical analysis. Here we show results of Raman spectroscopy to characterize the collected chert samples and determine the presence of specific minerals (Moscone et al., 2020). As an example, this kind of analysis is often useful to distinguish two polymorphs of silica, quartz and moganite. For each sample, different spots were analysed on areas with different colours and morphological characteristics, to achieve a representative description (Moscone et al., 2020). Finally, Raman spectroscopy was coupled with portable X-ray Fluorescence (pXRF), in order to obtain a chemical characterization of the investigated samples (Barone et al., 2018).

The PNRR project "CHANGES" was conceived to establish a multi-technological network in the Cultural Heritage, with a particular attention to the transdisciplinary. A key section of this project, the Spoke 5, focuses on the development of new scientific methods and approaches to deepen the study of cultural artefact materials and their historical context. Within this framework, a new protocol for the analysis and data interpretation of Cultural Heritage studies has been developed.

To validate and refine this protocol, several natural and artificial geomaterial samples were chosen and treated by both natural and artificial ageing. Samples of marble, travertine, wakestone, hydraulic and aerial mortars were exposed to open environment and analysed at intervals of three months, in order to evaluate variation in their infrared signal responses. In particular, the samples were studied applying three different Fourier transform infrared spectroscopy methods: attenuated total reflectance (FTIR-ATR), µTransmission (µ-FTIR) and external reflection (ER-FTIR) were employed for this purpose (Brunello et al., 2019). The first two methods are deemed micro-invasive, whereas the third is entirely non-invasive, which is a fundamental feature for the study of cultural heritage.

Subsequently, a multivariate statistical elaboration of the data collected from the samples with different analytical methods was applied, aiming to evaluate the efficacy of the protocol also to define the origin of raw materials and production techniques.

In conclusion, the project represents a significant step forward for the preservation of Cultural Heritage. Pioneering new scientific methods and the development of a novel protocol for analysing ancient geomaterials will marks a crucial advancement in the field with minimum or no damage to the finds. The ongoing testing and refinement of the protocol here described will provide further insights into material behaviour over time, ensuring the preservation and understanding of our cultural heritage for future generations.

Keywords: IR-spectroscopy, corrosion product, degradation processes.

The investigation of the chemical composition and microstructure of archaeological metal artifacts is essential for understanding degradation processes, with a particular attention to the corrosion, often triggered by prolonged periods of burial.

This study focuses on the characterisation of the metal structure of a set of agricultural tools remains dating from the 13th to 14th centuries, unearthed in the site of Cencelle, a medieval settlement near the Tolfa Mountains (central Italy), founded in the 9th century and abandoned since the 17th century AD (Annoscia, 2016). The main objective is to understand the underlying causes of degradation, assess conservation status, and unravel the composition of patinas and corrosion products formed during and after burial period (Grevey et al., 2020).

To achieve these objectives, a comprehensive multi-analytical approach has been adopted, encompassing techniques such as Optical Microscopy, Electron Microscopy coupled with Energy Dispersive X-ray analysis, and Infrared spectroscopy. Significantly, infrared spectroscopy plays a crucial role in identifying both organic and inorganic materials within the samples, as well as to identify the nature of the patinas and the corrosion products growth on the samples surfaces also after their preparation.

By analysing data acquired through Infrared spectroscopy, it becomes possible to identify compounds present in corrosion products and determine their implications on the conservation status of metal artifacts. This methodological framework offers detailed insights into the nature and composition of materials within the samples, enhancing understanding of degradation mechanisms, and guiding the formulation of conservation and restoration strategies.

In conclusion, integrating Infrared spectroscopy with complementary analytical methodologies provides a robust approach for the systematic examination of archaeological metal artifacts and their associated degradation processes. The outcomes of this investigation provide substantive contributions towards the preservation and valorisation of medieval cultural heritage.

Keywords: geopolymers, micro-Raman spectroscopy, XRD.

Geopolymers are inorganic materials obtained through alkaline activation of aluminosilicates. After a consolidation phase at RT, geopolymers can be used as restoration or construction materials. Geopolymers production may represent a promising alternative to traditional binders, reducing the CO_2 footprint in the building sector. Recent works showed that geopolymers have suitable properties for application in conservation/restoration (Fugazzotto et al., 2024). The use of waste materials (sawing sludges, Construction and Demolition Waste,…) as precursors is currently encouraged in a circular economy perspective (Portale et al., 2023; Volpintesta et al., 2024).

In this work, two sawing sludges were tested to produce geopolymers, consisting of basalt (Etna volcano, Italy), (FB), and granite from pink porphyry quarry (Cuasso al Monte, Varese, Italy), (FC). In the synthesis, metakaolin, Na hydroxide and Na silicate were used. Carbon fibers were added in the FB-geopolymers, to evaluate their effects on the structure.

Geopolymers were characterized through Polarized Light Microscopy (PLM), micro-Raman spectroscopy and X-Ray diffraction (XRD).

PLM observations highlighted the different mineral species in the products, which were confirmed by XRD and by micro-Raman spectra, acquired on the same crystals observed with PLM. Crystalline phases, typical of the precursors were distinguished: mainly feldspars, pyroxenes and olivines in FB-geopolymers; feldspars, quartz and micas in FC-geopolymers. In the case of olivines, the change in colour within a single crystal observed in PLM was correlated with a change in composition, evaluated from the positions of the two main Raman peaks (in the ranges 817.5-822.5 cm-1 and 847.5-852.5 cm-1, respectively): a contribution of forsterite between 60% and 80% was estimated.

In addition, through micro-Raman spectroscopy, the geopolymers were analysed both on the internal and the external parts: a uniform mineral composition was observed. Micro-Raman analyses revealed the nature of efflorescences which can form on the external surfaces by carbonation due to Na excess, consisting of trona ($Na_2CO_3 \cdot NaHCO_3 \cdot 2H_2O$), gaylussite ($Na_2Ca(CO_3)_2 \cdot 5H_2O$)/pirssonite ($Na_2Ca(CO_3)_2 \cdot 2H_2O$), natrite ($Na_2CO_3$).

XRD analyses revealed the amorphous content, amounting to ~25% and ~30% for FB- and FC-geopolymers, respectively. The amorphous content was not detected by micro-Raman analyses, probably due to the submicrometric size of the amorphous regions, whose signals could be covered by those related to the coexisting crystalline phases.

Overall, micro-Raman is a powerful technique to investigate the morphology and the mineralogical composition of geopolymers. A complete description of the residual phases from the precursors and the newly formed phases could be obtained from the Raman results. The combination of micro-Raman spectroscopy with XRD is fundamental to reveal the amorphous content of geopolymers, in addition to crystalline phases.

Keywords: marble, micro-Raman spectroscopy, stable isotopes.

During the recent archaeological excavations in the site of the Roman villa in Fiumana (Forlì-Cesena, Emilia Romagna, Italy), several white marbles were discovered. They are decorative elements, consisting of fragments of reliefs and slabs for floors and walls. The determination of the provenance of marbles is of great interest to identify marble quarries and trade routes in the antiquity.

In this work, white marbles were investigated by a multi-technique approach, by using polarized light microscopy (PLM), X-ray powder diffraction (XRPD), micro-Raman spectroscopy and stable isotope ratio analysis (δ18O and δ13C). PLM observations on thin sections revealed the mineralogical-petrographic features, in terms of microstructure and mineral phases. XRPD confirmed the mineral composition of the marbles, also distinguishing some accessory minerals (e.g. micas), in addition to calcite. Interestingly, all these features were highlighted by micro-Raman analyses, through the use of a single technique. Micro-Raman spectra were collected on different crystals on the thin sections and the mineral phases were identified in terms of both main and accessory species. Further, δ18O and δ13C were evaluated for the marbles and some possible provenance sites were suggested, by comparing the obtained results with the international databases and the available studies about Mediterranean white marble quarries used in antiquity (Capedri et al., 2004; Antonelli & Lazzarini, 2015; Taelman et al., 2020).

The combination of the isotopic results with the mineralogical and petrographic features was essential to define the provenance of marbles and decisive information to archaeologic investigations were revealed.

Keywords: spectroscopic techniques, medieval mosaics, multidisciplinary.

The integrated development of scientific research, promoting the value of mutual complementarity of human and hard sciences, has a paramount importance on the studies of cultural heritage. Considering both cultural and material aspects of artefacts is mandatory to reveal and precise chronology, provenance, workshops practices and to protect and transmits their material and cultural value. This paper describes an ambitious multidisciplinary research project aimed at the establish an in situ, non-invasive and non-destructive physico-chemical protocol (Tempesta et al., 2018; De Ceglia et al., 2024), to improve the knowledge, the conservation and the valorisation of the Apulian mosaic heritage.

This project considers the medieval floor mosaics (6^{th}-13^{th} centuries AD) in the Adriatic area. The historical-artistic and documentary study, fundamental for a coherent and correct interpretative definition of the mosaics examined will be carried out. The characterisation of the geo-materials and synthetic glasses, constituting commonly the mosaic tesserae, by means of complementary spectroscopic techniques (FORS, RAMAN, XRF) will carried out using portable instruments. A detailed mineralogical characterisation, that can contribute to obtain information on the source of materials, will be performed on symbolic regions of the mosaics, chosen valuating their historical, liturgical and artistic impact. The statistically significant chemical and mineralogical data will be completed by laboratory analyses on the most representative tesserae. The extensive data collected will constitute original content and will be made available to the scientific community on an open database. The study with the material information acquired will allow the identification of most suitable techniques for the optimal conservation of mosaic heritage. The extensive data that will be collected in situ will constitute original content and will be made available to the scientific community. The study also aims to develop a protocol for the archaeometric investigation of mosaics that can be applied in different contexts and that will allow for a proper comparison of the data. The study will allow the identification of more suitable techniques for the optimal conservation of mosaic heritage. Furthermore, the results of physico-chemical analyses on the Apulian mosaics will make it possible to identify the provenance of the raw materials, to precise the chronology, to understand the procedures used for the processing the tesserae and to distinguish the original ones from later replacement. (Neri, 2016). Finally, the research will promote knowledge and valorisation of the Apulian mosaic heritage to improve its fruition and public use.

Novel hybrid materials inspired by ancient technologies: the case of 'PALY@DAPI'

Keywords: palygorskite, DAPI, hybrid nanocomposite.

Maya Blue is a famous and extremely stable pigment used in Central America (VIII/ XV Century AD) for mural paintings, statues and pottery. The secret of its stability lies in the indissoluble 'marriage' between palygorskite – a fibrous and highly-hydrated microporous clay mineral – and the frail indigo dye – responsible for the blue colour. A heating-induced sorption and bonding of the dye in the inner tunnels and surface grooves that permeate the clay framework allows indigo to be aptly shielded from external agents, preventing its decay. Due to this, Maya Blue is duly considered an ancestor of hybrid nanocomposite materials. The proverbial 'dice' had been cast: borrowing the stimulus from the ancient Mayas, novel compounds may be thus be prepared by coupling the host palygorskite to other guest molecules, so as to obtain hybrid materials with peculiar features useable in the Materials Science and/or Cultural Heritage fields – valid and sustainable surrogates for other polluting compounds used nowadays.

DAPI is a fluorescent stain capable of binding to the major groove of DNA, thus allowing an imaging of the genetic material. Since the major groove of DNA and the superficial grooves of the palygorskite fibrils bear some similarities, we explored the possibility of synthesizing a stable fluorophore by trying to fasten the DAPI molecule on the hosting clay framework, following the ancient Mayan recipe (grinding, heating at 160°C and washing in water).

The obtained 'PALY@DAPI' composite was investigated with a multi-analytical protocol (FE-SEM-EDS, BET-SSA/micropore volume measurements, thermogravimetry, UV-vis, fluorescence and FT-IR spectroscopies), which proved that grinding involves at first an evident solvation of the guest in the host structure. Interactions between the clay and the dye tend to form already after grinding – being favoured by an incipient electrostatic attraction between the cationic guest molecule and the diffuse negative charge of the palygorskite fibrils surface. These preliminary interactions are also corroborated by H-bond formation between the dye amine groups and the zeolitic and structural water molecules occupying the host superficial grooves, which contribute to stabilize the composite and ensure a significant raise in the quantum yield (QY). Curiously, the following synthesis steps (heating and washing) – which are fundamental for Maya Blue to gain its stability – do not either improve the composite performances or strengthen the previously formed interactions, rather worsening both its stability and QY.

In light of its reactivity and structural features, this 'PALY@DAPI' hybrid composite may find application in the production of tailored, metal-free, fluorescent materials for sensors and optical devices, as well as in the field of imaging or design-targeted drug-delivery systems.

Answering archaeometric questions on technology and provenance relative to emblematic ancient ceramic productions in Basilicata by combining micro-Raman spectroscopy, micro X-ray fluorescence and micro X-ray diffraction to the study of pigments

Corresponding author email: grazia.lubraco@uniba.it

Keywords: pigment technology and provenance, archaeometry, archaeology of production.

In the present paper are showed the results of micro-Raman spectroscopy, micro X-ray fluorescence and micro X ray diffraction relative to ceramic artefacts from emblematic archaeological contexts in Basilicata region (southern Italy) as innovative, effective and sustainable solutions to answer questions on technology and provenance for pottery production. The compositional characterization of ceramic decorative elements (e.g. pigments and glazes) in quite different ceramic productions exhibiting an important change in technology and raw material supply in the Lucanian area will be investigated in the diachrony and the adjustment of tools and solution to the specific questions for the different ceramic production (e.g. presence of glaze) will be exerted. Regarding the matt painted pottery analyzed (V-VI B.C.), in order to understand pigment technological aspects, it is necessary to combine analysis of red and brown pigments using micro-Raman spectroscopy and powder/micro X-ray Diffraction as well as micro X-ray fluorescence. The 532 e 785 nm lasers can be alternatively adopted, depending on the portion of ceramics to investigate. Combination of spectroscopic and diffrattometric techniques thus allowed to detect, in the brown pigment the presence of jacobsite ($MnFe_2O_4$) (Lubraco et al., 2024). As the jacobsite formation is consequence of firing in an oxidant environment of manganese oxides (mainly MnO_2) and iron oxides (Fe_2O_3), a mixture of these oxides was used for the black pigment and the artefact was fired at temperatures ranging from 900-1000°C (Schweizer & Rinuy, 1982). A "before firing" application of the decoration can be hypothesized as well as the use of the well-known "manganese black technique". The manganese source for the jacobsite formation may be identified in the black sand from Mt. Vulture (PZ). The presence of glaze and different colored pigments in the Graffita ware (XII-XV A.C.) – with the presence of a large number of chromophores - necessitates a part from the use of new integrated methodology developed for the micro X-ray fluorescence (Lubraco, 2023) also the adoption of specific expedients in the use of micro-Raman spectroscopy, e.g. the compulsory analysis of the portion below the glaze to decipher the contribution of glaze to the spectra. Different technologies seem to have been adopted to produce Graffita ware from Moliterno Castle (PZ) in the diachrony. There is a Graffita ware characterized by a lead coating with traces of tin, containing abundant quartz and cristobalite, implying firing at high temperatures. The green decoration consists of a Cu pigment (likely the verdigris pigment) with aggregates of cassiterite (SnO2) (Annunziata et al., 2022; Lubraco, 2023). The olive-green decoration consists of bivalent and trivalent iron. A Graffita ware with arsenic in the glaze and in the blue pigment suggests postdating them to early 16th century. Besides, there is evidence that animal bone dust was intentionally used to make the engobe. A possible non-local provenance can be hypothesized for a fragment of Graffita ware.

Keywords: gems, gemmology, spectroscopy.

Raman spectroscopy is a well-established method for the analysis of gemstones, allowing the identification of minerals without the need for sample handling, which is particularly important in the case of precious goldworks.

Within the framework of an extensive project on the study of medieval goldsmithing (Martiniello, 2022), nineteen among relics, reliquaries, religious and imperial insignia preserved in Tuscany Museums, dating from the 10th to the 16th centuries and produced both in Italy and abroad (from Northern Europe to Byzantium) were studied, and a total of 850 gems and gem-like materials were analysed with a strict link between gemmological analysis and spectroscopic examinations.

Overall, the study showed the great advantage of such a multidisciplinary approach, demonstrating the fundamental role of gemmological analysis, intertwined with analytical investigation methods and art historical/archaeological evaluations, also as a tool for analysing the chaîne opératoire underlying the creation of jewellery, the provenance and circulation of gems and objects themselves (Martiniello et al., 2023). In fact, the preliminary step of identifying the materiality of the gemstones by means of spectroscopic methods must be accompanied by the analysis of the inclusions in gems, their cutting and setting, as well as the treatment of the gemstones, which are not always detectable by spectroscopic techniques. These are essential for a global interpretation of their historical significance and cultural context of gems and goldworks analysed.

The research project, which is still underway, has made it possible to reflect on the economic and philosophical value of gems and gems-like materials, by identifying a large number of natural gems from both European and Oriental regions, often reserved for religious or imperial ornaments, and often used in combination with glass. The study also provided an opportunity to identify and observe various types of treatment, among which the composite gemstones stand out for their peculiar manufacturing technique, which is only documented from the 16th century onwards, but which has now been discovered in the analysed 13th century goldworks (Martiniello et al., 2023).

This contribute intends to present a rich repertoire of evidence of gemstones and treatments, with a diachronic approach that also highlights aspects of economic history, considering how the trade in gemstones has evolved over time and tracing its trajectory from ancient practices to more recent ones. This longitudinal perspective allows the study of continuity and change in terms of gem technology, trade routes, consumption patterns and symbolic significance across different historical periods.

Keywords: archaeobotanical remains, mineralisation, FTIR.

Although most of the botanic remains recovered from archaeological sites in the Mediterranean area are constituted by charred samples, mineralized macro-remains obtained from excavations represent interesting case studies, because their actual chemical composition could be related to the archaeological context, while the chemotaxonomic data deriving from the identification of mineral phases could be used for the identification of fossil plant taxa, enriching the interpretations deriving from the morphological analysis (Vajda et al., 2017). In this study, a multi-disciplinary protocol combining Optical microscopy, Variable Pressure Scanning Electron Microscopy supported by dual-Energy Dispersive X-ray spectroscopy (VP-SEM-dEDS) and Fourier Transformed InfraRed spectroscopy (FTIR) was applied to investigate the fossilization of selected fruits and seeds retrieved in the Phoenician-Punic site of Motya (Sicily, Italy; Moricca et al., 2023). In the first steps, the archaeological remains were identified through a stereomicroscope using atlases (Neef et al., 2012; Sabato & Pena-Chocarro, 2021), while their mineralization conservation state was assessed. After this procedure, the carpological remains have been compared to those of their modern counterparts: both the archeological and modern samples were subjected to imaging, elemental and molecular analysis, in order to highlight processes attributable to biomineralization and to replacement mineralization. VP-SEM-dEDS was applied to observe the seed structure at higher magnification and to obtain elemental maps -both on the outer surface and on the cross section of archaeological and modern samples- to highlight the main differences in their elemental composition. In order to individuate the molecular compounds deriving from mineralization, FTIR spectroscopy was applied by means of two different approaches. Specular FTIR reflectance provided the fingerprints modern seeds and fruits and the chemical modifications on archaeobotanical remains. Besides, diffuse FTIR spectra on powdered samples revealed their bulk composition and the presence of organic residues in archaeological samples. The combination of the results obtained from microscopic and spectroscopic techniques resulted generally coherent in providing information about the chemical and mineral composition of the analyzed fossils, while the comparison with the imaging data provided preliminary hypotheses on the mineralization process, extending also the actual knowledge on the preservation condition of archaeobotanical materials from Motya.

Keywords: bronze corrosion, XRM, brochantite-sampleite.

This study examines an Etruscan bronze fibula dating back to the 8th century BC, which is part of the grave goods found in tomb number 129 from the Archaeological Park of Vulci (VT, Italy). The investigations were conducted using a multi-analytical approach based on non-destructive techniques, i.e., Energy Dispersive X-ray fluorescence (ED-XRF) combined with Monte Carlo simulation (MCS) (Golosio et al., 2014), micro-Raman spectroscopy, and X-ray microscopy (XRM). The results revealed that the fibula was produced in a single casting event with a ternary Cu-Sn-Pb alloy. XRM enabled 3-D reconstructions of the fibula, which allowed the investigation of its internal structure (Bernabale et al., 2023), production technology, and preservation state by distinguishing the metal core from the corrosion layer and highlighting areas of fragility. The patina was evenly and compactly distributed over the entire surface, with a thickness between 100 and 400 μm. Micro-Raman spectra indicated the presence cuprite (Cu_2O), malachite ($Cu_2CO_3(OH)_2$), brochantite ($Cu_4(OH)_6SO_4$) and sampleite ($NaCaCu5(PO_4)4Cl•5H_2O$). These latter two phases were also found in another tomb under similar environmental conditions. Indeed, the formation of sampleite and brochantite is promoted by the presence of bacteria and organic matter within burial environments (Muros & Scott, 2018).

Corresponding author email: marta.porcaro95@gmail.com

Keywords: copper alloys, etruscan metallurgy, corrosion processes.

In this study, several archaeological artifacts, i.e., arrowheads, nails, and aes rude, made of copper or copper alloys were examined (Esposito et al., 2019). They were found at the Etruscan site of Pyrgi (Santa Severa, Italy), dating back to the 6th to 4th century B.C. We explored the microstructure and composition of each sample, considering its relationship to the environmental storage, and the possible corrosion phenomena triggered on its surface. Such phenomena can produce irregular multilayer structures (patina) and possible selective enrichment or depletion processes of alloying elements. A multi-analytical approach, based on Scanning Electron Microscope, X-ray maps, and μ-Raman spectroscopy was used. The chemical composition of nails and aes rude is pure copper, while arrowheads are made of a ternary Cu-Sn-Pb alloy. In addition, it was possible to distinguish artifacts produced by simple casting from those that underwent additional processing. The μ-Raman spectra of the surface of the artifacts indicated the occurrence of cuprite, malachite, and copper trihydroxy-chlorides, indicating the occurrence of type I and type II patinas (Robbiola et al., 1998). The presence of chlorine even within the cores in some samples indicates a very corrosive environment. The chemical and microstructural information allowed hypotheses on the production and metallurgical processes of the artifacts and their application. The choice of using copper nails was quite unusual, but as reported in the literature (Dilo et al., 2010; Pomey et al., 2013), it could be due to their use in ship carpentry. As for the arrowheads, the data suggest that they are votive objects as their composition and structure would make them not particularly suitable as weapons. The aes rude, almost all composed of pure copper, represent one of the earliest forms of coinage. They are semi-finished products, rich in inclusions due to the process of smelting raw materials. These data provide valuable information on the processing techniques and materials used by the Etruscans, contributing to the understanding of their technological capabilities and conservation processes of artifacts found in a coastal archaeological context such as Pyrgi.

Corresponding author email: rea.1794917@studenti.uniroma1.it

Keywords: emerald, spectroscopy, provenance.

Throughout the history, emerald has always had an economic and religious importance, as evidenced by its widespread diffusion even far from its mines. Emerald belongs to beryl-group minerals with a general formula $Be_3Al_2Si_6O_{18}$, where tetrahedra form six-member rings filled by Si, whereas Al and Be ions are located at the octahedral and tetrahedral sites, respectively, which link together the columns of rings of six Si-O tetrahedra. The green color is due to the presence of Cr and/or V which replace Al at the octahedral site (Aurisicchio et al., 2018). Recent studies have proved that spectroscopies can be a useful non-invasive approach in the identification of emerald provenance. In particular, thanks to the shape and position of vibrational modes associated with the Si-O stretching (main peak ~1200 $^{cm-1}$ and shoulder at ~1140 $^{cm-1}$) and the bands associated with the OH stretching mode of water (in the range 3500-3800 $^{cm-1}$) of FTIR spectra, it could be possible define the genetic model for each deposit (Giuliani et al., 2019) and consequently their provenance. The present work reports for the first time the results of infrared external reflection spectroscopy on emerald samples from the main deposits exploited in antiquity such as Malyshevsk (Russia), Jos (Nigeria), Pajshir Valley (Afghanistan), Habactal (Austria), Sikait, Zabara (Egypt) and Swat Valley (Pakistan**).** The results are compared with FTIR spectra acquired in transmission mode to identify spectroscopic "markers" which could help in the reconstruction of the provenance.

Precious votive offerings in 17th- and 18th-century Sicilian production: non-invasive gemmological analyses

Spironello M.Y.*[1], Barone G.[2], Mazzoleni P.[2], Caggiani M.C.[2] & Fugazzotto M.[2]

[1] Dipartimento di Scienze Umanistiche, Università di Catania.
[2] Dipartimento di Scienze Biologiche, Geologiche e Ambientali, Università di Catania.

Keywords: Raman spectroscopy, x-ray fluorescence, ecclesiastical jewellery.

There is a vast production of ecclesiastical artefacts traceable in Sicily between the 17th and 18th centuries, a period in which there was a blossoming of the arts related to the creation of silverware, as well as goldsmithing of the highest level. The repertoire of objects also includes beautiful jewellery and ex votos of incredible richness. This vast corpus can be admired in many Diocesan Museums and Museums of Sacred Art in the area, known for exhibiting important collections marked by precious objects with refined decorations and gems set in the mouldings. But beyond the undisputed devotional value and historical document value that characterises these artefacts, it is necessary to understand whether the information reported is reliable. Traditional survey methodologies and autopsy observations do not allow for the classification and characterisation of gems of interest, and scientific studies are rarely used. Thanks to the investigations conducted with non-invasive and non-destructive portable instruments, it is possible to study these works in situ: the combined approach of portable Raman spectroscopy (with an excitation wavelength of 785 nm) and portable X-ray fluorescence (XRF), allowed for the exact identification of the gems (Barone et al., 2015) on some considerable works. The analyses, in some cases, confirmed what was stated in the caption, while in other cases they contradicted the information, revealing, however, lesser-known aspects. This method has made it possible, for example, to thoroughly analyse an ex voto erroneously attributed to the baroness Giovannella De Quadro, today known as De Quatris (1444 - 15 July 1529) (Mollica, 2015), who left all her possessions to the Church of Santa Maria Assunta in Randazzo (Italy). The jewel is not coeval to the reference chronological horizon and is rather associated with the model known as 'fiocco de Savignè' (Di Natale, 2008). In fact, the object follows a traditional Sicilian production type of Franco-Austrian derivation in vogue especially in the 18th century. The gems mentioned must have been rubies, garnets and diamonds, as in a similar specimen already studied in a previous campaign of analysis and currently included in the bust of the simulacrum of the Madonna Immacolata of Caltagirone or like some pendants currently exhibited in the Museum of Sacred Art of S. Nicolò in Militello in Val di Catania (Italy).

Non-invasive combined FT-IR and NMR protocol to assess the cleaning action of a lignin-based hydrogel on stones

Stagno V.*[1], Di Fazio M.[1], Giuliani L.[1] & Capuani S.[2]

[1] Dipartimento di Scienze della Terra, Sapienza Università di Roma.
[2] Istituto dei Sistemi Complessi, CNR, c/o Dipartimento di Fisica, Sapienza Università di Roma.

Keywords: lignin-based hydrogel, portable FT-IR, single-sided NMR.

Lignocellulosic biomass is found on top of agricultural waste and includes cellulose, lignin, and hemicellulose. Of the three polymers, only lignin is considered inexpensive and 98% is burned to generate energy (Vásquez-Garay et al., 2021). Lignin is also an important by-product of paper industry. Due to the growing interest in converting waste into high-value-added products and thanks to the key properties of lignin, such as biodegradability, biocompatibility, thermal stability, antioxidant and antimicrobial properties, several procedures have been developed to regenerate lignin into advanced materials, including hydrogels, nanotubes, films, nanofibers, and nanoparticles (Akhtar et al., 2016). These are suitable for a variety of applications, such as drug delivery systems for agriculture or medicine, in water remediation applications, and in sensors since they can serve as absorbents for heavy metal ions, controlled release agent for controlled delivery and water retention, smart materials for stimuli response, and biosensors and electrodes (Rico-Garcìa et al., 2020). In this scenario, a novel emerging application of lignin-based hydrogels could be in the cleaning practice of cultural heritage stones. This work aimed to evaluate the cleaning potential of a PVA-lignin hydrogel to remove metal ions from stone surfaces using a non-invasive protocol based on the combination of single-sided NMR and portable FT-IR (Stagno et al., 2021). Different stones were artificially stained with copper corrosion products and then cleaned using the lignin-based hydrogel. The spin-spin relaxation time (T2) and the IR spectra were collected on the stone surface before and after the artificial staining, as well as after the application of the lignin-based gel. Moreover, FT-IR spectroscopy was also used to study the changes in bonds within the PVA-lignin system before and after being used to clean the stone.

Keywords: ultramarine, fluorite, vermillion.

Raimondo di Sangro (1710–1771), Prince of Sansevero, is renowned for having made experiences on mineral palingenesis, among other things, using his creation for the embellishment of his masterpiece, the Sansevero Chapel. This multidisciplinary study led by Francesco Paolo de Ceglia within the project promoted by the Interuniversity Research Center "Seminario di Storia della Scienza" called "The uncertain borders of nature. Wonders and miracles in early modern Naples" allow, during two distinct surveys at Sansevero Chapel Museum, to identify geomaterials used or created by Raimondo to adorn the Chapel (de Ceglia et al., 2024). The results obtained by the analyses performed on-site on the cushion of St. Oderisius' statue, on St. Oderisius' Cardinal Hat and on the blue frame on the high altar, executed by means of portable Raman spectroscopy, Ultraviolet, Visible and Infrared spectroscopy (UV-VIS-NIR) and Ultraviolet luminescence are presented. The cushion, described as amethyst in an old guide of the Chapel, appears to be an aggregate (like breccias) consisting of centimetre-sized clasts that shows a strong blue fluorescence. Raman analysis confirmed the assumptions made from the appearance and the observed characteristic fluorescence with UV light, identifying the mineral as fluorite (CaF). As regards the traces of red pigment remains on the cardinal hat the VIS-NIR analyses show that Francesco Queirolo used vermilion, a mercury sulphide (HgS) mineral, to colour the white marble. Raman analyses confirmed the presence of cinnabar. The blue pigment of the frame, that looks like made by a slice of lapis lazuli rock, was analysed through the VIS-NIR spectrum. The analyses demonstrated its compatibility with ultramarine. This pigment was made of lazurite, a mineral responsible for imparting the characteristic blue hue to the natural rock lapis lazuli. It was a precious pigment more expensive than gold, at that time. Further, detailed analyses on micro-fragments of the pictorial layer were performed in the laboratory by means of Optical Microscope (OM), Scanning Electron Microscopy coupled with Energy Dispersive Spectroscopy (SEM-EDS), Ultraviolet, Visible and Infrared spectroscopy (UV-VIS-NIR) coupled with OM. Our analyses confirm for the first time that the Prince of Sansevero was able to create artificial ultramarine 50 to 70 years before Guimet's ultramarine synthesis. As of today, this seems to be the earliest ever recorded example of the production of this artificial pigment. Consequently, this study suggests that historical sources documenting di Sangro's experiences should be seriously reconsidered.

Spectroscopic studies of white and black pigments in a Dalì painting

Tempesta G.*[1-3], Calvano C.D.[2-3] & Rigante E.C.L.[2]

[1] Dipartimento di Scienze della Terra e Geoambientali, Università di Bari "Aldo Moro". [2] Dipartimento di Chimica, Università di Bari "Aldo Moro". [3] Interdepartmental Centre "Research Laboratory for the Diagnostics of Cultural Heritage", Università di Bari "Aldo Moro".

Corresponding author email: gioacchino.tempesta@uniba.it

Keywords: Dalì, white pigment, spectroscopy.

To get preliminary insights on a paint panel signed by Salvador Dalì, spectroscopic data from various techniques were acquired. In the specific case, Fiber Optic Reflectance Spectroscopy (FORS), portable Raman spectroscopy, portable X-ray fluorescence spectroscopy (PXRF) and infra-red spectroscopy with Fourier Transformed-Attenuated Total Reflectance (FTIR-ATR) were performed. The paint realized with a black pigment on a white substrate shows warp and cracks damages due to the ages on the wood panel. No references about diagnostic on Dalì paints were easily found, probably due to the existence of the "Gala - Salvador Dalí Foundation" that exclusively analyzes and verifies the attribution to the artist, not publishing and sharing the analytical data. So, the color palette of the artist is unknown. Only one study on the white zinc-oxide degradation was found (Keune & Boevé-Jones, 2014). The Raman spectroscopic data collected allow us to identify a white pigment, homogenous on all the panel, made by a mix of barium sulphate and titanium oxide. This pigment is different from zinc white described in literature, but this composition belongs to a white pigment produced in the early 20th century. These findings corroborate the paint datation suggested by the owner to 1936. The black pigment belongs to organic matter. Only a large black blemish on the upper right side of the panel has been distinguished by FORS from the other black paint. It probably belongs to an acrylic paint sprayed afterward. FTIR-ATR data permitted to recognize the presence of plastic matter on the edge and to assess the likely attribution of organic binder to plant gum. Due to the importance of this Dalì's panel, these first preliminary results need further investigation with innovative approach based on the use of highly retentive hydrogels and/or organogels for non-invasive analysis of organic binders, working as smart micro-reactor and micro-extractor directly on the object, followed by mass spectrometric acquisitions.

Virtual geological walk to discover the historical-artistic heritage of Rome and its lithoid resources: the Basilica di San Paolo fuori le mura

Adanti B.*, Corrado S., Cecili A. & Coppola D.

Dipartimento di Scienze, Università di Roma Tre.

Corresponding author email: beatrice.adanti@uniroma3.it

Keywords: geotourism, geological heritage, geodiversity.

Rome, the Caput Mundi in the imperial age, now the fourth among the one hundred european cities that the tourists visited most for its rich historical-cultural and natural heritage. A city whose territorial, political and economic growth is due to the Geo-diversity and the resources of the area on which it was expanding. These features need to be disseminated to raise awareness among citizens toward a more sustainable development. Among the resources to be protected, there are the lithotypes, both those quarried for a long time from the local geological formations, and those from the Mediterranean Basin, that during the centuries came to Rome, to build and decorate great works of historical-artistic interest in the City. A heritage to be safeguarded and handed down, to "tell" during geological walks in presence, outdoor and indoor, but also, thanks to the modern technologies, through virtual tours: from the recognition of the rock, to the geological formation and the country where it comes from; from the quarries to the evolution of the extractive techniques, up to the use and their expression in the historical monuments of the city, passing through a dense network of economic and social relationships. An example of "geological" Virtual Tour is that realized for the Basilica di San Paolo fuori le mura, selected among the numerous monuments of Rome for its long history, from the palaeo-christian age to nowadays. This history is made of reconstructions and structural and decorative readaptations, in response to natural and anthropic changes of the territory in the surrounding area, but, above all, for the variety and beauty of its "marbles", that contribute to the narration of its transformations and to its valorization.

URGERE: URban GEodiversity for a Resilient Environment

Alvioli M.*[1] & Melelli L.[2]

[1] Istituto di Ricerca per la Protezione Idrogeologica, CNR, Perugia.
[2] Dipartimento di Fisica e Geologia, Università di Perugia.

Corresponding author email: massimiliano.alvioli@irpi.cnr.it

Keywords: geomorphometry, multiscale analysis, urban areas.

The URGERE project is concerned with resiliency of cities and urban areas in Italy (Alvioli, 2020a), with respect to geo-hydrological hazards and environmental impact on ecosystem services, human life and infrastructure. To do that, it first focuses the variety of the abiotic parameters, mostly geomorphological: namely "geomorphodiversity" (Melelli et al., 2017) , as a measure of the potential of morphological evolution of the landscape. Human presence contributes substantially to the modification of the landscape, especially in urban areas.

Urbanization is a growing phenomenon, and human presence and activities enhance environmental fragilities in cities. We propose a quantitative geodiversity index, GmI, focused only on geomorphological parameters, and with a high-resolution set of elevation and thematic data, homogeneously available all over Italy (Burnelli et al., 2023).

The focus is mostly on the use of digital elevation data, for they are the basis for geomorphometric analysis and for an automated classification of landforms, in addition to thematic information. Interpretation of the resulting index is straightforward, allowing a wide range of applications, at relatively low cost. Implications of different values of the index, in combination with geo-hydrological hazard, are prominent within urban areas. To this end, we single out urban areas with a novel, parameter-free technique, and we aggregate results of statistical models for geohazards at slope unit level (Alvioli, 2020b). Within this framework, we can describe geodiversity, the degree of urbanization, and hazards, at comparable resolution at the national level.

At intermediate/regional and local/urban level we investigate the possibility of relying on a different class of data, stemming from advanced use of aerial photographs and LiDAR measurements with airborne drones, exploiting existing datasets and newly acquired data at very high resolution, in selected locations. Recently developed photogrammetry techniques applied to historical aerial photographs provide digital models of vegetation surface, showing its change in time in the last century and allowing study of the links with local geodiversity and hazards.

We match the national GmI and local analysis in data rich locations thanks to the high-resolution of GmI, providing a truly multi-level and validated approach. Geomorphological mapping and numerical modeling of hazards with very-high-resolution data in selected urban areas elucidates the role of geodiversity and its impact on the environment and human life for a meaningful planning of urbanization and infrastructure. A public release of the software to obtain GmI in GIS using a collection of morphometric, geologic and environmental data is under way.

Exploring geodiversity through historical fountains and ancient springs: geotouristic paths in the Premurgia Region for sustainable development (Puglia, Southern Italy)

Bellini F.*, Sabato S. & Tropeano M.

Dipartimento di Scienze della Terra e Geoambientali, Università di Bari "Aldo Moro".

Corresponding author email: filippo.bellini@uniba.it

Keywords: geodiversity, Premurge, springs.

Geodiversity can be defined as the natural range (diversity) of geological (rocks, minerals, fossils), geomorphological (land form, physical processes), soil, water and environmental features. It includes their assemblages, relationships, properties, interpretations and systems (Gray, 2013).

According to the Sustainable Development Goals of the 2030 Agenda, protection of geodiversity guarantees an essential framework for ensuring the conservation of biodiversity, the responsible management of natural resources, the reduction of natural hazards and the promotion of sustainable development models. Premurge area (Puglia, Southern Italy) offers a good opportunity to show how geodiversity could influence the development of historical settlements and enrich the biodiversity of a territory. Representing the transitional sector between the Apulian Foreland and the Bradanic Trough, this area includes the geological feature of both domains, respectively foreland and foredeep related to the evolution of the Southern Apennines Chain. The foreland (locally the Murgia Materana region), characterized by topographical up and down, is made up of fractured Cretaceous limestones which represent also the substrate of the foredeep (locally the Premurge region, Here the Cretaceous rocks are covered by Quaternary deposits. The latter, from the bottom to the top, comprise: coarse-grained calcarenites (Calcarenite di Gravina Fm) passing to clays (Argille subappennine Fm), in turn covered by sands and gravels (Regressive Deposits of the Bradanic Trough). The key position of clays below coarse-grained porous deposits favours the presence of local surface aquifers and several shallow springs. To discover these different geological features, it could be possible to promote a geotouristic itinerary along the old towns of Laterza, Gravina in Puglia, Matera, Poggiorsini and Spinazzola. Towns with different landscapes, from rugged and barren (such as the rock towns of Laterza, Matera and Gravina in Puglia) to humid and hilly (Poggiorsini and Spinazzola), are indeed linked by an important element: the water. The accessibility of surface water resources, fundamental in pre-modern times for the development of human settlements, is the important difference between the Premurgia area and the top of the Murge area, where towns lack.

The objective of the geotouristic itinerary is to outline how geodiversity enriches both the landscapes and resources of an area. Furthermore, promoting geotourism in these communities provides an opportunity to revitalise historic springs and restore access to drinking water sources, in line with the principles of sustainability and environmental management. By using geodiversity as a tool for education and cultural enrichment, these geotourism trails not only preserve the legacy of our ancestors, but also open the way for a more sustainable future. Targeted investment in the conservation and enhancement of geodiversity is therefore crucial to ensuring a equitable future for present and future generations.

Gray M. (2013) - Geodiversity: valuing and conserving abiotic nature. John Wiley & Sons (eds.).

High-resolution geomorphodiversity and anthropization indices of Italy for urban geomorphology

Burnelli M.*[1-2], Melelli L.[1] & Alvioli M.[2]

[1] Dipartimento di Fisica e Geologia, Università di Perugia.
[2] Istituto di Ricerca per la Protezione Idrogeologica, CNR, Perugia.

Corresponding author email: martina.burnelli@dottorandi.unipg.it

Keywords: geomorphodiversity, multiscale analysis, urban geology.

Urban geomorphology analyses morphological and topographic arrangement caused by human activity in urban areas. Urban sprawl modifies ecosystems, but most of the global actions for future sustainability focus on the biosphere, overlooking the role of the abiotic components, embedded in the geosphere. The geosphere and its diversity support natural processes and human health through a range of ecosystem services (Melelli et al., 2017).

Here, we propose the joint study of indicators of land surface variability and of anthropic modifications. We consider geomorphodiversity as a discrete measure of richness of abiotic components, previously obtained for the whole of Italy at high resolution (Burnelli et al., 2023), and a newly defined index describing the degree of human impact inferred from observed land cover classes. We specifically study the combination of the two indicators within urban areas of different sizes across Italy. Results show that the geomorphodiversity indexes are possible at large scale, using public datasets and consistently at high resolution, which permits simultaneously to study the national scale, and the local scale, within individual urban areas. The use of geomorphodiversity and anthropization indices is complementary, in that they describe different quantities whose change in time due to natural and anthropic actions occurs at completely different time scales.

We show that urban development in Italy was fostered in areas where the land surface is characterized by lowlands, alluvial plains or hills. Urban areas with large values of geomorphodiversity host larger numbers of natural areas. Studying ensembles of urban areas, we show that the particular shape and size of different definitions of urban boundaries are essential to investigate different aspects of human impact on the landscape (Alvioli, 2020).

We suggest that quantitative geomorphodiversity in combination with time–dependent indicators of land cover changes and of human impact may represent an additional tool to study the inherent relationship between the geosphere, the natural environment, and the anthropic modifications on the landscape (Del Monte et al., 2016). Our results provide a new approach to urban planning that considers the diversity abiotic parameters as a fundamental reference point for shaping future city development.

Keywords: geomorphodiversity, geomorphological map, urban geomorphology.

Geomorphodiversity, as an element of the geodiversity assessment, is defined by the variety of landforms and processes of a landscape resulting from the interaction between the lithological types, the surface processes and the climatic variables . The quantitative assessment of geomorphodiversity produces numerical indices objective, reproducible and scalable to different spatial resolutions (Melelli et al., 2017) as for the Land surface diversity index (GmI, Burnelli et al., 2023). It is assessed within a GIS-based approach using topographic variables derived from a Digital Elevation Models (DEM), and geological and hydrological data. The validation of the GmI is fundamental for the worth of the output data which depend on the type and spatial resolution of the DEM, the algorithms that process the attributes, and the moving windows radius for the variety. To date an effective validation method is the comparison with geomorphological maps.

This approach is particularly pertinent in urban environments and on high resolution analysis where anthropogenic transformations due to urbanization and human activities can significantly modify the early morphology over time. Geomorphodiversity indices assessed using high-resolution and relatively recent DEMs, are unable to depict the pre-settlement topography.

The case study in this work is Perugia, the capital city of the Umbria region (central Italy). The city's geological history and geomorphological conformation provide a clear example of how these factors have conditioned the expansion of the urban fabric for centuries.

The first geomorphological map of the city historical center is presented here , it summarizes the natural landforms and the anthropogenic transformations to the topographical surface from around the 3rd century B.C. to the present day.

The aim of this work is to compare the map and the GmI assessed using both the current DEM and the pre-settlement DEM, obtained combining geognostic surveys and historical-archaeological data (Vergari et al., 2022).

The results are two different geomorphodiversity indexes pre- and post- urbanization. A comparison with the geomorphological map allows for timely validation. The mapping of the variation of geomorphodiversity over time due to anthropogenic transformations is original and incisive for the evaluation on the human impact on geodiversity.

Unveiling the interplay of mining activities and geo-tourism: an analysis in the Northern Italian region

Casale M.*[1], Gambino F.[2], Borghi A.[2], Beltramo R.[1], Vesce E.[1], Varì C.[1], Giardino M.[2] & Dino G.A.[2]

Keywords: industrial tourism, geo-tourism, mining tourism.

Mining activities leave a lasting imprint on the landscapes they inhabit, manifesting in a multitude of ways. Physically, their presence is marked by tunnels into the earth, extractive waste facilities, and industrial dressing plants. Yet, their impact extends beyond the tangible; they weave a complex web of economic, social, and environmental consequences.

In the context of the Germanasca Valley, nestled within the majestic embrace of the Alps, mining has been an enduring companion to both the landscape and the local population for centuries. It has entrenched itself as an integral facet of the region, intricately interwoven with its economic and social fabric. The symbiotic relationship between mining and the valley has fostered a sense of interconnectedness, shaping the landscape and the livelihoods of its inhabitants.

As mining operations gradually migrated to lower altitudes, they left behind a tapestry of historic mining structures. Remarkably, these remnants have found new purpose, albeit partially, as catalysts for emerging forms of industrial and geo-tourism (Ólafsdóttir & Tverijonaite, 2018). This adaptive reuse stands as a testament to the resilience of the local community and their ability to harness the legacy of their mining heritage (Jelen, 2018) for contemporary endeavors.

Closely, the technological advance and the evolution of mining production, towards a higher quality product, with a consequent reduction in the quantities exploited has led over time to a progressive reduction in the number of miners employed.

The contraction of work in the mine has been partially absorbed by transforming former miners in tourist guides and increasing the activities induced, passing from the previous model “in house” to an “outsourcing” model, where many mine-related activities are outsourced.

The transformation of old mines into museums has certainly contributed to the development of the area, particularly considering a rediscovery tourism that has little to do with the “fast and junk” tourism that has grown lately.

The allure of the Germanasca Valley lies not only in its scenic vistas but also in the intricate tapestry of its mining legacy. It serves as a microcosm, a living laboratory, where the dynamic interplay between active mining endeavors and territorial development unfolds before our eyes. Here, mineral extraction and geo-tourism converge, shaping the landscape and enriching the human experience.

Indeed, the Germanasca Valley stands as a compelling case study, illuminating the profound interdependence between mining activities and the holistic development of a region (Moyle et al., 2018). It underscores the symbiotic relationship between resource extraction and the burgeoning geo-tourism industry, underscoring the imperative of sustainable practices and mindful stewardship of our natural and cultural heritage.

This flourishing form of geo-tourism stands in stark contrast to the superficial allure of mass tourism, offering a nuanced exploration of the valley’s cultural and geological heritage (Varriale et al., 2023), beckoning travelers seeking more profound and authentic experiences.

The PanAfGeo Project: the role and experience of ISPRA, Geological Survey of Italy for the enhancement and protection of geological heritage

Delmonaco G.*, Brustia E., Pompili R., Primerano P. & Traversa F.

Dipartimento per il Servizio Geologico d'Italia, ISPRA, Roma.

Corresponding author email: giuseppe.delmonaco@isprambiente.it

Keywords: geoheritage, Africa, training.

In April 2024, ISPRA participated in a training program on Geoheritage in Lobatse (Botswana) in the framework of the EC PanAfGeo-2 Project.

The project, started in 2014, is aimed at strengthening the relationship between EU and African countries and providing a set of training sessions to geoscientific staff from African Geological Surveys on several topics related to Geosciences for e.g. sustainable mineral exploitation and related infrastructures, natural disaster prevention and mitigation, geoscientific mapping, and conservation and enhancement of geological heritage.

As a matter of fact, the African continent is particularly rich in geological diversity. Presently, the main efforts are being devoted to exploitation of mineral raw materials; nonetheless, this does not sufficiently contribute to the improvement of the overall living conditions of the African population. Being either still unexplored or unclassified, most of the continent's mineral resources are still widely under-exploited.

Detailed and reliable geological data and information are vitally important to the economy of African countries as well as to the protection of its bio and geodiversity and population. In this regard, Geological Surveys can provide services that can be used by state agencies, consultants, industry, developers and the public as key input for local and regional socio-economic development plans, being of support to the achievement of objectives related to, among others, environmental protection (especially water and soil), natural and anthropogenic hazards, energy and mineral resources, land-use planning, agriculture, economic development, earth resources development, climate change, sustainability, and tourism.

In Botswana, seminars with practical desk and field activities were held, attended by 45 geologists from African and European Geological Services, during which the state-of-the-art on geological heritage was presented, based on distinct experiences and methods. A specific effort was done to identification of sites of high geological interest (geosites) and implementation of national inventories as well as supporting sustainable management of territorial resources to promote geological culture and develop potential geotourism routes in Africa. The systematic identification of "geosites" will also assist in UNESCO Geoparks nominations which, in Africa, are very few and highly underestimated. During the training, some potentialities of open-access Lidar remote sensing tools were also applied, tested, and shared with local Geological Service; actually, ISPRA is applying such tools as part of the EC-funded GeosciencesIR- PNRR project for the digitalization of geosites, and precisely to promote and make the geological heritage more accessible to specialists, stakeholders and public.

Geology and cultural heritage in Petra (Jordan): evolution and degradation in relation with tourism management

Delmonaco G.*, Pompili R., Puzzilli L.M. & Traversa F.

Dipartimento per il Servizio Geologico, ISPRA, Roma.

Corresponding author email: giuseppe.delmonaco@isprambiente.it

Keywords: geotourism, Petra WH site, geological risks.

Tourism plays a significant role in enhancing destinations' economies, social life, culture, and the environment. On the other hand, unplanned and uncontrolled tourism growth can lead to negative outcomes and harmful influences, not only upon the destination environment but also on the social and cultural values of a community. The case of Petra (Jordan) a World Heritage site since 1985 can well encompass and represent the positive and negative impacts of tourism development on this worldwide known 'marvel' of the modern World. As a matter of fact, the tourism in Petra provided job opportunities to local people, alleviating poverty, improving infrastructures, tourism investments, and greatly supports the GDP of Jordan. At the same time, the excess of tourism capacity recorded in the last decade in Petra has caused also negative impacts on the conservation of the monuments as well as on the natural, and geological environments.

The archaeological site of Petra is characterized by Nabataean monuments, hand-carved in the local sandstone rock. From a geological point of view, Petra's tangible cultural heritage suffers from several natural and human-induced hazards, such as earthquakes, landslides, floods, weathering that pose a threaten to the site and visitors. The major risk for the tourists is represented by the occurrence of flash-floods and rock falls in the 'Siq', a 1.2 km natural gorge which serves as to main entrance to the site. The consciousness of this permanent danger in the Siq resulted in the implementation of the 'Siq Stability Programme', a series of UNESCO project initiatives started in 2009 in cooperation with the Jordanian authorities, scientifically coordinated by ISPRA, Dept. for the Geological Survey of Italy. This initiative was also in line with the Hyogo Framework for Action 2005-2015, the main UN-wide policy on Disaster Reduction, which encourages the awareness of the importance of disaster reduction policies as a key objective to ensure the substantial reduction of disaster losses and enhance the resilience of local communities.

The 'Siq Stability Programme' was then implemented with the main objective to ensure that preventative measure were in place in the main tourist areas for the protection of the Petra's cultural heritage again natural risks and the safety of thousands of tourists who visit Petra each year.

The programme included a phase of preliminary multi-discipline studies, implementation of landslide mitigation works including rock slope consolidation with a team of expert rock climbers with the involvement of the local community and park rangers. Several scientific and technical trainings were also organized for Jordanian technicians, and a series of awareness campaigns addressed to the local community and visitors. This initiative can be considered as a best practice for the geological conservation in a UNESCO World Heritage site.

Multidisciplinary scientific investigation supporting assessment, valorisation, and management of geoheritage: lessons from CLIMATE@COA project

Dimuccio L.A.*[1], Aubry T.[2], Rodrigues N.[3] & Cunha L.[1]

[1] Department of Geography and Tourism, University of Coimbra, CEGOT, Portugal.
[2] Côa Parque, Fundação para a Salvaguarda e Valorização do Vale do Côa, Vila Nova de Foz Côa, Portugal.
[3] Department of Earth Sciences, University of Coimbra, Portugal.

Corresponding author email: luca@ci.uc.pt

Keywords: fluvial landscape, open-air prehistoric rock art, UNESCO world heritage.

The CLIMATE@COA project (COA/CAC/0031/2019) – '*Climate and human adaptation during the Last Glacial Period in the Côa Valley region (Portugal)*' is an integrated multidisciplinary scientific initiative funded by the Ministry of Science, Technology and Higher Education of Portugal (www.climatecoa.org). Its distinctive approach involves the analysis of various terrestrial records (natural and cultural) preserved in northeast Portugal's Côa River Valley region. This territory is not only home to exceptional open-air prehistoric rock art classified as a UNESCO World Heritage site since 1998 but also contains fluvial landforms and sediments that hold significant information concerning the climate evolution of the Last Glacial Period, as well as archaeological remains that allow us to understand coeval human occupation. The ongoing investigation is based on a multi-scalar analytical approach that utilises stratigraphical, sedimentological, geochemical, geomorphological, archaeological, and geochronological research to decipher long- and short-term landscape evolution and deduce the environmental forcing factors for such evolution, namely climate and ecosystem changes. The collected data also help us better understand the societies and behaviours of Middle-Upper Palaeolithic hunter-gatherer human populations in the Iberian Atlantic façade. The execution of this project highlights the importance of multidisciplinary scientific investigation in supporting the assessment, valorisation, and management of the geological, geomorphological, and archaeological uniqueness of the study area, as well as its history, scientific value, educational potential, and geotourism opportunities, encompassing a wide range of geodiversity (from local sedimentary outcrops to UNESCO recognition). Indeed, to properly appreciate and monitor its intrinsic geoheritage and geotouristic values, it is crucial to deeply understand the natural dynamics of the territories. Additionally, it is necessary to assess, classify, appreciate, and monitor these elements to ensure their preservation and promotion for future generations. In this context, the project's results and conclusions are valuable only if shared with stakeholders responsible for planning, management, conservation, culture, economics, and social issues. Thus, the information produced can provide original and valuable data that are scientifically valid and applicable in supporting territorial planning, environmental management, and geotourism. For instance, exploring the natural and cultural heritage and diversifying tourism can be improved through these data - e.g., revitalising scientific information and contents of the Côa Museum and associated Archaeological Park. This, in turn, can assist in defining strategies for a more integrated and sustainable local and regional development.

Degradation risk and sensitivity to climate change of geosites: a methodology for quantitative assessment

Ferrando A.*[1], Faccini F.[1], Coratza P.[2], Vandelli V.[2] & Reynard E.[3]

[1] Dipartimento di Scienze della Terra, dell'Ambiente e della Vita, Università di Genova. [2] Dipartimento di Scienze Chimiche e Geologiche, Università di Modena e Reggio Emilia. [3] Institute of Geography and Sustainability and Interdisciplinary Centre for Mountain Research, University of Lausanne, Switzerland.

Corresponding author email: andrea.ferrando@edu.unige.it

Keywords: geosites, degradation risk, vulnerability.

In recent years, research on geoheritage has gradually focused on the risk of degradation of geosites. The identification of threats to geoheritage, whether natural or anthropogenic in origin, and the consequent assessment of degradation risk, is considered a fundamental aspect in any geoconservation strategy. Several methodologies, both qualitative and quantitative, have been proposed in scientific literature to assess the degradation risk of geosites. In most cases, these assessments are incorporated into the general geosite value assessment procedure (e.g. Brilha, 2018), and revolve around the concepts of "fragility", "vulnerability", "sensitivity" etc., terms that have been used inconsistently over the years (Garcia-Ortiz et al., 2014).

In this paper, in addition to a brief review of specific terminology, a quantitative methodology is proposed for assessing the degradation risk of geosites. The procedure is divided into four blocks, concerning: i) fragility, dependent on the intrinsic characteristics of the geosite; ii) natural vulnerability, i.e. the sensitivity to degradation dependent on natural processes; iii) anthropogenic vulnerability, i.e. due to human action; iv) sensitivity to climate change. Each of these four blocks was assessed by means of a set of indicators, to which numerical scores are attributed.

The methodology was tested on two different inventories of geosites, the first concerning the Liguria region (North-Western Italy), the second in the Hérens Valley of the Pennine Alps (Valais, Switzerland). The methodology is structured to be easily replicable in other study areas and in different geographical-geomorphological contexts, and the results may constitute an important tool for the outlining of effective management and valorisation strategies for geosites.

In search for a key area for geotourism? The example of "Sassi", the old town of Matera (Southern Italy)

Festa V.*, Sabato L. & Tropeano M.

Dipartimento di Scienze della Terra e Geoambientali, Università di Bari "Aldo Moro".

Corresponding author email: vincenzo.festa@uniba.it

Keywords: geotourism, Sassi di Matera, rupestrian town.

The rupestrian old town of Matera (southern Italy) is an urban area included in the UNESCO World Heritage List since 1993 and designated as European Capital of Culture for the 2019. Since prehistoric times, the old town, called "Sassi di Matera" ("sassi" is the Italian word for stones), has been spectacularly dug in a "soft rock" (a quaternary calcarenite). This rupestrian settlement is perched in the upper part of the right side of the "Gravina di Matera", a canyon cutting the so called "Murgia Materana", the barren rocky high in front of the town.

An increasing number of tourists is attracted by itineraries crossing the "Sassi di Matera", and, due to the intimate connection between the old town and the geological anatomy of the area, each touristic itinerary could become an urban geotour or could be enriched by geological information (Tropeano et al., 2018). Therefore, tourists visiting the old town of Matera and admiring several amazing panoramic view from easy points, may be intrigued in understanding the development of the crossed landscape.

Tropeano M. et al. (2018) - "Sassi", the Old Town of Matera (Southern Italy): First Aid for Geotourists in the "European Capital of Culture 2019". Alp. Mediterr. Quat., 31, 133-145, https://doi.org/10.26382/AMQ.2018.09

Geotourism as a tool for geoheritage promotion: a geotrail project in Beigua UNESCO Global Geopark (Liguria, Italy)

Gianoglio F.*[1], Caprioglio M.C.[2], Castello G.[2], Fiori C.[2] & Marescotti P.[1]

[1] Dipartimento di Scienze della Terra, dell'Ambiente e della Vita, Università di Genova.
[2] Parco del Beigua UNESCO Global Geopark.

Corresponding author email: fedra.gianoglio@edu.unige.it

Keywords: geodiversity, european charter for sustainable tourism, geosites.

The geoparks contribution to the development of geotourism is widely recognized (Farsani et al., 2014; Albani et al., 2022) and the UNESCO Global Geoparks (UGGp) are among the most suitable place to perform geotouristic studies, to develop and to promote geotourism as well as to test innovative tools. The European Geoparks Network (EGN) guidelines (Zouros, 2004) stated the pivotal role of geoparks in the economic development through the enhancement of geoheritage and the development of geotourism. This study was performed in the Beigua UGGp, which is located in northwestern part of Italy, in the junction between the Ligurian Alps and the Northern Apennines. It covers 42,376 hectares and includes the whole territory of Beigua Regional Nature Park (8,791 hectares), straddling the provinces of Genova and Savona. The geopark area is mostly composed by metamorphosed ophiolites and their oceanic sedimentary cover, with minor occurrences of metamorphosed rocks of continental crust; in addition, all lithologies are covered by limited outcrops of clastic sedimentary rocks and Quaternary sediments. The outstanding geodiversity of Beigua UGGp is well represented in fifty-four geosites covering a wide number of geological aspects of the complex tectono-metamorphic evolution of the area.

Beigua UGGp is actively involved in the development of sustainable tourism, particularly geotourism, to create a virtuous circle leading to the awareness on the importance of geoheritage and nature conservation. In 2023, Beigua UGGp applied to the European Charter of Sustainable Tourism in Protected Areas (ECST) to integrate tourism development within parks with the protection of natural environment. An action plan including ninety actions, to be developed between 2024 and 2028, was submitted by Beigua UGGp and forty-four stakeholders comprising local authorities, tour operators, farms, museum, territorial associations, and university. The proposed actions are included in the following four strategic axes of the plan: biodiversity, geodiversity, landscapes, and sustainable tourism development. The action described in this works concern the "Geosites and geodiversity valorization" and aims to promote geoheritage in Beigua UGGp through the scientific investigation of the most representative geosites followed by the creation of innovative geotouristic tools and thematic geotrails.

Fifteen geosites, covering the most important geological features of the geopark, were chosen basing on several aspects, such as scientific and cultural importance, representativeness, didactic and touristic potential, scenery, accessibility as well as fragility and vulnerability. The geotrails were designed and mapped according to the existing network of hiking and biking trails within the Beigua UGGp that pass near the selected geosites. Moreover, the geotrails include several noticeable geological points of interest ("geostops") suitable to show peculiar geological insights.

Albani R.A. et al. (2022) - New approach on the quantitative assessment of geotouristic potential: A case study in the northern area of the Rio De Janeiro Cliffs and Lagoons Geopark project. Geoherit., 14(2), 72, https://doi.org/10.1007/s12371-022-00707-7.

Zouros N. (2004) - The European Geoparks Network-Geological heritage protection and local development. Episodes J. Int. Geosci., 27(3), 165-171, https://doi.org/10.18814/epiiugs/2004/v27i3/002.

The role of geosciences to activate the virtuous circle: awareness of geodiversity values - enhancement of geoheritage - growth of sustainable geotourism - public engagement

Giardino M.*[1], Negri A.[1], Storta E.[1], Mantovani A.[1-2] & Guerini M.[1-3]

[1] Dipartimento di Scienze della Terra, Università di Torino. [2] Istituto di geoscienze e georisorse, CNR, Torino.
[3] EDYTEM, Université Savoie Mont Blanc.

Corresponding author email: marco.giardino@unito.it

Keywords: geodiversity, geoheritage, geotourism.

Geosciences play a fundamental role in promoting awareness of geodiversity and its possible contributions to the enhancement of natural and cultural heritage. This is a fundamental role that can be strengthened by territorial policies that develop geoheritage assessment and at the same time promote sustainable use of the environment, particularly through environmentally friendly geotourism.

The GeoSIT-Piemonte team has developed an innovative -conceptual and operational- "circular, approach" to the geoheritage in the Piemonte region: 1) to use digital knowledge for assessing geodiversity, useful for 2) inventorying geosites and enhancing geoheritage, therefore allowing 3) growth of sustainable geotourism, and 4) public recognition of the whole "virtuous circle", also by means of adequate administrative and policy actions, culminating in the L.23/2023 Regional Law on geoheritage conservation, management and valorization.

Comparative analyses of scientific literature on the rich Piemonte geodiversity lead to the identification of the most representative geothematic areas and related geosites, including landforms, geological units and processes of different ages and environments. Description and interpretation forms on scientific and additional values of geosites, related to educational, cultural, aesthetic and other interests, allowed comprehensive assessments of natural and cultural heritage; these are supporting promotion and management initiatives in the regional territory. To ensure a balance between the protection of Nature and the need for local economic development, we aim at a sustainable use of geosites of high scientific value for educational activities, geotourism itineraries, cultural proposals, thus enhancing their local economic resources.

For effective activation of the virtuous circle, some important issues of the public engagement on geodiversity and geoheritage of the territory were taken into consideration:

In order to spread information and geoscience knowledge, the geotouristic offers need to be for everybody, with the planning of paths to be accessible to people with disability and specific itinerary adapted for blind and/or deaf people, in which other senses can be used.

For enhanced link between cultural and geological heritage, a central role is played by the self-guided tours and itineraries. In this way, the geotourist is guided during the visit of the cultural and geological sites in the identification of the connection between the geoheritage and the cultural heritage.

Furthermore, local communities usually preserve original ideas, stories, and customs that have been transmitted along over decades. These contributions help to deepen understanding of a certain area's geological history and significance while underscoring the intimate relationship between humans and their environment. Incorporating local knowledge improves understanding of geoheritage, generating a sense of caring and community among both inhabitants and tourists. Thus, it is critical for geoheritage to recognize and appreciate local and vernacular knowledge.

Dynamic geodiversity and environmental sustainability within alpine glacial areas: educational values for the secondary schools

Lozar F.*[1], Gerbaudo A.[1], Giardino M.[1], Perona S.[3] & Zambrotta M.[3]

[1] Dipartimento di Scienze della Terra, Università di Torino.
[2] Comitato Glaciologico Italiano, Torino.
[3] IIS Santorre di Santarosa, Torino.

Corresponding author email: francesca.lozar@unito.it

Keywords: sustainability, glacial areas, education.

Due to the present day accelerated climate change, Alpine environments are experiencing increased warming, resulting in a rapid change of the interaction of landforms, rocks, soils, water, air, and living organisms. This in turn is causing accelerated geodiversity changes within mountain glaciated areas. Therefore the concept of dynamic geodiversity is of increasing importance for enhanced awareness on sustainability issues, both in educational plans, and environmental management.

Based on data on dynamic geodiversity (from the historical archive of the Italian Glaciological committee) we proposed a laboratory activity targeted to the analysis of some of the most clear example of the interaction of the planet and climate change: glaciers (SDG 13 of the Sustainable Development Goals; UN Agenda 2030). In particular, we analysed data from the northernmost valleys of Piemonte region: the Lepontine Alps (Ossola valley).

We worked with 16 students aged 17, and offered them with a selection of glaciological data (description and measurement from the reports of the annual glaciological campaign) and related images (terrestrial and aerial pictures of glaciated areas). The students accessed this material online and were asked to create diagrams and make interpretation for describing the dynamic evolution of glaciated areas within a time interval of several decades (1970-2022).

Students could recognize some relevant facts of climate-glacier interaction: the progressive but uneven withdrawal of glaciated areas related to temperature rise, the pulsed behaviour of glacial masses, the accelerated glacial instabilities during last decades.

For highlighting the relationship within dynamic geodiversity and sustainability, we tested student knowledge on these concepts before and after the laboratory activity, thus proving the virtuous outcome of working on the natural environment to increase the awareness of young generations on the current climate crisis, its effects on the mountain areas and its resources, and stimulating good practices for mitigating impacts and climate hazards, and enhancing resilience.

Geosites as a tool for climate change education: a case study in Piedmont, IT

Keywords: geodiversity, outdoor education, sustainable development.

The objective of raising awareness on geodiversity cannot be fully achieved without a strategy that involves schools of all levels as much as possible: in particular, to use geosites in school education is one of the important ways to promote geoheritage values (Zgłobicki et al., 2024). This is why, for example, in Piedmont the recent regional law on geodiversity (LR Piemonte 23/23) stipulates that the inventory of geosites must also indicate their possible educational value: this potential does not always correspond to their scientific importance, as the visibility and comprehensibility of the phenomena are more important for didactic purposes (Drápela, 2022). This study presents the results of an analysis conducted among the students of 3 classes of I grade secondary schools that took part in an outdoor activity entitled "Earth Sciences and climate change", in which, after an introductory meeting held in the classroom, a didactic excursion was planned to the Spiaggia dei Cristalli (Verduno, CN), an important outcrop allowing to explore Messinian deep marine sediments and gypsum deposits and to unravel the paleoclimatic clues they record. Here, an inquiry-based method was adopted through a sensory exploration of the area that prompted participants to reflect on their own relationship with Nature and the role of humans in the current ecological crisis. The students' answers to the pre- and post-experience questionnaires show that the visit to the geosite was fundamental for learning some basics of stratigraphy, paleoceanography, paleoclimatology and sedimentology, as well as for effectively understanding how Earth Sciences systemic thinking applied to the study of past climatic changes helps to compare them with those taking place today and to address their causes and impacts. Our suggestion is therefore to enhance the use of geosites as a teaching tool, as they allow for a transdisciplinary and transformative outdoor education approach, which aligns geoscience education with the goals of education for sustainability: this will make it even more evident the extremely important and unique contributions of Earth Sciences for the understanding of Earth's past, clearly connected with a sustainable future for both humankind and non-humans (Gerbaudo et al., 2022).

Geosites inventory and territorial planning

Lucarini M.*, Brustia E., Olivetta L., Pompili R. & Primerano P.

Keywords: geodiversity, geoconservation, inventory.

The geological heritage, by its intrinsic nature, holds scientific, environmental, cultural, and tourist-recreational value. Fundamental elements of geological heritage are geosites. Geosites represent a distributed archive of non-renewable natural resources that allow for the recognition, study, and interpretation of the evolution of Earth's geological history, particularly within the area they are located in, to the extent of determining an interest in their conservation. These are "geological singularities" (sites rich in fossils, minerals, landscape morphological elements, etc.) that, due to their rarity, scientific value, scenic beauty, cultural and educational usability, can be considered true geological "monuments" to be protected, safeguarded, and enhanced (APAT, 2005).

Thanks to its geological and geomorphological peculiarities, Italy is particularly rich in geodiversity, which is closely linked to biodiversity. The geological characteristics of the substrate influence the diversity of life and are in turn influenced by it. The state of conservation of geodiversity thus affects that of biodiversity and must therefore be protected to ensure the balance of the environmental system. Often, but not always, geosites are found within protected areas; however, this does not exempt them from dangers, just as those outside naturalistic areas are certainly more exposed.

Their correct cataloging allows both long-term protection and potential enhancement in the case of possible tourist-recreational use, making them an absolute testimony of the landscape of which they are part.

Geosites constitute the geological heritage, a component of natural heritage, the protection of which is provided for in legislation on protected areas, cultural heritage, landscape protection, and also in the Constitution (Fabbri et al., 2014). Once geosites are identified, it is necessary to adequately plan the geoconservation process, for example through a series of procedural phases: geosite proposal; geosite validation; insertion of the geosite into the database; establishment of territorial management models aimed at environmental protection; incorporation of the database into higher-level territorial planning; incorporation of the database into local territorial planning.

The inventory of Geosites, implemented by the Italian Geological Survey (ISPRA), is an indispensable knowledge tool for their enhancement and protection, also through the promotion of local development forms such as geotourism.

Their census also contributes to increasing awareness of the natural risks to which the territory is exposed, giving local administrations the opportunity to take them into account for the purpose of better territorial planning.

Geosites as natural scientific laboratory: investigating the links between geology, soil chemistry and botany

Micheletti F.[1], Fanelli G.*[2], Festa V.[1], Fornelli A.[1], Bruno G.[3], Gjata I.[2] & Tommasi F.[2]

[1] Dipartimento di Scienze della Terra e Geoambientali, Università di Bari "Aldo Moro". [2] Dipartimento di Bioscienze, Biotecnologie e Ambiente, Università di Bari "Aldo Moro". [3] Dipartimento di Scienze del Suolo, della Pianta e degli Alimenti, Università di Bari "Aldo Moro".

Corresponding author email: giovanni.fanelli@uniba.it

Keywords: geodiversity, biodiversity, REEs.

Geosites are commonly considered as an expression of the geodiversity of a territory, as a range of geological, geomorphological and soil features. These characteristics are crucial for the different species that live in these areas. Consequently, the conservation of geodiversity and geological heritage contributes to the integrity of the ecosystems combatting the loss of biodiversity.

The present research starts from a competitive call promoted by the University of Bari, Horizon Europe Seeds 2021, within the project "Rare earths, geochemical elements of strategic importance: presence in subsoil and soil, and effects in model organisms". This project aims to synthesize the literature data about the occurrence of REEs in abiotic matrices (rocks and soils) and to unravel their mechanisms of transfer in biological ones (microalgae, terrestrial and aquatic plants), their environmental behavior and potential toxicity in biological matrices. Rare earth elements (REEs) playing an important role in several industrial and chemical applications are extracted from rocks and minerals in large quantities. Overuse promotes their increase in ecosystems with effects on the environment and on the biotic communities that still partially escape our knowledge.

The investigation of the distribution and the behavior of some minor and trace elements (with particular attention to REEs) in karst limestones during progressive chemical alteration processes is proposed as a case study. We present and discuss the first evidence from a geosite selected as a natural scientific laboratory along the Apulian Murge Area (southern Italy).

Preliminary data indicate that the karst alteration process on limestone was promoted and accelerated by allochthonous siliciclastic material supply and silicate solution circulation between the carbonate bedrock and the overhead pelite material (Micheletti et al., 2023). These processes seem to favor mobility and increase of REEs contents from the carbonate substrate to the residual deposits ("terra rossa" and bauxites).

Ongoing experiments aim to evaluate the adverse and/or positive effects of REEs exposures in plants, soil-borne plant-pathogenic fungi and animal models and their physiological/molecular evidence. The overall information points to shifts from toxic to favorable effects in model systems according to their concentrations, suggesting the occurrence of hormetic behavior (Gjata et al., 2022; Tommasi et al., 2022).

Understanding the transfer mechanism and the behavior of REEs on some model organisms may be useful to better define the close relationships between abiotic and biotic factors. This analytical approach will be easily extended to anthropic sources of contaminant elements such as active or inactive mining/industrial sites.

This research also has an educational value as it was the inspiration for joining the "GeoEventi 2022" call promoted by the aspiring UNESCO Geoparck "Alta Murgia National Park" through didactic walks favoring Citizen Science.

Urban geology and geoheritage conservation: enhancing aspiring UNESCO geopark development in the Gargano promontory

Morsilli M.*

Dipartimento di Fisica e Scienze della Terra, Università di Ferrara.

Corresponding author email: mrh@unife.it

Keywords: urban geology, geoheritage, geoparks.

The Gargano Promontory is an ideal candidate for UNESCO Global Geopark due to its size (about 2000 kmq), well-defined geographic boundaries, unique geology, partially distinct from the rest of the Apulia Region, rich biodiversity, and cultural heritage featuring significant archaeological sites (Morsilli & Gianolla, 2022).

Noteworthy geological features include internationally renowned sites like Punta delle Pietre Nere, showcasing the oldest rocks in Apulia, and Dolina Pozzatina, one of Europe's largest dolines. The region's geological composition spans from Upper Jurassic to Miocene carbonate rocks alongside prominent structural elements like the Mattinata Fault. These geological complexities have contributed to the creation of the region's captivating natural landscape, characterized by karst features, valleys, small canyons, rocky cliffs, sandy beaches, and lagoons. Sedimentological highlights encompass diverse settings from shallow-water to basin environments with inner-platform peritidal cycles, marginal facies with stromatoporoids or ooids, as well as well-exposed slope and base-of-slope facies showcasing a diverse array of gravity-flow deposits, and basinal white limestones with colored cherts and frequent slumpings (Morsilli et al., 2021).

In addition to its geological significance, the Gargano boasts a rich cultural heritage, including the legend of Archangel Michael's apparition, which has contributed to its historical and cultural amalgamation (Piccardi, 2005).

Furthermore, recognizing that many Apulian towns are situated on carbonate rock, this study will delve into the role of urban geology, and particularly the visible sedimentologic features, in geoheritage conservation and geotourism development thus adding an additional layer of significance to the region's geological and cultural assets.

The new geosites identified by the Sezione Geologica regionale and the geological forms of the landscape in Umbria

Motti A.*, Berti F. & Natali N.

Regione Umbria, Sezione Geologica.

Corresponding author email: amotti@regione.umbria.it

Keywords: geosite, landscape, geology.

The Sezione Geologica of the Regione Umbria has reviewed all the geosites that had been defined with article 86 of the Regional Law 21 January 2015 n. 1 which defines and protects the "Areas of particular geological interest and geological singularities". The complete review work began in 2021 and this activity was carried out in coordination with the thematic table "Geological Heritage" established by the Board of Directors of the State-Regions and Autonomous Provinces Geological Committee. In the review, the definitions and criteria that define the geosite were taken into account and all the areas of particular geological interest were reviewed, identifying the changes that needed to be made also following specific inspections and surveys. The work, compared to the 43 previous geosites, defined: 24 confirmed geosites; 8 unified geosites with changes to the perimeter; 3 new geosites; 8 geological singularities erased. For the geosites, in the descriptive sheets it has also been indicated in which domain of the geological forms of the Umbrian landscape they fall. In Umbria, detailed geological information is available for the entire regional territory and this has allowed the identification of 10 different domains of geological landscape forms which indicates the most prominent forms of the landscape that derive from the geological characteristics. Geological syntheses of Umbria were developed in 5 different geological domains in which the geological units were grouped. The geological-morphological characteristics of the Umbrian alluvial valleys were also considered, which vary depending on the size of the river. Globally, alluvial deposits of different ages occupy 36.3% of the regional territory, well over 1/3 of the entire region. Alluvial deposits are characterized by the characteristic of being lenticular; their thicknesses are very variable. The situation changes if we analyze the geological representativeness (ref. the geological Representativeness https://doi.org/10.13140/RG.2.2.15393.76642) of the different alluvial deposits, i.e. going to the geological representativeness of the current and terraced alluvial deposits is 0.56%, while that of the ancient and very ancient alluvial is 26%. These numbers indicate unequivocally that the current and terraced alluvial deposits have a different geological representativeness from the ancient ones: the former extend areally but are film-like with a shape factor of approximately 1/45, while the ancient ones sometimes have thicknesses even greater than their areal extension. In many cases there are inversions of the relief with areas that were previously depressed, i.e. occupied by alluvial valleys, now found high up, constituting a large part of the Umbrian hills and vice versa. The lithological characteristics of the rocks and ancient alluvial deposits are the main cause of the landscape shapes present in Umbria. Through selective erosion, the least erodible deposits have formed reliefs and most of the historic inhabited centers and localities of Umbria have been built on these reliefs. The detailed geological information available for Umbria allows us to have a very precise picture of the geological units, or parts of them, which are more resistant and those which are less resistant, allowing us to identify the forms which are in relief or very prominent from those which are valleys, in addition of course to the flat alluvial valleys.

Geotourism: empowering geologists or engaging the masses?

Motti A.*, Berti F., Natali N. & Ogna M.

Regione Umbria, Sezione Geologica.

Corresponding author email: amotti@regione.umbria.it

Keywords: geotourism, geosite, heritage.

A geosite is a geological asset worthy of protection due to its representation of "geodiversity", showcasing the geological richness of a region and its intricate links with landscape, social, cultural, human, and economic aspects. Geotourism plays a pivotal role in appreciating and preserving geosites sustainably. The Sezione Geologica has established an online platform for proposing geosites to involve a wider audience, but minimal proposals have been received despite significant efforts in information dissemination. This highlights the perception that only industry experts possess the requisite knowledge for accurate identification and dissemination of geosites. Information provided by tourist operators or economic entities often tends to be biased, disseminating irrelevant or erroneous information. The challenge lies in balancing the expertise of geologists with engaging the broader community in identifying and promoting geosites. Collaborative efforts are needed to leverage both the specialized knowledge of geologists and the insights of local communities and tourists. To address the limited public response, the regional Sezione Geologica initiated a project to design the "Spoleto-Norcia geo-tourist route," accompanied by general and geological information, photos, and brief explanations accessible to non-experts. The project utilizes apps like Komoot and Conota Camera for route planning, photo capturing, and note-taking, enhancing user experience with additional data such as project details, GPS coordinates, and environmental information. The objective of this initiative is to enhance public understanding of the region's geological heritage by invoking emotions, imagination, and curiosity among hikers. Notable historical and artistic landmarks, as well as efforts aimed at preserving cultural heritage and public safety, are highlighted, with special attention to remnants of railway infrastructure. The former Spoleto-Norcia railway route is being traversed on foot, focusing on identifying visible geological features along 5 km segments. The project timeline includes 5 months for data acquisition and three additional months for finalizing products. In conclusion, the project aims to balance leveraging geologists' expertise with fostering community engagement in exploring and promoting geosites. Through collaborative efforts, sustainable management and appreciation of geological heritage for present and future generations are ensured.

The relevance and current state of the Villaggio del Pescatore lagerstätte (Campanian, Italy)

Muscioni M.*[1-2], Arbulla D.[3] & Fanti F.[1-2]

[1] Dipartimento di Scienze Biologiche Geologiche e Ambientali, Università di Bologna. [2] Museo Geologico G. Capellini, Università di Bologna. [3] Museo Civico di Storia Naturale di Treste.

Corresponding author email: marco.muscioni2@unibo.it

Keywords: Villaggio del Pescatore, paleobiology, geosites.

Located in the Duino-Aurisina municipality, about 20 km to the north-west of Trieste, the Villaggio del Pescatore (VdP) paleontological site stands as the most informative early/middle Campanian lagerstätte in southern Europe. The site is geographically located in a territory that includes a remarkable number of geological, archaeological, and environmental gems and not by chance is formally included into the ISPRA Italian Geosites Inventory. Ever since the 1990's, fossil beds have resulted extremely productive, yielding an unparalleled sample of the diversity in the Cretaceous European ecoregion. In addition to multiple articulated hadrosauroid dinosaurs, crocodylomorphs and teleosts, abundant invertebrate and floral remains were recently reevaluated, revealing a greatly underestimated diversity. In particular, the systematic revision of historic, neglected, and newly acquired data into a unified framework (which include all stratigraphic, taphonomic, geochemical, palaeobotanical, micro-anatomical, and palaeoecological aspects) set the ground for determining lines of investigations with immediate effects. Relevant examples are new micro-tomographic and fluorescence analyses on vertebrate remains (in collaboration with the Elettra Synchrotron, Trieste), the identification of a diverse associated biota (including articulated insects, crustaceans and megafloral remains), and microbiological interactions as a key component on the taphonomy and genesis of the site. Furthermore, careful inspections at the quarry in 2024 allowed to identify and map many diagnostic, in situ specimens exposed to weathering agents. Unfortunately, the lack of fundings and the complex management requirements have hindered extracting activities, which are currently at a standstill. From a scientific perspective, the VdP stands as one of the most relevant geosites in Italy having, in addition, a potential for promoting educational activities related to geosciences and economic income related to cultural tourism. A clear stance by the scientific community may effectively trigger positive institutional actions toward its protection and promotion.

Geoheritage and cultural heritage in the Sesia Val Grande UNESCO Global Geopark (North-West Italy): new approach for monitoring and assessing geosites and cultural sites

Negri A.*[1], Storta E.[1], Guerini M.[1-2], Khoso R.B.[1], Mantovani A.[3] & Giardino M.[1]

[1] Dipartimento di Scienze della Terra, Università di Torino. [2] EDYTEM - Université Savoie Mont Blanc.
[3] Istituto di Geoscienze e Georisorse, CNR, Torino.

Corresponding author email: arianna.negri@unito.it

Keywords: geoheritage, geoparks, geosites.

UNESCO Global Geoparks (UGGp) are defined as single, unified geographical areas where sites and landscapes of international geological significance are managed in a holistic manner, i.e. with a comprehensive approach to protection, education, and sustainable development. The territory of a UGGp usually contains an extraordinary geodiversity, such as a great variety of abiotic natural elements and landscapes, deriving from different geological processes. The Sesia Val Grande UNESCO Global Geopark (SVUGGp) is recognised for its high geodiversity, but several sites with historical, cultural and archaeological interest can be found. However, while the scientific community acknowledges the significant cultural value of geosites, cultural heritage inside UGGps is usually undervalued, receiving insufficient attention in the context of UGGps, even though many cultural sites exhibit deep connections with geological features. Cultural sites are a valuable resource for the geopark, especially those showing strong relationships with geological features. Since currently no methodologies allow a comparable qualitative assessment between geosites and cultural sites, it is important to fill this gap in order to provide the SVUGGp and other geoparks with a tool for integrating the geoheritage and the cultural heritage in the administration of the territory. Therefore, we propose a specific assessment for cultural sites, including parameters that are comparable with those adopted for geosite assessments. The research aims to enhance knowledge on effectively safeguarding, preserving, and promoting cultural heritage within the framework of a UGGp. In order to successfully integrate cultural heritage within the SVUGGp management and promotion strategies, the assessment methodology developed by (Brilha, 2016) has been adapted for the cultural sites, including criteria of cultural significance. This allowed the comparison of the assessment of cultural sites with the assessment of geosites within a geopark. Due to its exceptional geodiversity and remarkable cultural heritage, the SVUGGp exemplifies the characteristics necessary for a first attempt at applying the modified methodology. A comparable number of geosites and cultural sites have been selected due to their high importance, and they have been equally considered during the assessment process. Finally, the comparison of the two types of sites allows the promotion of a comprehensive approach for the conservation and the management of both cultural and natural heritage, preserving the natural resources and safeguarding the cultural heritage of the area, by successfully incorporating cultural sites into the geopark management framework.

Brilha J. (2016) - Inventory and Quantitative Assessment of Geosites and Geodiversity Sites: a Review. Geoheritage, 8, 119–134, https://doi.org/10.1007/s12371-014-0139-3.

Geodiversity - biodiversity relationship for the identification and conservation of priority natural areas in urban ecosystems. The case study of the city of Rome

Pica A.*[1], Montaldi A.[2], Capotorti G.[2] & Del Monte M.[1]

[1] Dipartimento di Scienze della Terra, Sapienza Università di Roma.
[2] Dipartimento di Biologia Ambientale, Sapienza Università di Roma.

Corresponding author email: alessia.pica@uniroma1.it

Keywords: geo-biodiversity relationship, urban environment, anthropogenic erosion/accumulation impact.

The increasing cities' expansion and density of population poses many challenges upon sustainability of urban ecosystems. Scientific knowledge about urban habitats - species relationships became essential to improve biodiversity conservation success, ecosystem service provision, and human well-being. The recent trend in nature conservation studies considers the abiotic conditions of importance for the selection of areas for biodiversity conservation.

In such a context, the analysis of the urban geomorphology of Rome (Italy) highlighted how prevailing landforms and processes in the city current landscape are related to anthropogenic erosion and accumulation (Del Monte et al., 2016; Vergari et al., 2020; 2022) affecting the natural vegetation potential (PNV; Farris et al., 2010), because of the alteration in both structural and compositional terms, consequent to changing in outcropping lithologies and natural morphology.

The aim of this work is the analysis of natural and anthropogenic geomorphodiversity effects on PNV, based on urban geomorphological survey and geometric and morphometric analysis of the anthropogenic landforms.

The procedure to characterize anthropogenic landforms and study responses and adaptation of actual vegetation within them is illustrated here by means of specific case studies. Morphometric analyses first allow volumes of anthropogenic deposits to be quantified, intercepted lithologies to be recognised, and soil and drainage changes to be estimated. Following targeted vegetation surveys allow the shift from undisturbed successional models to be assessed.

Understanding where and how morphological alterations modify local PNV is crucial for planning and designing suitable geodiversity-biodiversity restoration actions and resilient Nature based Solutions.

Corresponding author email: g.pira68@gmail.com

Keywords: geo-environmental heritage, nature trails, religious tourism.

This contribution aims to disseminate some geological, naturalistic, and historical-cultural aspects of a rural area with low population density and for many years the subject of progressive depopulation, falling within the seismic crater of 2016 and little known, in which it is necessary to conserve the environment and enhance territorial resources. A first element of interest is represented by the ancient Ginocchielli mine located near the municipality of Poggio San Vicino (MC), subject to limited exploitation of manganese, in which atypical mineralogical species were found in the sedimentary environment of the region. The deposit is in an external position of the Umbria-Marche thrust system, in the Mesozoic limestone succession adjacent to the External Marche Basin, in the central Ancona sector between the Esino and Musone rivers. Based on the mineralogical studies carried out (Cozzupoli & Matteucci, 1983), the origin of the mineralizing fluids of probable epithermal origin should be traced back to a crystalline basement, the position, nature, and depth of which are still unclear. Between the Upper Messinian and the Upper Pliocene-Lower Quaternary, regional-scale extensional tectonics (Centamore et al., 1980) would have induced hydrothermal manifestations of deep origin also in the Marche, which led to the deposition of singular mineralization otherwise found in the Tyrrhenian margin. The former mining site is located adjacent to the Gola della Rossa Natural Park - San Vicino and Canfaito Mountains Nature Reserve, which together constitute the largest protected area in the Marche (~12,000 ha). The territory, being characterized by limestone gorges alternating with small areas of the valley floor, reveals a notable naturalistic value due to the fauna, the conservation of plant environments and their extension, together with the presence of biological corridors (Biondi et al., 2008). We must then include the numerous monuments and places of worship present in the area, some of which are characterized by millenary stories and legends (Castagnari, 1990), whose architecture is closely connected to the use and processing of native stones and materials. Among these we note the Abbey of San Salvatore di Valdicastro (AN), the Benedictine Abbey of Sant'Urbano all'Esinante (MC) and the Sanctuary Madonna della Grotta (AN). The objective of this work is to promote the territory and avoid further depopulation by virtue of the huge heritage present. Being also connected by a network of routes and paths, the area lends itself to naturalistic hiking activities involving flora, fauna, geology, environment and culture, a territory in the past the subject of pilgrimages and religious walks.

The Italian Geosites Inventory: making travellers aware through knowledge of geodiversity

Primerano P.*, Brustia E., Funaro M., Gerardi M., Lucarini M., Olivetta L. & Pompili R.

Dipartimento per il Servizio Geologico d'Italia, ISPRA, Roma.

Corresponding author email: paolo.primerano@isprambiente.it

Keywords: geoheritage, geodiversity, geosciencesIR.

Since the early 2000s the Italian peninsula geoheritage has been catalogued to promote the conservation and the dissemination of geological knowledge (Giovagnoli, 2023). The Italian Geosites Inventory is a free access geodatabase, in which users can consult, around them and in the territories they wish to discover, places where it is possible to appreciate geological characteristics.

An interactive map and a search service is available in the Inventory for searching information about approximately 3000 geosites registered across the national territory. This is a number that is continuously updated as the work proceeds simultaneously with the insertion of new geosites, with the revision and if necessary, the elimination of geosites already present in the database, or outdated.

Each user can actively participate in the database growth and maintenance proposing new geosites by the submission to ISPRA (Italian Institute for Environmental Protection and Research), of a form template with the relevant descriptions. The geologists of the Geological Survey of Italy will deal with the proposal and in some cases the Italian Geological Surveys Network (RISG) could even be involved.

In some cases, in fact, the collaboration between ISPRA and the Geological Regional Surveys will lead to shared inventories at a regional level. This kind of interchange of information has already led to the drafting and implementation of some regional laws that have been approved to protect and enhance the regional geological heritage. The geoheritage is in fact not protected in Italy by national law yet.

In the year 2023, a total of approximately 12.000 accesses on the National Geosite Inventory were detected by the ICT systems, with an average of 1.000 accesses per month. Only accesses via the homepage were considered. Furthermore, the pages visited were almost 42.000 with a daily average of 115 pages (3.450 per month).

To reach even as many citizens and professionals as possible, on the occasion of the GeoSciencesIR project, a harmonized GeoSciML/INSPIRE compliant database will be published.

The INSPIRE Consolidated UML model for geosites is the application schema Geology (GE). The semantic harmonization will take place through the use of code list. The dataset will be harmonized and shared in compliance with the FAIR (Findable, Accessible, Interoperable, Reusable) principles.

A work of updating is being carried out and all the records will agree with the recently revised and validated geosite definition. The first update concerns the integration with the information deriving from the national coverage of the geological cartography at the 1:100,000 scale, the CARG cartography with the related explanatory notes, and the information deriving from the reports filled by the proposers themself, attached within each form of the Italian Geosites Inventory.

Giovagnoli M.C. (2023) - The Italian Geosite Inventory: Past, Present, and Future. Geoherit., 15(2), 69, https://doi.org/10.1007/s12371-023-00843-8.

Gabara Park: a magic place to recall sicilian mining history

Punturo R.[1], La Rosa A.[2], Maniscalco R.[1] & Cirrincione R.*[1]

[1] Dipartimento di Scienze Biologiche Geologiche e Amabinetali, Università di Catania. [2] Comune di San Cataldo.

Corresponding author email: rosolino.cirrincione@unict.it

Keywords: geoturism.

The "Gabara" sulfur mine area, dates to the early 19th century, and is located within the Municipality of San Cataldo (CL) on the western side of Gabara Mt, about 3.5 km north-west of the village.

It lies in a Protected forestry eucalyptus area, with trees planted during the late 1950s.

At least ten mining concessions, rich in about 30 underground tunnels allowed the sulfur mineralized layer to be reached via stairways carved into the rock. The rock was then transported on the shoulders of young guys, "carusi", or carried on inclined slopes by wagons pulled by winches. Some tunnels "discenderie" are today still accessible. "Calcaroni" and Gill ovens, for separating the sulfur from the gangue, are also scattered around the park. Remains of old buildings, used as residences for the sulfur mine operators, rooms for steam winches, stables for the mules used to transport the mineral to the town, and roast waste are present.

Gabara is starting to become a popular geo-mining park since has a particular charm testifing to an almost family-run sulfur extraction activity. It preserves the memory of past generations for the benefit of the present and future ones. Thanks to the active collaboration of several institutions (municipal administration, mining district, Superintendence of the BB.CC., Forestry Company and Forestry Inspectorate) and the donations of many entrepreneurs, artisans and artists it is possible to transform a place of memory in an exciting tourist route, capable of telling the story of a ancient mining civilization.

A tourist route called in memory of the the early twentieth century Pirandello novel "Ciàula scopre la Luna makes known the story of the sulfur – called devil's gold - which for over two hundred years was the driving force of the national and Sicilian economy national.

The site, whose valorization started in April 2015 and still ongoing, is today an exciting journey into the world of sulfur, between geology, mining archaeology, anthropological history, literature, contemporary art and theatre.

The geology is clearly readable in the rocks, which tell the history of the "Messinian salinity crisis of the Mediterranean"; mining archeology is present with the remnants of sulfur mines, historical photos tell the anthropological life in the sulfur mine. Along the tracks you will also encounter writers who gave voice to the sicilian mining world, such as Sciascia, Verga, Consolo, Hamilton, Bonavia, Pirandello and poets such as Giuliana, Buttitta, Lo Presti Russo. The park is also enriched with installations of contemporary art works by Giuliana, Barba, Politano. During the visit, some actors recall the terrible illegal sale or rental of boys and actresses portray mothers who accept to give a child to the picconiere or perform the desperation after an underground accident.

Today, Gabara has been included in the National Network of Museum and Mining Parks ReMi_ISPRA and an agreement for fruition and valorization has been signed with the University of Catania , Department of Biological, Geological and Environmental Sciences.

Paintings and writings by Carlo Levi: an unlikely combination with geology?

Sabato L.* & Tropeano M.

Dipartimento di Scienze della Terra e Geoambientali, Università di Bari "Aldo Moro".

Keywords: dissemination, geotourism.

Portions of the three orogenetic elements (foreland, foredeep and chain) characterizing the geology of southern Italy can be observed in the Matera Territory. These elements are represented by the Apulian Foreland, the Bradanic Trough and the southern Apennines. It is possible to briefly outline the evolution of this orogenic system by tracing an itinerary that starts from the city of Matera (located within the Apulia Foreland), continues in the small town of Grassano (within the Bradanic Trough) and then reaches the small town of Aliano (within the Apennines Chain). This proposed itinerary connects three places linked together by the presence in the '30s of Carlo Levi, political exile during the fascist regime in such localities. This artist, who came from a big and modern city, Turin, narrated and painted places of the "deep South", capturing not only relevant aspects of Lucanian cultural anthropology but also the geological ones, almost unconsciously. Indeed, the people and the landscape are often the protagonists of his paintings and of the well-known book "Christ Stopped at Eboli" (Levi, 1945; 1947).

A selection of Levi's artworks can be utilized to guide tourists along a journey (Tropeano et al., 2011; Sabato et al., 2019), illustrating the geology of the area through the eyes (i.e. the paintings), and, above all, the words (i.e. the book) of Carlo Levi.

Keywords: Adria, Murge and Premurge, southern Italy.

In southern Italy, the Puglia Region and the estern part of the Basilicata Region, as a whole, correspond to the largest in situ remnant of the Adria Plate, the old continental plate almost entirely squeezed between the Africa and Eurasia Plates. In such a context, Puglia and estern Basilicata respectively represent the foreland and the foredeep of the Southern Apennines Chain. Both are virtually undeformed sectors of Adria (where the crust is still rooted to its mantle), while other territories of the plate are and/or were involved in subduction/collision processes. Such a worldwide geological uniqueness can be geotouristically appreciated in the Murge territory, where a Cretaceous sector of the Apulia Carbonate Platform (one of the largest peri-Tethys carbonate platforms) crops out, and in the adjacent Premurge territory, where the southwestward lateral continuation of the same platform (being flexed toward the Southern Apennines Chain) is covered by thin Plio-Quaternary foredeep deposits.

An "anomalous" regional middle-late Quaternary uplift led to expose both a thick Cretaceous succession in the Murge area, where shallow-water carbonates of the Apulia Platform crop out and record part of the ancient evolution of the continent, and a Plio-Quaternary covering succession, recording the outer Southern Apennines foredeep development.

Despite the presence of numerous geological singularities of international relevance, it would be important, from a geotourist point of view, to propose a regional framework of the geology of the area before introducing visitors to the significance of the individual geosites, whose importance could be amplified if included in the geoevolutionary context (Tropeano et al., 2023).

Tropeano et al. (2023) - Geological uniqueness and potential geotouristic appeal of Murge and Premurge, the first territory in Puglia (Southern Italy) aspiring to become a UNESCO Global Geopark. Geosci., 13, 131, https://doi.org/10.3390/geosciences13050131.

Heritage stones: the case of Aurisina Limestone to promote geodiversity in the Classical Karst cross-border area

Urban I.*, Bridi E., Cesare B., Mazzoli C. & Preto N.

Dipartimento di Geoscienze, Università di Padova.

Corresponding author email: ingrid.urban@unipd.it

Keywords: Kras-Carso, Aurisina limestone, heritage stone.

The Classical Karst Region (Kras-Carso) is a cross-border area shared by Italy and Slovenia, from which the international scientific term "karst" was adopted (Jurkovšek et al., 2016). The geodiversity of the Classical Karst is expressed by superficial and underground features, a particular hydrogeological network and a rich paleontological record correlated to the Cretaceous-Paleogene evolution of the former Adriatic-Dinaric Carbonate Platform (Jurkovšek et al., 2016; Bensi et al., 2022). The Cretaceous-Paleogene sedimentary succession comprises the Upper Cretaceous, rudist-rich and shallow water "Aurisina Limestone" (Bensi et al., 2022), which has historically played a significant role in the Karst region. Indeed, it has been used since Roman times for construction purposes, due to its geotechnical and ornamental attributes. This is confirmed by evidence of quarrying activities and by the widespread use of this material on both regional and extra-regional scales (Previato, 2015). The export of the Aurisina limestone re-experienced a significant growth in the 18th and 19th century with the establishment of the free-trade port of Trieste and the construction of the Austrian Southern Railway, linking Vienna to the Adriatic Sea (Carulli & Onofri, 1969) and continues nowadays worldwide. The preservation and promotion of the geodiversity of the Classical Karst Region has been the object of European cross-border projects for at least two decades. Following the definition of the Kras Carso Geopark within the KRAS-CARSO 2007-2013 project, the 36 months long Interreg project Kras-Carso II (2023-2026) was funded. The project partners, belonging to local administrations and scientific institutions, are involved in the creation of the EGCT (European Group for Territorial Cooperation). As one of the project partners, the Department of Geosciences of the University of Padova has two main objectives: the listing of the Aurisina Limestone among the Heritage Stones recognised by the IUGS (International Union of Geological Sciences) and the scientific support to the creation of educational contents. The ratification as an IUGS-Heritage Stone is subordinated to the submission of a detailed report of quarry exploitation and architectural use through time. Here we present a first dataset from the literature and the historical archives. Additionally, as part of a wider network of integrated tourism products, we display a collection of artistic photomicrographs of rocks, representing the geological uniqueness of the Classical Karst Region. This collection will be the focus of a series of traveling exhibitions for the general public.

The Water and the Rock: a geotouristic route through the geology of springs and fountains in Matera (Basilicata, Southern Italy)

Venezia V.*, Bellini F., Festa V., Sabato L. & Tropeano M.

Dipartimento di Scienze della Terra e Geoambientali, Università di Bari "Aldo Moro".

Corresponding author email: vitantonio.venezia@uniba.it

Keywords: Sassi di Matera, springs, geotourism.

The old town of Matera is one of the most known tourist destinations in Italy, since his complex network of caves, tunnels, cisterns, houses, and churches, dug in carbonate soft-rocks is a worldwide example of perfect and unique integration between human urban development and natural abiotic background. This bond lies not only in the excavation of the stunning landscape of the "Sassi" (the local name of the old town) in the outcropping calcarenite rock, but also in the capacity of the local population to manage and exploit the natural source of water occurring near the town and in the surroundings. In this work we propose a geotouristic route to discover this bond, showing some historic fountains present in the town centre (Fontana Ferdinandea) or in the surroundings (Fontana di Vite, Fontana Santa Candida and Fontana Cilivestri) and enhancing the geological settings that determine the presence of the water. This fountains in fact are built in correspondence or near natural springs, often located at the top of clay hills overlied by sandy and gravelly (and then porous) deposits. Once captured, the water was used in place or displaced to the town, where was stored both in domestic cisterns and in a very big public one, called "Palombaro lungo", now already become a tourist attraction.

Starting from the countryside, the path will conduct the visitors to a journey within the geology of the area until the deep heart of the town. On this way, the visitors will better understand why and how the Sassi could have been habitable from ancient times to the modern era.

Promotion and enhancement of the geoheritage of the Dindéfélo Geopark Project of the Dindéfélo Community Nature Reserve (Kédougou, Senegal)

Youm C.I.*[1], Doumbouya M.F.[1], Gueye A.[1], García-Villalba E.[4], Sow I.S.[3], Samba R.[5], Thiao G.[5], Errami E.[2], Morales J.A.[4] & Sow E.[1]

Keywords: Senegal, geo-development, geopark.

In 2020, the Ministry of Mines and Geology, through the Directorate of Prospecting and Mining Promotion (DPPM) and the National Geological Servey of Senegal (SGNS) implemented a geo-development strategy for exceptional geosites, aimed at the conservation and enhancement of Senegal's geological heritage. The pilot site of the project as a potential Geopark is Dindéfélo, a Community Natural Reserve (RNCD) created in 2010 and located in the Bassari Country (Kedougou region), declared a UNESCO World Heritage Cultural Landscape. The development of this geoheritage will promote economic growth in this area below the poverty line.

This reserve has a geological history that extends from the Paleoproterozoic to the Neoproterozoic. Postdating the Birimian, the initiation of the Meso-Neoproterozoic Madina-Kouta basin (C. Delor et al., 2010) is triggered by a filling of coastal and glacial deposits. The series begins with fluvial deposits (Kafori Formation) fed by the alteration of the Birimian bedrock and continues with the local installation of a carbonate platform (Pelel Formation). Then come the coastal deposits (Dindéfelo Formation). The deposits of glacial tillites around 700 to 630 Ma testify to periods of glaciation (Walidiala Formation) in addition to horizons of post-sedimentary alteration and volcanic activity. This long and rich geological history, which lasted about 2000 Ma, has given rise to a Geoheritage which, in addition to scientific, educational and socio-economic interests, is a real ecological bulwark for highly threatened biological species in Senegal (Youm et al., 2018).

To this end, a geodiversity assessment study was carried out with the objective of enhancing and disseminating geosites. In collaboration with the Cheikh Anta Diop University of Dakar, the University of Chouaïb Doukkali of Morocco and the University of Huelva of Spain, the following achievements have been made on the Dindéfélo Geopark Project: the characterization of geological formations, a census and mapping of geosites (about sixty). A series of tourist and communication panels and posters have been designed to facilitate understanding and support for explanations of the different aspects in line with the needs of guides. And installed in the geology room (lithotheque), the ecomuseum, the Visitor Centre with a local management committee, and at the level of the main tourist circuits. On the other hand, a summary guide on the geology of the reserve. Documentaries for the public were made as well as the construction of roads and access tracks.

The key activity remains the training of tourist guides and teachers and the sensitization of the local population. The training of tourism stakeholders has helped to establish a foundation of knowledge in geology. Two very interesting examples of valorization: the Polyclinic Hospital and the Museum of Earth Sciences of the Cheikh Anta Diop University in Dakar

Corresponding author email: filippo.bellini@uniba.it

Keywords: geotouristic map, Laterza, digital tools.

Geotourism, with its focus on geological knowledge, is emerging as an important tool for the appreciation and conservation of natural heritage. In addition to its cultural and educational importance, geotourism offers a sustainable approach, in line with the goals of the 2030 Agenda, by diversifying tourism patterns. A key development is the use of digital tools, in particular geotouristic maps, to facilitate sustainable tourism initiatives.

The proposal covers the territory of Laterza, a rural town in the Murgia Materana region of southern Italy, characterised by Cretaceous limestone overlain by Quaternary deposits. The landscape has been shaped by the impressive "Gravina di Laterza", an up to 167 m deep canyon stretching for almost 14 kilometres. In order to highlight the geological importance and resources of the area, a geotouristic map has been developed highlighting the geotouristic path outlined, the outcropping sites, the panoramic viewpoints and the cultural landmarks. In addition, the integration of geotouristic data into OpenStreetMap, a collaborative mapping tool, increases accessibility and community engagement.

Digital tools play a crucial role in enhancing the geotourism experience. Geotouristic maps, accessible through mobile devices and online platforms, provide visitors with detailed information about geological sites and cultural attractions. In order to make the geotouristic map proposal more precise, a 3D graphic has been created of a specific area related to the so-called "Via Concerie" of Laterza. Thanks to the development of satellite images and remote sensing techniques, it is possible to create 3D maps within Geographic Information Systems (GIS). The integration of satellite imagery, digital terrain model data, geological information from the Geological Survey and urban details (from OpenStreetMap) into GIS allows the generation of detailed 3D representations of the terrain.

By combining geological narratives with digital mapping technologies, this initiative lays the groundwork for a comprehensive geotouristic proposal, ensuring a nuanced appreciation of Laterza's geological heritage.

Monitoring and identification of environmental crimes: a satellite imagery and machine learning approach

Binetti M.S.*[1-2], Massarelli C.[2] & Uricchio V.F.[2]

Keywords: semi-automatic classification plugin, eco-crimes, machine learning.

The analysis of territory using remote data is crucial for monitoring and identifying environmental changes. Environmental crimes, known as eco-crimes, are regrettable in many areas worldwide. To address this issue, we use an automated procedural approach to identify specific eco-crimes through changes in land cover. Using the Semi-Automatic Classification Plugin (SCP) in the QGIS environment, we can conduct a semi-automatic classification of images obtained through remote sensing sensors, allowing automatic data download and pre- and post-processing (Congedo, 2016). The SCP facilitates direct connection to the Copernicus Open Access Hub, the primary data source acquired from the Sentinel mission (ESA). A wide range of spectral indices can be calculated, including NDVI (Normalized Difference Vegetation Index), SMI (Soil Moisture Index), NDWI (Normalized Difference Water Index), NDTI (Normalized Difference Tillage Index), EVI (Enhanced Vegetation Index), ARVI (Atmospherically Resistant Vegetation Index), SAVI (Soil Adjusted Vegetation Index), BSI (Bispectral Index), TCB and TCG (Tasseled Cap Brightness and Greenness). These indices allow a comprehensive assessment of the state of the territory, from vegetation health to soil moisture, from the presence of water to urbanization, thus enabling the identification of significant changes. Subsequently, the extracted spectral signatures are subjected to a change detection analysis to identify variations over time, essential for identifying territorial changes. Through machine learning (ML) algorithms, the processed data are classified to automatically identify features of interest, such as potential illegal activities or significant environmental alterations. At the end of the classification process, the results obtained are subjected to a validation phase to confirm the accuracy of the analyses conducted. In conclusion, this study demonstrates the effectiveness of using satellite images and the SCP plugin in QGIS for monitoring and identifying territorial changes (Tempa & Aryal, 2022). This methodology represents an effective and efficient approach to environmental monitoring and for conducting analyses on the state of the territory and environmental protection.

Corresponding author email: manuel.roda@unimi.it

Keywords: 3D outcrop models, quantitative multiscale structural analysis, high-temperature deformation.

Due to the ongoing development of new technologies, numerous instruments are now available to assist in geological investigations across various scales. These techniques, such as 3D outcrop modeling through aerial photogrammetry and quantitative microstructural analysis, prove valuable in studies of crystalline basement rocks. This contribution merges traditional and quantitative multiscale structural analysis techniques applied to the migmatitic rocks of the Valpelline Series within the Dent-Blanche Tectonic System in the Western Alps. Conventional structural analysis is augmented by extracting structural data from 3D models of representative, smoothly exposed outcrops. Quantitative microstructural and mineral-chemical analyses are integrated to establish links between structural and metamorphic evolution.

This approach enables the identification and correlation of foliations that evolved during three tectono-metamorphic stages. The first stage (D1) involves solid-state deformation, characterized by an early foliation (S1) preserved within metabasite boudins enclosed within migmatite gneiss. The second stage (D2) corresponds to the dominant foliation in migmatite gneiss (S2), concurrent with regional-scale anatexis and the growth of garnet and cordierite. The third stage (D3) is associated with the late folding of S2 and the development of a sillimanite-rich axial plane foliation (S3), which wraps around garnet and cordierite.Finally, this work discusses the advantages and limitations of each innovative methodology while emphasizing the importance of using manually acquired field data as ground control (Caso et al., 2024).

Caso F. et al. (2024) - Combining traditional and quantitative multiscale structural analysis to reconstruct the tectono-metamorphic evolution of migmatitic basements: the case of the Valpelline Series, Dent-Blanche Tectonic System, Western Alps. Corresponding author email: amerigo.corradetti@units.it

Keywords: SfM-photogrammetry, fault analysis, orthorectification.

In the realm of geological studies, inaccessible, obstructed, and potentially distorted outcrops have long posed challenges to achieving clear interpretations. However, over the past decade, the proliferation of easily deployable multi-sensor Uncrewed Aerial Vehicles (UAVs), commonly known as drones, alongside the rapid advancement of digital photogrammetric processes, has facilitated the creation of three-dimensional representations of geological exposures. These representations, termed virtual outcrop models, provide a means to extract quantitative data from otherwise inaccessible outcrops and generate orthorectified views conducive to meaningful, undistorted, and reproducible interpretations.

In this study, we investigated a quarry exhibiting platform carbonates from the Cretaceous period. These well-layered carbonates are prominently exposed throughout the quarry, lending three-dimensionality to the site. Although the quarry is inactive, its internal space is presently utilized for commercial purposes. The primary geological feature observed within the quarry is a conjugated normal fault system, which served as the primary focus of data acquisition.

Significant geological structures were only discernible after overcoming accessibility barriers through drone-based photo acquisition, followed by the construction of VOMs using Structure-from-Motion Multi-View Stereo (SfM-MVS) photogrammetry workflows, and subsequent data extraction and analysis. The establishment of statistically derived viewpoints facilitated the creation of meaningful orthomosaics, enabling further observation and measurements, such as fault stratigraphic separation diagrams. Notably, this workflow unveiled deformation stages not initially recognized in the field.

Drawing fault and bedding lines on the orthomosaic, which was favorably oriented, enabled the interpretation of the primary fault system, leading to the identification of multiple deformation events and serving as the foundation for generating fault separation diagrams.

Improving geological understanding through the integration of UAV aerial survey and LiDAR scanning: advantages and limitations of a multiscale hybrid approach

Fazio E.* & Cirrincione R.

Dipartimento di Scienze Biologiche, Geologiche e Ambientali, Università di Catania.

Corresponding author email: eugenio.fazio@unict.it

Keywords: multiscale investigation, UAV survey, portable LiDAR.

Integrating Unmanned Aerial Vehicles (UAVs) and Light Detection and Ranging (LiDAR) technology has led to significant advances in geological studies to obtain accurate data about the Earth's surface and subsurface features. This hybrid approach has greatly improved our understanding of geological processes. Here we explore its applications, benefits, and limitations through a selection of study cases. UAVs equipped with cameras or LiDAR sensors capture high-resolution images and elevation data. LiDAR sensors emit laser pulses and measure the time it takes for the light to travel to the ground and back, resulting in detailed elevation models (point clouds). Cameras provide visual information about the landscape. The advantages of this technology are based on: rapid data acquisition, high spatial resolution, and 3D modelling. UAVs cover large areas efficiently, even in rugged terrain and hazardous areas. Geological mapping, landform identification, and hazard assessment benefit from rapid data collection. Detailed images help identify geological features such as rock outcrops, fault lines and sedimentary layers. Geologists analyze these images to decipher the geological history of an area. Combining LiDAR data with imagery enables accurate 3D reconstructions of the terrain. Virtual exploration of rock formations and fault networks becomes possible. On the other hand, there are several limitations to consider: local coverage, weather dependency, and complexity of data processing. UAV surveys are area-specific. Researchers need to plan flight paths carefully. Large area coverage requires additional methods (e.g. satellite imagery). Adverse weather conditions (rain, wind, low cloud cover) affect data quality. Optimal survey times must be chosen based on weather forecasts. Handling large data sets from UAV surveys requires robust algorithms. Extracting meaningful geological information requires thorough processing. Classically, ground-based LiDAR systems, mounted on tripods or vehicles, emit laser pulses horizontally or vertically, capturing detailed point clouds of the terrain. More recently, terrestrial LiDAR scanning can also be performed using portable devices (smartphones, tablets). Advantages are high accuracy, 3D visualization, change detection, and mineral exploration: LiDAR provides accurate elevation data for topographic variation, slope stability assessment and fault mapping. Subtle changes in the landscape are revealed by LiDAR accuracy. Detailed LiDAR models improve geological interpretation. Researchers can virtually explore rock formations, fault geometries and sedimentary layers. Repeated LiDAR scans over time allow monitoring of landscape changes (erosion, landslides, fault movements). Hazard assessment benefits from this temporal perspective. LiDAR helps locate potential mineral deposits by mapping geological structures and alteration patterns. Limitations are: cost, vegetation interference, and instrumental accuracy challenges. Terrestrial LiDAR systems can be expensive to deploy and operate. Researchers must weigh the benefits against the costs. A dense forest interferes with ground measurements and affects LiDAR accuracy. Careful selection of scan locations minimizes interference. Surface roughness, reflectivity and sensor limitations affect data quality. Calibration and quality control are essential.In summary, aerial UAV surveys and terrestrial LiDAR scanning complement each other. Geologists use these tools strategically to overcome limitations and gain comprehensive insights into the Earth's dynamic processes. Whether mapping fault lines, assessing landslide risk or exploring mineral deposits, these technologies continue to advance geological research. As a result of this methodology, the role of the geoscientist and digital cartographer will remain strategic throughout the data publication process and will be able to maintain control of dissemination and communication.

Development of innovative digital methods for assessing the stability of rock masses in the context of railway infrastructure

Foletti M.G.*[1], Menegoni N.[2], Poggi E.[3], Maino M.[1] & Benedetti G.[3]

[1] Dipartimento di Scienze della Terra e dell'Ambiente, Università di Pavia. [2] Ali I. Al-Naimi Petroleum Engineering Research Center ANPERC, King Abdullah University of Science and Technology KAUST . [3] Italferr S.p.A.

Keywords: digital outcrop model, slope stability, tunneling.

In the recent years, the fracture analysis and the geomechanical characterization of rock masses has been significantly improved by the advancements in photogrammetric surveying techniques and the utilization of Structure from Motion (SM) algorithms. This has enabled a more efficient, secure, and accurate approach to extracting a large amount of 3D information from Digital Outcrop Models (DOMs). Particularly, the improvement of sensors and Remotely Piloted Aircraft Systems (RPAS), becoming increasingly manageable, reliable, high-performing, and cost-effective, has greatly facilitated the use of digital photogrammetry in the geomechanical characterization of rock slopes in the field of geological and engineering design. Moreover, the recent increase in hardware and software processing capabilities (e.g., Agisoft Metashape) has reduced the processing time of DOMs and increased the quantity of 3D information that can be extracted, with particular attention to the discontinuity network and its characteristics. The lack of automatic or semi-automatic procedures for the analysis and parameterization of large three-dimensional datasets limits the adequate evaluation of fracturing and stability analysis of rock slopes. Often, analyses such as the Markland Test are employed; however, this approach, while useful, does not fully utilize geometric (such as spacing, fracture intensity, persistence of discontinuities) and spatial information (such as rock mass heterogeneity and the identification of critical areas). Moreover, traditional geomechanical surveys are manually conducted, following outdated methodologies. In this contribute we show a new approach aimed to improve both the robustness and smartness in the identification, targeting, and evaluation of criticalities of fractured rock slopes. The proposed workflow consists of the combination of i) manual extraction of discontinuity data from the DOM combined with ii) a kinematic analysis performed through an automated algorithm (ROKA) that provides an upgraded version of the traditional Markland's test. The results are validated through selected case studies derived from railway linear infrastructures designed or in progress thanks to the collaboration with Italferr S.p.A.

Characterization of Sardinian mine residues using Remote Sensing

Grita S.*[1-2], Casu M.[3], Sedda L.[3], Asadzadeh S.[4], Boccardo P.[2], Melis M.T.[3], Naitza S.[3] & De Giudici G.[3]

Corresponding author email: susanna.grita@uniroma1.it

Keywords: mine drainage, earth observations, iron minerals.

Southwestern Sardinia used to be the most important mining region in Italy and among the most relevant at the European scale. Extracted minerals include barium and polymetallic minerals bearing Pb, Ag, Cu, and Zn. Today, all these mines are closed, and their residues are now a potential source of pollution for soil, water, and air due to the weathering of the dumpsites (e.g. Cidu et al., 2011). However, results of recent scientific research have shown that the materials in these deposits can hold significant quantities of base metals and strategic elements, becoming a potential source of critical raw materials (Sedda et al., 2024).

Mapping and monitoring the acidity (pH) and geochemical conditions of legacy mine sites using non-contact sensing systems can be beneficial to understanding the spatial distribution of pollutants and the potential sources of acid mine drainage.

Spectral remote sensing data has proven effective in characterizing mine wastes from a geochemical/mineralogical point of view, allowing for an estimation of environmental pH conditions. Specific iron-bearing minerals, such as jarosite, which is considered a good proxy for acid mine drainage, can be unambiguously mapped via hyperspectral remote sensing data (Flores et al., 2021). Yet, this research domain remains largely understudied, due to the challenges related to spatial resolution in combination with the geometry and topography of the tailing sites. In addition, there is barely any study on the characterization of historical mine sites and tailings in Sardinia using remote sensing technology.

In this context, the present study aims to propose a methodology for characterizing the mineralogical and geochemical composition of mine wastes, by using a combination of proximal and remote sensing techniques over the legacy mines of Montevecchio and Ingurtosu.

During an initial field campaign, different parts of the mine site were sampled considering the texture and color variation of the surface. The sampling sites were also measured spectrally using a handheld spectrometer.

A combination of Sentinel-2 and WorldView-3 data coupled with ground/lab spectroscopy was used to determine the potential acid mine drainage of the test sites. The surface mineralogy was mapped using band ratios and a semi-automatic classification method. The resulting maps were verified by XRD, ICP-OES/MS analysis carried out on the collected samples. The aim was to see whether the technique was suitable for distinguishing different mineral phases in the test areas. This preliminary analysis is meant to pave the way for further research on detecting and mapping acid mine drainage using hyperspectral data acquired by satellite and airborne systems. As there is an increasing interest in mine residues as a potential secondary source of critical minerals, the proposed methods can also provide key information on the re-mining of such critical minerals in the environment.

InSAR pattern recognition and data analysis in characterizing high-risk seismic areas: a case study from L'Aquila city, Italy

Guerriero V.*[1], Sciortino A.[1], Marini R.[2], Mazzanti P.[2-3] & Tallini M.[1]

[1] Dipartimento di Ingegneria Civile, Edile-Architettura e Ambientale, Università degli Studi dell'Aquila. [2] NHAZCA S.r.l., start-up, Sapienza Università di Roma. [3] Dipartimento di Scienze della Terra & centro di ricerca CERI, Sapienza Università di Roma.

Corresponding author email: vincenzo.guerriero@univaq.it

Keywords: DInSAR, statistical analysis, high-risk seismic areas.

A statistical analysis of time series of A-DInSAR post-seismic data, acquired at the historical centre of L'Aquila city (Italy), in the time range 2010-2021, from the Cosmo-SkyMed and Sentinel-1 missions, has been carried out. This has allowed analysing the relationships between ground deformations and geological, hydrogeological features of the study area, as well as the level of seismic damage to budlings.

The analysis of these data is still ongoing and offers promising research perspectives in the field of subsoil characterization, based on satellite ground deformation data, also useful in seismic hazard characterization and mitigation.

This study is structured into three phases:

– Correlation between Permanent Scatterers (PSs) displacement and earthquake related building damage,
– Correlation between seasonal ground deformation and precipitation fluctuations,
– Correlation between PSs displacement and geological features.

The data analysis revealed a subsidence phenomenon still ongoing, involving the whole study area and showing local heterogeneities. A pattern analysis, involving cluster analysis and inferential statistics, has highlighted that higher ground deformation rate values are associated with higher damage levels to buildings (Sciortino et al., 2024). The correlation analysis between predisposing geological factors and SAR deformation has corroborated the hypothesis that subsidence rates are substantially controlled by the properties and thicknesses of shallower rock layers.

The main results are summarized below.

PSs displacements (i.e., ground deformation) are correlated with earthquake related building damage intensity,

Seasonal average subsidence rate fluctuations and precipitation oscillations exhibit significant statistical correlation,

PSs velocities are mainly controlled by the properties and thicknesses of shallower rock layers.

These evidences pave the way for a potential use of SAR data in mapping and characterizing high-risk seismic areas, at urban scale and at relatively low costs.

A 3D model to enhance, study and make an inaccessible quarry "virtually accessible": the example of Cava Porcili (Minervino, southern Italy)

Lippolis E.*, Spalluto L. & Tropeano M.

Dipartimento di Scienze della Terra e Geoambientali, Università di Bari "Aldo Moro".

Corresponding author email: elio.lippolis@uniba.it

Keywords: 3d models, Cretaceous quarry, photogrammetry.

The Apulian territory is rich in quarries, which have been used since ancient times to extract and produce materials for modern and traditional construction and architecture. Some of these quarries represent true windows into the geological past of the area, and especially those that have been abandoned deserve a second life. Cava Porcili is a limestone quarry located south of the town of Minervino Murge (southern Italy), situated on the western edge of the Apulian Foreland. The quarry presents a Cretaceous succession, which is rich in peculiar geological features: a thick succession of shallow water limestone, about 90 meters in total, numerous karst cavities, faults, and slumps, which can be very interesting for scientific, educational, and outreach purposes. The quarry is currently inaccessible for geotourism purposes, and given its great educational and scientific potential, an alternative way to admire it using new technologies is proposed here.

Our research aims to unlock the educational and scientific potential of Cava Porcili through the creation of two distinct 3D models, using drone photogrammetry. The first model will be a comprehensive 3D reconstruction of the entire quarry, offering a virtual tour of its geological wonders. The second model will focus on a specific portion of the exposed succession currently under study. These 3D models will not only deepen our understanding of this well-exposed Cretaceous succession but also make this geological treasure accessible to a global audience, enhancing it and making it known worldwide.

Fiastra DSGSD spatio-temporal evolution analysis by means of GPS and DinSAR data

Marino L.*[1-2], Cecere G.[2], Di Maio R.[1], Di Martire D.[1], Devoti R.[3], Calcaterra D.[1] & Vicari A.[2]

[1] Dipartimento di Scienze della Terra, dell'Ambiente e delle Risorse, Università di Napoli "Federico II".

Corresponding author email: lucia.marino@unina.it

Keywords: DSGSD, GPS, DInSAR.

Deep Seated Gravitational Slope Deformations (DSGSDs) are rock mass movements that affect entire slopes or valleys. These movements are typically characterized by low deformation rates and are influenced by various factors, including erosional processes, precipitation, post-glacial debuttressing, among others. Seismic activity, in particular, can trigger accelerations or even collapse phases. Consequently, many authors have studied the correlation between ground movements and earthquakes.

The DSGSD being the focus of our study is located on the eastern flank of the Marche Apennines and spans the entire slope from the summit of Mt. Frascare to the valley floor, where the hydroelectric reservoir and the Fiastra dam are situated. This area is characterized by the presence of the formations belonging to the Jurassic and Cretaceous units of the Umbria-Marchigiana stratigraphic succession, which underwent two main tectonic phases: a compressional phase during the Upper Miocene-Lower Pliocene, which later transitioned to an extensional phase during the Upper Pliocene and Quaternary. This seismically active region was struck by the 2016-2017 Central Italy earthquake sequence. This significant event began with the Accumoli earthquake (Mw 6.0) on August 24, 2016. Two months later, two earthquakes (Mw 5.9 and Mw 5.4) preceded the strongest earthquake of the sequence, which occurred 6 km north of Norcia with a magnitude of Mw 6.5 on October 30, 2016. Then, on January 18, 2017, four earthquakes ranging from Mw 5.0 to 5.4 struck 20 km south of Accumoli.

Preliminary studies on the stability of this DSGSD were conducted by Albano et al. (2015), who performed a preliminary stability assessment and proposed the installation of GPS stations and corner reflectors to improve the poor radar coherence of the observed scene. Subsequent research by Polcari et al. in 2017 utilized multiband Differential Interferometry SAR (DInSAR) to analyse displacements induced by the earthquake sequence in Central Italy, while Amato et al. (2018) explored the integration of DInSAR and GPS data as a monitoring system for earthquake-triggered and slow-moving landslides.

The objective of this work is to characterize the displacements linked to the deformation of the Fiastra DSGSD and those related to the ground shaking of the 2016-2017 sequence using remote sensing methods. Unlike the previously mentioned studies, this study was based on a different dataset, covering the period 2015-2019 for both GPS and DInSAR data. The GPS data were processed with RTKlib libraries in both static and kinematic positioning modes. The DInSAR with its wide-ranging analysis capabilities, helps us overcome the limitations of GPS monitoring, which only provides point-specific data. Moreover, these methods produce highly accurate results, which are crucial, especially in the case of landslides characterised by displacement rates of centimetres to millimetres per year.

Monitoring badland features and dynamics through LiDAR and UAV technology

Marsico A.*, Colacicco R., La Salandra M. & Capolongo D.

Dipartimento di Scienze della Terra e Geoambientali, Università di Bari "Aldo Moro".

Corresponding author email: antonella.marsico@uniba.it

Keywords: badlands, high-detailed point cloud, survey accuracy.

Badlands are typical landforms on clayey, bare, and sparsely vegetated slopes, characterized by high rates of erosion. In particular, Biancane are Badlands distinguished by small domes protruding several meters above gently sloping micropediments. The drainage patterns within these formations are primarily dictated by erosive pipes and rills on the slopes, while sheet flow predominates on the pediments (Torri et al., 2013) .

Nowadays, modern advancements in geomorphological analysis favour high-detailed Point Cloud (PC) reconstruction derived from Terrestrial Laser Scanner (TLS) and drone-based surveys.

The very high-resolution of PC enables the detection of topographical changes in the range of few cm/y or mm/y (Llena et al., 2020; Marsico et al., 2021). However, each approach exhibits distinct advantages and limitations. TLS-derived PC offer superior resolution for directly exposed slopes (Biancane) but lack coverage of background micropediments and domes. Conversely, drone-based PC provides broader scene coverage but often suffers from lower density and limited penetration under canopy.

This study aims to compare the efficacy of high-resolution PC derived from TLS and drone technologies in comprehensively characterizing Biancane. We evaluated the combined TLS and drone-derived (RGB sensor) PCs against those obtained from drone-borne LiDAR, considering parameters such as density, scene coverage, surface roughness and accuracy. Validation against in-situ data further informed the assessment, acknowledging the inherent limitations of each methodology.

Furthermore, the evaluation of PC density and processing accuracy is crucial for robust survey quality and accurate analysis of erosion/deposition rate. Various sources of error stemming from data acquisition (e.g., strip overlapping, point density, data gaps, etc.), data processing (e.g., geo-referencing, inadequate strip adjustment), and terrain properties (e.g., roughness, surface reflectivity) must be considered (Kamp et al., 2022).

The findings gained from this study contribute to a deeper understanding of topographical change detection and its implications for the evolution of Badlands, providing valuable insights for sustainable land management practices and conservation strategies in fragile environments.

Kamp N. et al. (2022) - Comparability of Multi–Temporal DTMs derived from different LiDAR Platforms: Error Sources and Uncertainties in the Application of Geomorphic Impact Studies. Earth Surf. Proc. Land., 48(6), 1152–1175, https://doi.org/10.1002/esp.5540.

Monitoring and quantifying soil erosion rates using LiDAR data and soil erosion models in a Post-Fire area: the Pisticci (Italy) case study

Minervino Amodio A.*[1], Gioia D.[1], Corrado G.[2], Abate N.[1], Masini N.[1], Lasaponara R.[3] & Schiattarella M.[2]

[1] Istituto di Scienze del Patrimonio Culturale, CNR, Tito Scalo (PZ). [2] Dipartimento delle Culture Europee e del Mediterraneo, Università della Basilicata. [3] Istituto di metodologie per l'analisi ambientale, CNR, Tito Scalo (PZ).

Corresponding author email: antoniominervinoamodio@cnr.it

Keywords: soil erosion, lidar, usped.

One of the main factors in the natural processes of soil degradation is soil erosion, which is caused by the physical forces of wind and water acting on exposed soil surfaces. Post-fire erosion is an important area of study that focuses on understanding and minimizing the increased erosion hazard caused by wildfires. Indeed, it is obvious that modifications in vegetation structure and soil composition, especially following recurrent fires, can have dramatic implications on erosional processes and the overall recovery of ecosystems. This study aims to offer a methodological approach for monitoring and measuring soil erosion and sedimentation rates in post-fire conditions using: i) ultra-high resolution topographic data obtained using multitemporal UAV Lidar data; ii) airborne Lidar data; iii) soil erosion models and iv) landscape evolution models. In July 2023, a wildfire affected a watershed near the town of Pisticci southern Italy. The study area exposes the Early Pleistocene foredeep deposits of the southern Apennine chain, , which includes marine silty clay. The aim of this work is to understand the extent to which the consequences of fire on soil can trigger erosion phenomena. To do this, pre- and post-fire Lidar data were acquired. In particular, the pre-fire data are Lidar data acquired from aircraft in 2013 (acquired by the Basilicata region), while the post-fire data were acquired using a drone lidar in September 2022 and more than a year later in December 2023. Using these Lidar data, DEMs were generated, from which DoDs were made. The results of these differences show how soil erosion is greatly affected by rainfall and land cover. After the wildfire there is an increase in the erosion trend. This trend is also confirmed by the application of erosion (USPED) and landscape evolution (CAESAR Lisflood) models. Overall, this research clearly demonstrates that after monitoring the study area under post-fire conditions, the method using LiDAR data on a cm scale offers a realistic assessment of the amount of soil eroded after fire. These data are confirmed by using erosion and landscape evolution models. These observations are particularly important for assessing impacts in fire-affected areas, the implementation of mitigation strategies and management planning.

SNAP2DQuake: an implemented and automatic tool of ESA SNAP's Python module for DInSAR technique on ground deformation estimation from Sentinel-1 data

Keywords: DInSAR, earthquakes, SNAP software.

Differential SAR Interferometry (DInSAR) is a largely exploited technique applicable to different case studies involving ground deformation on Earth. A key application is the detection of the effects promoted by large earthquakes, comprising detailed variations in ground deformations at large an local scales. Since one limit of this technique relies on the costs that may be present for the access of some satellitary imagery or software licenses for the data processing, this latter problematic can be solved with the adoption of an alternative processing performed via scripts. In this work, an automatic open-source implemented Python script (Snap2DQuake) based on the "snappy" module by SNAP software 9.0.8 (ESA) for the processing of Sentinel-1 images is presented. The main feature of the script is the reproduction of all the operators contained in SNAP software using the tools of "snappy", in order to avoid some issues that can occurr using the software, and to build a complete, simple and automatic workflow to obtain LOS deformation maps and the derived Horizontal (E-W) and Vertical deformation maps. The automatization of the processing makes Snap2DQuake easy to use and suitable with basic users of programming. The proposed tool has been tested on two case studies referred two different tectonic contexts: the Mw 6.4 Petrinja earthquake (Croatia, December 2020) and the Mw 5.7 to Mw 6.3 seismic sequence occured near Tyrnavós (Greece, March 2021). The output maps of Snap2DQuake, in agreement with field observations and previous work, furnish new insights insights into the deformation pattern linked to earthquakes, demonstrating the reliability of Snap2DQuake as an alternative tool for users working on different applications, even with basic coding skills.

Multiscale geological structural analysis of the late-Eocene to Early-Miocene mylonites from the southern Calabrian Peloritani Orogen (Aspromonte Massif-Southern Italy): new insights for the western Mediterranean geodynamics

Ortolano G.*, Fazio E., Visalli R., D'Agostino A., Menta S., Portale S. & Cirrincione R.

Dipartimento di Scienze Biologiche, Geologiche e Ambientali, Università di Catania.

Corresponding author email: gaetano.ortolano@unict.it

Keywords: multiscale geological data analysis, vorticity analysis, Mediterranean geodynamics.

In recent years, most of the thematic cartography can now be truly catalogued numerically through well-defined sharing protocols (e.g., geosciml.org/), and are ready to be used, in turn, for further multiple uses. This is particularly relevant in the multiscale and multi-source analytical approach used in geological investigations, spanning data acquired by satellite image processing, UAV surveys, field investigations, direct (e.g. drilling), and undirect (e.g. geophysical) surveys, increasingly integrated by more or less complex laboratory investigations (e.g., optical microscopy, EDS and/or WDS analysis and so on).

In this contribution, we present multiscale geological investigations starting from the digital restitution of the UAV survey campaign up to the microscale quantitative data analyses of opportunely oriented tourmaline-bearing pegmatitic mylonites for vorticity analysis purposes, passing through portable LiDAR and Micro-CT fabric analysis.

Specifically, the case study outcrops are located in the eastern sector of the Aspromonte Massif, where most of the basement rocks were involved in the activity of late-Eocene to Early-Miocene Montalto Shear Zone (MSZ). MSZ activity is dated from at least 36 Ma by Heymes et al. (2010) and produced mylonites cropping out over an area of about 200 km2, locally reaching an apparent thickness of 900 m.

The present study contributes to better defining the different paleo-domains of the Calabrian Peloritani Orogen (CPO), where the Aspromonte Massif, together with the Peloritani Mountains in Sicily, can be interpreted as the southernmost termination of the southern CPO (sCPO), a piece of the original continental southern European Variscan margin, which differs substantially from both the Serre and the Sila Massifs basement rocks. This sCPO sector is composed of a first order nappe-like structure, subvisible from bottom to top into three main tectonic complexes: (i) the Lower complex (Cirrincione et al., 2015), exclusively surfacing in the most external part of the Peloritani Mountains nappe-edifice; (ii) the Upper complex, exposed on both sides of the Messina Strait in the Peloritani Mountains and Aspromonte Massif, respectively; (iii) the Stilo Unit (Fazio et al., 2015), occupying the most internal and highest part of the tectonically-stacked system, and exclusively occurring on the Aspromonte side. The entire nappe-edifice is characterized by an exclusive SE-ward nappe emplacement, consistent with a constant Africa-verging tectonic structure, at least since the Eocene.

The research study area is distinguished by the presence of highly informative outcrops of the brittle tectonic contacts between the Stilo Unit klippe and the underlying Upper Complex units. Additionally, there are amazing evidences of the deep-seated tectonic processes that have driven the juxtaposition of the two lowermost tectonic units of the Upper Complex, namely the Madonna di Polsi Unit (MPU) and the Aspromonte Unit (AU), which are actually marked by the MSZ mylonites (Pezzino et al., 2008).

An outcrop of tourmaline-bearing pegmatitic mylonites has been investigated in detail by an integrated multiscale structural approach. This was useful to better constrain quantitatively the kinematics and strain-rate of this most recent deep-seated mylonitic horizon of the CPO structural evolution, favoring new insights for the western Mediterranean geodynamic reconstruction.

Cirrincione R. et al. (2015) - The Calabria-Peloritani Orogen, a composite terrane in Central Mediterranean; its overall architecture and geodynamic significance for a pre-Alpine scenario around the Tethyan basin. Period Mineral, 84, 701–749, https://doi.org/10.2451/2015PM0446.

The overturned nappe-like structure of the Peloritani Mountains Upper Complex in the light of the new multiscale structural investigations (Peloritani Mountains - Sicily): new insights for the western Mediterranean geodynamics

Ortolano G.*, Fazio E., Visalli R., D'Agostino A., Menta S., Portale S. & Cirrincione R.

Dipartimento di Scienze Biologiche, Geologiche e Ambientali, Università di Catania.

Corresponding author email: gaetano.ortolano@unict.it

Keywords: multiscale geological data analysis, vorticity analysis, Mediterranean geodynamics.

New and more detailed multiscale structural investigations confirmed the overturned framework of the Peloritani Mountains nappe-like structure.

The Peloritani Mountains, together with the Aspromonte Massif, in southern Calabria, constitutes the southernmost termination of the Calabrian Paloritani Orogen (CPO), that can be subdivided from bottom to top into a first order three piled up tectonic complexes: (i) the Lower complex (Cirrincione et al., 2012), exclusively outcropping in the most external part of the Peloritani Mountains nappe-edifice; (ii) the Upper complex, outcropping on both sides of the Messina Strait in the Peloritani Mountains and Aspromonte Massif, respectively; (iii) the Stilo Unit, occupying the most internal and highest part of the tectonically-stacked system, and exclusively outcropping on the Aspromonte side.

The Upper Complex, in turn, is characterized by an overturned second order nappe-like structure formed during the Apennine stage of the Alpine orogenic cycle (Pezzino et al., 2008; Cirrincione et al., 2012). This asymmetrical Africa-verging fold system involved part of the original Variscan basement units, and its Mesozoic sedimentary sequences forming an Eocene to Oligocene paleo-accretionary wedge (Cirrincione et al., 2012). According to Pezzino et al. (2008), this exclusively Alpine metamorphic unit was successively extruded along the suture of the collisional zone along a late–Eocene to early-Miocene retrograde shear-zone linked with the youngest mylonitic process that have driven the former CPO formation (i.e., the Montalto Shear Zone, Pezzino et al., 2008; Cirrincione et al., 2012; 2015). The present contribution confirmed, with new and more detailed multiscale structural data, as the Variscan basement units of the Upper Complex are preserved in the core of a constant Africa-verging regional recumbent fold system, where the overturned limb, mostly outcropping on the Peloritani side, comprises a reversed tectono-stratigraphic nappe characterized, at the base, by the anchimetamorphic metasedimentary Ali sequence (AS), overlain by the low- to medium-grade Variscan metamorphic Mandanici Unit (MU), with lithotypes ranging from phyllites (at the base) to garnet-staurolite micaschists (at the top). The MU is overprinted by the same low- to very low grade prograde to retrograde Alpine metamorphic cycle affecting the Alì sequence (Cirrincione & Pezzino, 1991).

Keywords: PRISMA mission, hyperspectral data, Solfatara.

The Campi Flegrei (CF) area (Southern Italy) is a typical example of a large collapse caldera in which post-caldera volcanic activity is polygenetic (Pedone et al., 2017 and references therein) characterized by fumarolic emissions, "bradismic crisis" and uplift phases still ongoing.

We may propose that the CF area has a "dual" value which makes it a highly interesting place for scientific research. On the one hand, from a volcanic and natural hazard assessment point of view, CF is one of the most dangerous volcanoes on Earth in terms of its proximity to a densely populated urban area (the Neapolitan district is home to about three million people living between CF, Vesuvius and Ischia). On the other, from a Planetary Science point of view, the Solfatara crater (and Pisciarelli site) high-temperature geothermal environment is comparable to terrestrial analogue of Early Mars, Early Earth, as well as Early rocky bodies inside the Solar System.

Fumarolic characterization was carried out at Solfatara by using in-situ analysis (e.g., Aiuppa et al., 2013) or proximal by using Tunable Diode Laser Spectroscopy (Pedone et al., 2014). The adoption of novel technologies to estimate fumarolic CO_2 fluxes has revealed that the fumarolic contribution to the whole CO_2 flux of the area is substantial, representing ~50% of the soil CO_2 output (Aiuppa et al., 2013; Pedone et al., 2014). In a study by Pedone et al. (2017), fumarolic CO_2 emissions at Campi Flegrei and their dispersion in the lowest atmospheric boundary layer were investigated, innovatively utilizing a Lagrangian Stochastic dispersion model combined with the Eulerian model (DISGAS) to diagnose the dispersion of diluted gas plumes over large and complex topographic domains.

Due to the scientific value this site represents, in the view of a comprehensive characterization, we show the preliminary results of the exploitation of PRISMA (Caporusso et al., 2020) data for the spectral characterization of the acidic products of the Solfatara crater and for the fumarolic gases detection.

Keywords: flood, hydrodynamic models, rivers.

River flooding affects more people worldwide than any other natural hazard, increasing the importance of the capability to predict and prevent the related harm. There are several methods used to estimate flood hazard whose performance depends on the catchment features, dimension, timespan, resolution and uncertainty level. In this contribution, a catchment-scale application of the probabilistic model proposed in La Salandra et al., 2022 is combined with hydrodynamic models, in order to assess flood hazard and flood mapping on a test case of the Basento river (Basilicata, southern Italy). Hydraulic parameters and peak discharge rates were estimated in five different cross-sections of the main river channel, spanning different morphologies from braided to meandering channels. A sensitivity analysis was carried on to investigate the difference in flood probability by means of high-resolution drone-derived multitemporal Digital Terrain Models (DTMs), highlighting the areas where morphological changes can occur more frequently. FLO-2D and HEC-RAS hydrodynamic models were used for flood simulations for each river cross-section area, by using the same digital terrain models and the same inflow input calculated with the Probabilistic model. Results demonstrate the control of morphology on the flood hazard among the different cross-sections (from 0.05% to 6.65% related to a 10-years reference period). The comparison of the simulations outcomes with the Probabilistic model results shows a good agreement regarding the flow depth and flow velocity outputs. The performance of FLO-2D and HEC-RAS models is better in the downstream and upstream catchment area, respectively. The combination of these models represents a useful tool for improving flood mapping and flood hazard assessment.

Keywords: remote sensing, UAV, 3D VOM.

Different remote sensing technologies, including drone-based photogrammetry and LIDAR (light detection and ranging), allow creating 3D digital representations of outcrop surfaces that can be used in mapping geology. We applied this integrated approach to Michelino Beach in Parghelia (38°41’07”N, 15°55’15”E), one of the rare places in southern Calabria with a well-exposed sector of the lower-intermediate levels of the Serre Batholith, a c. 13-km thick composite sheeted-like late Variscan granitoid complex. Indeed, in this area, biotite tonalites (BT) come into contact with overlying K-feldspar megacrystic two-mica granodiorites and granites (PMBG) by means of sharp intrusive contact. In more detail, at the roof of the tonalitic unit, emplacement of the overlying porphyritic granodioritic magma involved incorporation of small rounded to angular blocks of tonalite, but also displacement of the mushy tonalite, with its local disaggregation in rounded blocks up to 1.5 meter in size. Such latter evidence indicates a rigid state of the tonalites at the time of granodiorite emplacement, even though rare occurrence of hybrid rocks in the contact zone testifies for possible mixing processes also between the granodioritic magma and the mushy tonalite. Moreover, Michelino Beach is an ideal location to investigate the emplacement dynamics of granitic magma with significant implications on the construction of magmatic complexes. Petro-structural mapping, assisted by LIDAR-equipped iPad, of the orientation of K-feldspar megacrysts in MBPG identified an ESE-WNW and E-W direction as preferential magma flow directions associated to a dominant NNE-SSW shortening axis. This work would like to contribute to the advance of digital field mapping methodologies, not only facilitating a better understanding of the spatial distribution and structural relationships within magmatic units but also opening up new possibilities for quantitative analysis and modelling of geological processes.

Macro- to micro-scale investigation of the relationships between granitoid magma emplacement and tectonics at Capo Vaticano Promontory (southern Calabria, Italy)

Russo D.*[1], Fiannacca P.[1], Fazio E.[1], Portale S.[1], Cirrincione R.[1] & Mamtani M.A.[2]

Keywords: field relationships, batholith architecture, deformation microstructures.

This study offers new macro- to micro-scale insights into batholith architecture and the link between shear zone and granitoid magmatism at Capo Vaticano Promontory, a dislocated segment of the late Variscan Serre Batholith in southern Italy. Through comprehensive field surveys and detailed petrographic analyses, we present the first geological map of the area at a scale of 1:140.000, illustrating the intricate relationships and the structural characteristics of the exposed magmatic units. Our findings reveal two main sectors: a northern sector representing a coherent cross-section of the Serre Batholith, ranging from strongly foliated amphibole-biotite tonalites and quartz diorites at lower depths to less foliated intermediate-seated porphyritic two-mica granodiorites and granites at shallower levels. In contrast, the southern sector exhibits a more irregular distribution of the magmatic units. Widespread supra- to subsolidus deformation microstructures, coupled with the presence of kinematic indicators and a well-defined fabric, suggest that the emplacement of early tonalites/quartz diorites was controlled by shear zones. Subsequent emplacement of the less deformed porphyritic granitoids likely occurred during phases of reduced shear zone activity. Field foliations for the deep-intermediate seated granitoids exposed in the northern Capo Vaticano Promontory sector, after removing the effects of the Miocene to recent rotation, are in accordance with the NW-SE shortening axis recorded for the same granitoid units in the Serre Massif. Recorded dominant shortening, along with field and microscopic indications of sub-simple shear, reveal a transpressional regime for the emplacement of the deep-intermediate seated granitoids from Capo Vaticano Promontory.

The role of advanced surveying technologies for geomechanical analysis of artificial caves: the case study of Gravina in Puglia (Puglia region, Southern Italy)

Spadaro A.*[1], Piras M.[1], Grasso N.[1], Lollino P.[2], Parisi A.[3] & Giordan D.[4]

Keywords: artificial caves, geomatic modeling, geomechanical analysis.

Accurate modeling of natural and artificial caves is crucial for understanding the genesis and evolution of these underground environments, which is necessary for hazard assessment and urban planning of built-up areas and critical infrastructures. This research leverages advanced geomatic technologies, including terrestrial laser scanning (TLS), SLAM-based mobile mapping systems (MMS), and digital photogrammetry with 360-degree cameras, to create detailed three-dimensional models of artificial caves, which can be complex and hard-to-access environments (Giordan et al., 2021). The integration of these high-resolution technologies enables the detailed mapping and analysis of these caves, enhancing the understanding of their spatial distribution and structural integrity.

Dealing with the artificial caves of Gravina in Puglia (Puglia region, Southern Italy), characterized by significant architectural, historical, and cultural value (Parisi et al., 2020), this study focuses on two main objectives: (i) improving the understanding of the planimetric development of the artificial caves with reference to the built-up environment; (ii) integrating geological and geomechanical data to support structural monitoring, sinkhole hazard assessment, and the identification of areas at high risk of structural degradation (Fazio et al., 2017).

The performance of various geomatic techniques, including TLS based on VIS (Visual Inertial System), SLAM, and spherical photogrammetry, for three-dimensional model reconstruction and geomechanical stability assessment has been evaluated. The comparative analysis aims to determine the efficacy of each method to enhance the accuracy of geotechnical evaluation and risk assessment (Idrees & Pradhan, 2016). This comprehensive approach helps to address the immediate challenges posed by the underground environments, as well as it contributes to the broader field of geotechnical engineering by providing essential data for future urban development and conservation strategies.

In conclusion, this research will provide insights related to the optimal use of these advanced surveying technologies for modeling complex underground caves, thus offering a methodological framework that can be applied to similar geological settings. This will ultimately aid in the hazard assessment associated with underground caves, as well as in leading to the development of more resilient urban settlements.

Keywords: virtual outcrop models, best-fit plane, trace digitization.

Over the past two decades, major advancements in close-range remote sensing techniques that facilitate the 3D digitization of geological structures have resulted in the rapid proliferation of virtual outcrop models (VOMs) within the geosciences. The emergence and refinement of accessible and highly portable sensory platforms, such as terrestrial lidar, digital cameras, smartphones, tablets, and uncrewed aerial vehicles, have played a pivotal role in catalyzing this digital revolution. The analysis of geological discontinuities represents a key component of many VOM studies. Specifically, establishing the orientation distribution of discontinuities, such as fractures, faults, or bedding planes, represents the preliminary analysis in many applications. In this context, there is a growing need to establish standards for the digital measurement of geological discontinuities exposed in VOMs. Such standards should be tailored towards the complexities of natural outcrops, where geological discontinuities often intersect the outcrop topography and are expressed as 3D traces. Digitizing geological discontinuities expressed as trace data is typically conducted manually via polyline interpolation along the exposed trace, with discontinuity orientation estimated through planar model fitting through the polyline's component nodes. Presently, establishing quality control for such measurements lacks standardization due to the absence of robust benchmarks, with the validity of the resultant orientation data heavily relying on the interpreter's expertise.

With the aim of bridging this gap, we present the results of the manual digitization and orientation estimation of bedding planes expressed as traces across seven natural outcrops. We use two digitization strategies: one employing a previewed best-fit plane during digitization and another without. These methods represent active model-guided and unguided digitization approaches, respectively, with their comparison aimed at building benchmarks and best practices. Specifically, we analyze parameters derived from the digitized traces and their corresponding best-fit planes. We compare these parameters with the deviation of the best-fit plane from the true orientation of the bedding surface. Such a comparison highlights the impact of node collinearity on best-fit plane precision and accuracy, with a robust benchmark for this parameter provided. This quantitative comparative analysis is complemented by recommended best practices for 3D trace digitization, such as a high value of coplanarity, maintaining a quasi-constant node-to-node distance relative to the model's resolution, and ensuring a minimum number of nodes to guarantee the robustness of the fitted planar model.

The role of ASI in the development of novel user-driven EO-based products for geo-hazards applications: the "Multi-mission and Multi-frequency SAR" and "I4DP_SCIENCE" Programs

Ursi A.*, Tapete D., Montuori A., Sacco P., Virelli M., Zoffoli S. & Coletta A.

Agenzia Spaziale Italiana (ASI), Roma.

Keywords: Earth observation, synthetic aperture radar, geo-hazards.

Nowadays, geo-hazard scientific research and practice in Italy substantially rely on Earth Observation (EO). This was achieved owing to a growing ecosystem of research bodies and universities that developed world-leading competence in forefront EO technologies, among which Synthetic Aperture Radar (SAR) and SAR Interferometry (InSAR) represent an unquestionable excellence.

To consolidate this strength, the Italian Space Agency (ASI) promotes new SAR missions, SAR/InSAR-based scientific research, and demonstration of novel downstream applications. The most recent national R&D program was the *"*Multi-mission and multi-frequency SAR*"* program (Tapete et al., 2022; 2023), during which innovative algorithms to process SAR data were tested (e.g., for natural hazards applications).

To move from pure R&D to exploitation in pre-operational contexts and provision of useful input into final users' workflows, in 2022 ASI launched the *"*Innovation for Downstream Preparation*"* (I4DP) program, promoting the development of downstream through the use of spatial data, acquired and provided by national and European space systems (e.g., PRISMA, COSMO-SkyMed, SAOCOM, etc.). In particular, the I4DP_SCIENCE channel focuses on "Scientific Downstream" and is mainly addressed to the Scientific User Community (i.e., Italian Universities, Public Research Bodies, etc.). I4DP_SCIENCE consists of joint projects with ASI, devoted to the demonstration and dissemination of the usefulness of novel methods and algorithms in supporting applications of user's interest, regarding topics of national relevance (e.g., National Copernicus User Forum), and/or outlined in international agendas (e.g., UN Sustainable Development Goals, SDGs). To date, two thematic calls were released: *"*Sustainable Cities" and "Agriculture and Sustainable Use of Water Resources".

Out of the projects selected in the first call, GEORES specifically addresses the theme of metropolitan cities and urban sustainability. The project is led by the University of Bari (UNIBA) and the Institute for Electromagnetic Sensing of the Environment (IREA) of the National Research Council of Italy (CNR), together with ASI. Aim of GEORES is the development of a geospatial application to improve environmental sustainability and resilience to climate changes in urban areas, by setting up a multi-risk WebGIS platform, consisting of four main modules: Sediment Connectivity, Land Displacement, Urban Floods, and Urban Wildfires. Each module makes use of EO data, calculation models, and algorithms, integrated together to identify high-risk "hot-spots" in the urban and peri-urban territory, in order to point out regions interested by land degradation due to hydrogeological instability, sediment flow, or vegetation fires. Main targets of GEORES are the Metropolitan City of Bari and the urban settlements in Gargano Promontory, Apulia Region, southern Italy.

Leveraging machine learning for ground motion prediction: advancements in seismic hazard assessment

Zaragoza Alonzo A.D.*[1], Zambrano M.[1], Luzi L.[2] & Tondi E.[1]

[1] Scuola di Scienze e Tecnologie, Sezione Geologia, Università di Camerino. [2] INGV, Milano.

Corresponding author email: abel.zaragozaalonzo@unicam.it

Keywords: natural hazard, ground motion prediction, machine learning implementation.

Ground motion intensity measures are crucial for seismic hazard assessment and design, traditionally derived from Ground-Motion-Prediction-Equations (GMPEs). However, recent decades have witnessed a paradigm shift towards the integration of artificial intelligence, particularly Machine Learning (ML), that aims to address nonlinear phenomena in seismology.

This study is based on a rich dataset compiled from seismic events in central Italy, including the earthquakes in L'Aquila (2009) and the Amatrice-Visso-Norcia sequence (2016-2018). Approximately 34000 waveforms constitute this robust dataset, meticulously curated by previous researchers, thereby establishing a foundation for accurate prediction models.

We employ supervised ML algorithms to calibrate prediction models, contrasting their performance with the widely used Italian Ground Motion Prediction Equation (GMPE, ITA18). Notably, XGBoost emerges as the optimal algorithm, offering a blend of error minimization, interpretability, and computational efficiency.

Evaluation metrics encompass various Intensity Measures (IMs), including Peak Ground Acceleration (PGA), Peak Ground Velocity (PGV), and Acceleration Response Spectra (SA) across different time periods. The ML model developed herein demonstrates superior accuracy, surpassing traditional GMPEs. These results signify a significant stride in seismic hazard assessment, with implications transcending local contexts to global applicability, contingent on the availability of seismic data.

Cascading landslide risk assessment by means of an integrated approach

Zito C.*[1], Mangifesta M.[2], Francioni M.[3], Guerriero L.[4], Di Martire D.[4], Calcaterra D.[4], Pasculli A.[2] & Sciarra N.[2]

[1] Dipartimento di Ingegneria e Geologia, Università "G. d'Annunzio" di Chieti-Pescara. [2] Dipartimento di Scienze Psicologiche, della Salute e del Territorio, Università "G. d'Annunzio" di Chieti-Pescara. [3] Dipartimento di Scienze Pure e Applicate, Università di Urbino "Carlo Bo". Corresponding author email: claudia.zito@unich.it

Keywords: landslide risk assesment, FEM modeling, remote sensing tecnique.

Cascading landslides represent a dynamic and hazardous geological phenomenon, characterized by a sequential chain reaction of slope failures triggered by various factors such as heavy rainfall, seismic activity, wildfires, or anthropogenic activities (i.e. excavation or deforestation). This phenomenon generally starts when an initial landslide destabilizes the surrounding terrain, leading to subsequent landslides that may intensify the damage caused by the initial event or create a predisposed environment for subsequent slope failures, (Hungr et al., 2014) often resulting in significant environmental and societal impact.The Morino-Rendinara cascading landslide is one of the most significant Italian appenine examples of cascading landslides in terms of landslide mechanism, impact. The municipality of Morino is situated in the Ernici mountains along the border of Abruzzo and Lazio in Italy. Local geology consists of Mesozoic formations displaced by normal faults, overlain by Messinian arenaceous-pelitic formations and Quaternary deposits. Significant-flow springs are present at the landslide head and fed by highly fractured carbonaceous aquifer cropping out immediately upslope. Morino Renidnara landslide is formed by a rock fall/avalanche landslide in the upper sector of slope, a deep-seated rotational slide in the middle sector of the slope and a debris flow that dammed Liri River as consequence of the last recorded reactivation in March 2021. This study employs a multidisciplinary approach, combining different advanced technologies, to comprehensively understand the complexities of the Morino-Rendinara landslide. Field activities, UAV image acquisition, Differential Interferometry SAR (DInSAR) using SENTINEL-1 images processed by the SUSIDENCE software, and pixel offset analysis based on the procedure applied on high-resolution Google Earth images (Guerriero et al., 2020) offer insights into the geological and hydrogeological conditions contributing to slope instability through an analysis of elaborated rainfall data and time series derived from interferometric analysis. The study aims to reconstruct a subsurface model and basal failure surface through specific Finite Element Method (FEM) slope stability analyses, with a particular emphasis on the water's contribution to slope stability. Through the integration of FEM slope stability analyses and remote sensing techniques, it is possible to assess the risk associated with this complex phenomenon and understand its impact on the environment. The integration of these techniques enables a deep comprehension of the landslide, providing valuable information on velocity, components, displacement, foundament to assess the risk.

Keywords: nitrogen isotopes, water quality, environmental management.

Agricultural and industrial activities are regarded as the main responsible for the discharge of pollutants in natural environments, and river waters are extremely sensitive to anthropogenic contamination. Over the years, the influence of man-related activities, together with the effects of climate change, has led to an impoverishment of water quality. N-bearing species (i.e., NO^{3-}, NO^{2-}, and NH^{4+}) are considered to be among the main pollutants in surface waters and shallow aquifers at global scale, these compounds being released by multiple sources (industrial discharges, domestic and agro-zootechnical wastes, nursery and agricultural activities). Nitrogenated species are strictly regulated since the consumption of water containing high levels of nitrogenated species can cause severe health problems, i.e., cancer, birth defects, methemoglobinemia, and other adverse effects. Therefore, assessing the sources of N-bearing species is a pivotal step to improve water management.

The Arno River Basin (ARB) has been suffered more than a century of industrial and demographic development and it is currently affected by a significant anthropogenic pressure due to the presence of relatively large cities (e.g., Florence, Prato, Pisa) and widespread industrial and agricultural activities. In this work, 26 water samples (13 from the Arno River and 13 from the main tributaries) were analyzed to assess the water pollution status. Moreover, the $\delta^{15}N$ and $\delta^{18}O$ values in both nitrate (NO^{3-}) and nitrite (NO^{2-}) were determined to understand the origin and fate of nitrogenated species. The Arno River composition evolves from Ca-HCO_3 to Na-Cl(SO_4) from the source to the mouth with an increasing deterioration in terms of quality of the surface waters. The significant increment of the Na^+ and Cl^- contents downstream of Florence has to be attributed to anthropogenic contributions (i.e., untreated, or partly treated, wastewaters from industrial activities) and, eventually, to seawater instrusion. Critical concentrations in nitrate and nitrite (up to 63 and 9 mg/L, respectively) were detected in the Middle and Lower Valdarno sub-basins. The Ombrone and Usciana tributaries are the main contributors of anthropogenic pollutants into the Arno River, whilst the Elsa tributary supplies the main course with significant contents of geogenic sulfate. The Sieve, Pesa, Egola and Era tributaries act as diluters of the Arno River waters, partially decreasing the Na^+ and Cl^- impact. The combined application of $\delta^{15}N^-$ and $\delta^{18}O$-NO_3 allowed to identify sewage and domestic wastes as primary sources for dissolved NO3- in the ARB running waters. Moreover, the isotopic data of $\delta^{15}N$ and $\delta^{18}O$ in NO_2 clearly suggest that the nitrification process (oxidation of NH^{4+} to $NO^{3-}$with NO^{2-} as an intermediate product) affects the waters flowing in the ARB, thus playing an important role in terms of abundances and respective proportion of the nitrogenated species.

Geothermal energy as an integration of existing district heating and cooling grids: evaluation of the thermal performance of the system and of thermal disturbance on the ground from a real case study in NW Italy

Chicco J.M.*[1], Giordano N.[1], Mandrone G.[1] & Comina C.[2]

[1] Dipartimento Interateneo di Scienze, Progetto e Politiche del Territorio, Università di Torino.
[2] Dipartimento di Scienze della Terra, Università di Torino.

Corresponding author email: jessica.chicco@unito.it

Keywords: geothermal energy, numerical simulations, district heating.

The geopolitical situation since February 2022, has led governments to find solutions to reduce energy imports, and fight against climate change impacts. New approaches for the decarbonisation of the heating and cooling sector, which is still responsible for almost half of the final energy consumption in Europe and significantly depends on energy imports, are strongly required. Therefore, European government has to put in place short and long-term measures aimed at shielding consumers from the direct impact of the rising energy prices across Europe, and to counteract the continuous economic volatility (Sgaravatti et al., 2023). In this framework, low carbon sources such as geothermal energy can substantially decrease energy consumptions and costs, especially if included into decarbonized heating and cooling grids (Goetzl et al., 2022) The recent multiple crises have led to increased interest in using geothermal energy in district heating and cooling grids to substitute fossil fuels, especially gas boilers and air conditioners for the heating and cooling demands, respectively. However, due to shortcomings in the market development efforts in the past years, services needed for the rollout of heating and cooling networks in Europe are limited and require significant ramp-up periods (Costa et al., 2017).

To this regard, this work deals with an integration of shallow geothermal energy for a small existing district heating in small city in NW Italy (at about 70 Km SE from the city of Turin). Specific field tests in a real case study such as hydrogeological, geophysical, and thermo-physical surveys of the underground soils were conducted. Moreover, the realization of a field ground response test (GRT) together with a continuous thermal monitoring at different depths, allowed to better evaluate the thermo-physical parameters of the underground soils inside a real pilot borehole. Starting from the real data obtained from these specific field surveys, a further sensitive analysis through the use of the FeFlow software which uses a finite element code, allowed simulating the thermal behaviour of the ground and the thermal performances of the whole system, during the plant operation in the short and long term. Thermal performances were also simulated using different geothermal pipe configurations: this revealed useful to better understand the thermal power extraction from each borehole as well as to know how much the thermal plume can expand around it over time. All these data allowed for a very useful information in better designing a shallow geothermal plant, as an integration for a district heating and cooling system as that planned in the investigated area.

Keywords: fluid inclusions, LA-ICP-MS, Larderello geothermal system.

The study of fluid inclusions (FIs) is a valuable tool to investigate fluids that permeated geothermal reservoirs, now or in the past. One of the advantages of FIs is that they general exhibit "closed system" post-entrapment behaviour. Although this is often the case, fluid inclusions can reequilibrate (via diffusion, deformation or reaction with the host mineral), or undergo changes in volume or shape (i.e., necking down processes). Petrographic observations are thus key to identify pristine inclusions that are representative of the original trapped fluid.

We undertook a comprehensive FIs study on samples recovered from a deep well of the Larderello geothermal system (Italy), where no FI analysis of trace element chemistry on modern fluids has been conducted. This well, named Sesta6bis, from the north-western part of the system, reaches a depth of 3921 m b.s.l., with temperatures of about 300°C measured in the well during production tests (Barelli et al., 2000). We targeted three core samples, obtained from 2733-2737 m, 3085 m, and 3803 m depths in order to study quartz-hosted FIs. Our ultimate goal is to reconstruct the hydrothermal fluid history in this vapor-dominated geothermal system.

Following petrographic classification of FIs assemblages, we performed micro-thermometric analyses on assemblages from all three core samples. The shallower samples contain multiphase inclusions in combination with primary two-phase liquid-rich (L-rich) and vapor-rich (V-rich) inclusions. The latter two inclusion types are also present in the deeper samples, highlighting an ongoing boiling process at the time of entrapment. Homogenization temperatures for the primary FI assemblages range between 340 and 370°C. In contrast, secondary L-rich FIs observed in the deeper samples are characterized by a lower homogenization temperature, in the range of 310-325°C. These lower temperature are in good agreement with the present-day fluid temperature recorded at the wellhead during production tests, suggesting the secondary inclusions represent trapping of the current geothermal reservoir fluids.

In addition to microthermometric determinations, we conducted laser ablation-inductively coupled plasma-mass spectrometry (LA-ICP-MS) analyses on the above described FIs. In advance of LA-ICP-MS analyses, quartz grains were imaged by scanning electron microscopy (SEM) based cathodoluminescence imaging, with the aim to identify potential growth zones in quartz and later recrystallization of fractures. This CL-mapping was used to more definitively target both primary and secondary FIs. The trace element composition of these well-characterized FIs assemblages can be assumed as representative of the recent and current hydrothermal fluids circulating in the deep Larderello geothermal reservoir. We report preliminary results of these LA-ICP-MS analysis and provide insights on the evolution of the fluids that circulated in the portion of the Larderello geothermal system.

Keywords: groundwater pollution, stable isotopes, environmental hydrogeology.

Water is regarded as one of the most important natural resources. Indeed, water resources and water quality are important and indispensable for human survival, the ecological environment and sustainable economic and regional development. Nowadays, one of the serious environmental threats is groundwater contamination due to leachate from municipal solid waste landfills with a significant organic component.

In recent years, the use of stable isotopes as environmental tracers to identify groundwater contamination phenomena has found application in environmental hydrogeology as they can be used to determine the sources, pathways and timescales of environmental processes. Deuterium (^{2}H) and oxygen (^{18}O) isotopes have been successfully applied to assess contamination phenomena when groundwater interacts with leachate. In these cases, the groundwater presents isotopic compositions relating to ^{2}H and ^{18}O, highlighting an enrichment of $\delta^{2}H$, probably caused by methanogenesis phenomena in which bacteria preferentially use the "lighter" isotope of hydrogen (^{1}H). In this way, the remaining hydrogen is enriched in ^{2}H, the "heaviest" isotope, without producing a proportional increase in ^{18}O. Deuterium excess (d-excess) influences the isotopic content of deuterium and oxygen 18 and can be used to identify processes that occur under non-equilibrium conditions. Therefore, an early warning model based on the d isotope is used, dependent on evaluating changes in deuterium excess in groundwater samples. This model involves the determination of an F index as a percentage change in d-excess, which allows the definition of a system of three alert levels to evaluate and control groundwater contamination by leachate. F index values higher than 1.1 highlight possible contamination phenomena of the aquifers due to leachate.

In this study, we compare two different municipal solid waste landfills in central Italy. In particular, we applied this isotopic model both in a site where contamination of groundwater by leachate occurred and a variation in the isotopic content was therefore recorded, and in a site where there was no contamination and consequently no variations in isotopic contents were recorded. This demonstrates the effectiveness of the application of deuterium as a tracer of the leachate presence in groundwater near municipal solid waste landfills. Furthermore, it highlights how innovative monitoring tools that achieve high sampling frequencies with low-cost procedures or analyses represent a significant improvement likened to traditional approaches.

Geochemical characterization and biotechnology potential of marine sediments from a small maritime area around Elba-Argentario Basin (Tyrrhenian Sea, Italy)

Funari V.*[1-2-5], Toller S.[3], Nestola Y.[3], Riminucci F.[3-4], Iorio M.[1], Mercadante A.[1], Angelino A.[1], Ape F.[3], Greggio N.[2], Dinelli E.[2], Varola G.[5], Graziano L.[5], Coppola D.[5], Vitale L.[5], Tedesco P.[5], de Pascale D.[5] & Mantovani L.[6]

Keywords: marine sediments, metal distribution, microbiology.

Bottom sediments representing an average stratigraphic depth of 20 cm across northern-central Tyrrhenian Sea, approximately between the Arno river mouth and the Argentario Promontory are this work focus in the framework of the CNR project named SeaGMA. Preliminary analytical effort included aqua-regia digestion of selected samples followed by ICP-MS determinations while X-Ray fluorescence spectrometry in combination with gravimetric analysis for the evaluation of total composition and volatile content was for all samples. Data analysis helped recognising three major areas:

- a wide population of fine grained samples characterized by relatively high concentrations of As, Cr, Cu, Zn and other elements that can source from volcanic rocks.
- a second population with a likely enhanced content in carbonates and contributions from the ophiolitic rocks outcropping inland.
- the smallest population includes mostly sandy sediments with elevated CaO and Sr contents in the westernmost sectors near main islands.

These geochemical signals (e.g., volcanic vs terrigenous) helped to select relevant sites for microbiological exploration toward discovering new microorganisms and natural processes functioning as environmental bioremediation tools. In a multidisciplinary effort, we isolated 60 strains among 22 genera from five selected sampling sites based on their capacity to resist harsh conditions. Biotechnology potential from marine sediments is elevated according to tested strains tolerance to selected stressors such as pH (pH Tolerance assay) and industrial waste leachates (Maximum tolerance concentration assay).

We promptly found bacteria suitable for CCS or capable of other interesting processes, likely because of local anthropic stressors. The causal association between geochemical anomalies and extremophiles would unlock biotechnology potential at producing new substances or recovering raw materials.

S behavior, sulfate and SO_2 emissions during a basaltic eruption in Central America: the case-study of the December 29th, 2013 eruption of the San Miguel volcano, El Salvador

Keywords: Ca-sulfate, SO2, San Miguel volcano (El Salvador).

The San Miguel or Chaparrastique volcano (E of El Salvador) is a medium size (1.500 m of vertical development) basaltic-andesite basaltic stratovolcano representative of a large number of similar active arc volcanoes outcropping along a 1400 km long transect at the frontal pacific coast from the Mexico-Guatemala border sector till central-western Panamá. This volcanic front is related to the subduction of the Cocos plate under the Caribean one, a moderately thick continental crust. These basic volcanoes represent the recurrent volcanism at the region, being the silicic large lake calderas related to much lesser frequent and much larger eruptions. In this context, a great number of surveillance efforts in the regions are devoted to the forecasting of the volcanic activity of these medium-sized basaltic stratovolcanoes, including SO2 surveys. However, the SO_2 emissions prior to the eruption of December 29th 2013 eruption of the San Miguel volcano were not predictive, while emissions after the explosive event provided deveral cycles much higher contents along the successive month.

The December 29th, 2013 eruption was associated to an important emission of ash along a vector around 90 km long, thus traversing most of the El Salvador republic. A set of 13 pristine samples distributed along this vector were sampled in the 36 successive hours before raining. These samples were physically and chemically characterized, including granulometry, SEM+EDS morphoscopy and microchemical composition, XRF whole rock chemistry, Rietvelt refined XRD mineral and glass composition, ATD-TG profile of degassing, etc. An aliquot of these samples was also leached with ultrapure water and the leachates characterized (conductivity, pH, chemical composition by ICP-MS).

The ash and leachate studies provide a number of evidence that allows for the explanation of the non-forecasting behavior of preeruptive SO_2 emission. First of all, calcium sulfate (mostly compatible with anhydrite) is widespread, and looks not just like a sublimate generated in the eruptive column, but also as a magmatic primary phase in ash, a fact that have been also described in a number of subduction volcanoes everywhere. The morphoscopy of ash grains provides a good image of how proceed the liquid fragmentation in the course of this short-lived eruptive event. All of these features strongly suggest that SO_2 behavior might be related at least pro-parte to magmatic sulfate phenocrysts breakdown in a context of an open conduct. On other hand, leachate provides excellent evidence of a chemical zonation of trace elements along the 90 k, vector of diffusion of the ash plume, a fact easily correlatable to the geochemically well-known mobility of some elements and the gradual cooling of the plume along the path traveled. This fact might be very common, but as well as we know it is usually not reported neither used in the geochemical models of dispersion related to environmental effects of volcanic ash dispersion.

Decadal geochemical monitoring of CO_2 and SO_2 outgassing activity of Vulcano Island, Aeolian Archipelago, Italy

Keywords: geochemical monitoring, soil CO_2 degassing, SO_2 plume output.

The Active cone of La Fossa caldera is a close conduit volcano affected by solphataric activity, manifested in the hot fluids released from fumaroles and the associated thermal anomalies in groundwater and exposed ground.

The evaluation of the volcanic activity changes was inferred by the near real-time monitoring of soil CO_2 fluxes diffused at the La Fossa Cone and the peripheral areas of Palizzi and Levante Bay and by the discontinuous monitoring of CO_2 fluxes diffused by soil in areas around the CO_2 continuous monitoring stations, La Fossa Cone, Palizzi and Levante Bay (Inguaggiato et al., 2022a).

In particular, three main changes in degassing activity were recorded in 2009, 2021, and 2022 and allowed us to evaluate in near real-time the level and duration of the exhaling crisis affecting the Island of Vulcano, by measuring the changes in mass and energy carried by the fluid release (Inguaggiato et al., 2022b).

The strong and deep input of volatiles released, in the last decades, from the underlying magma batch strongly modified the chemical composition of the shallow plumbing system, leading the system to an increase in the level of CO_2 over time.

Moreover, near continuous plume SO_2 fluxes, measurements have been carried out by a network system of SO2 measurements at Vulcano Island, Italy. Two Scan-DOAS stations belonging to the NOVAC Project are located respectively at NE and SW of volcanic cone.

The fluxes of SO_2 plume acquired by the UV-scanning DOAS network showed, in the study period (2021 – 2022), monthly average values between 20 and 121 t d-1. Starting from June 2021 onwards, the SO_2 output showed a positive trend with an abrupt increase reaching the highest monthly value in September 2021 (monthly average value= 121 t d-1) and the highest daily measurement 16 November 2021 (daily average = 248 t d-1).

The atmospheric dispersion model (AERMOD), designed for simulate the dispersion of air pollutant from stationary anthropogenic and natural emission source, have been utilized to produce the dispersion SO_2 maps and evaluate the air SO_2 concentrations in the neighboring areas of the Vulcano island. These maps have been constructed using environmental parameters such as wind speed and direction measured by the local network installed in different points of the island and at different altitudes. These SO2 iso-concentration maps compared with the limit values shown in the human health tables have made it possible to identify the most harmful areas (Vita et al., 2023).

Keywords: water isotopes, landfills, groundwater.

Water plays a crucial role in landfill biogeochemistry, influencing waste degradation, leachate composition, and environmental impacts. At the same time, the movement of groundwater below and in the vicinity of landfills interacts with surrounding slopes and man-made structures built to contain the waste, such as earth dams and embankments. Such interaction can be relevant in presence of low permeability soils and when large excavations and filling are carried out, two conditions that are typical for landfills area. In this context isotopic analysis of water molecules provides valuable insights into the sources, movement, and transformation flow paths within landfill unraveling the hydrological dynamics, their implications for slope stability, and therefore facilitating targeted remediation efforts and monitoring strategies to safeguard water quality and geotechnical works. Actually, several studies demonstrated that variations in isotopic signatures can indicate changes in the source of water feeding into landfills, such as precipitation, surface water, or groundwater, which may have implications for dam safety.

This study investigates the relationship between landfill water isotopes and the potential for dam instabilities. Indeed, in the year 2016, the large downstream embankment of the Corinaldo landfill (Marche Region, central Italy) experienced a geotechnical failure, precipitating the implementation of extensive stabilization and monitoring measures. These initiatives were aimed at arresting further embankment displacement guaranteeing monitoring groundwater dynamics and characteristics within the study site.

Integrating isotopic analysis with traditional geotechnical and hydrological investigations, such as infiltrometer tests, and artificial tracer tests within the piezometers, we obtained the vertical hydraulic conductivity of the vadose zone (≈10-5 -10-6 m/s) and the effective groundwater velocity of the saturated zone (≈ 10-7 – 10-9 m/s), assessing the presence of a possible paleochannel responsible for preferential groundwater drainage and movement within the site, which crosses the dam foundation and which was linked to the geotechnical failure. Moreover, using tritium on leachate and groundwater we explored the possible dispersion of leachate into the water table through the identified paleochannel. The tritium values found in groundwater are low respect to those of the local meteoric waters, while the stable isotope values are consistent with local infiltration of rainwater, excluding hydraulic contact between the landfill and the groundwater body. This interdisciplinary study underscores the importance of considering isotopic signatures in assessing the potential impacts of groundwater movement below landfills on associated geotechnical works stability, besides emphasizes the role exerted by heterogeneous lenses or layers in low permeability lithologies where landfills are usually located.

Isotope composition of dissolved sulfates reveals solutes origin and groundwater flows: insights from aquifer systems in Tuscany

Keywords: sulfate isotopes, groundwater.

Groundwater is a vital resource, providing fresh water for drinking use, agriculture, industry, and ecosystems across the globe. However, overexploitation and pollution make groundwater vulnerable, requiring careful management and protection to ensure its availability for future human society. Stable isotopes are widely used in many disciplines of earth and environmental sciences as tracers of several natural and anthropogenic processes. Their use allows us to unravel the origin of water and solutes and to recognize groundwater flows and circulation patterns, especially in environments where the geologic and geomorphologic evolution has played an important role (e.g., tectonics, metamorphism and mineralization, karst processes). The stable isotope composition of dissolved sulfates is widely used to recognize different sources, both natural and anthropogenic, and trace the sulfur cycle (e.g., Urresti-Estala et al., 2015). $\delta^{34}S$ and $\delta^{18}O$ of sulfate are controlled by 1) the isotopic signature of SO_4 sources, 2) isotope exchange reactions, and 3) isotope fractionation during biogeochemical processes. Here we present the results of an isotopic screening of dissolved sulfates carried out in the period 2018-2022 on groundwater of some important aquifers in Tuscany. 28 water samples were collected from springs (13), wells (4), surface waters (3), and acid mine drainage (1) in three main areas from north to south: the Apuan Alps, the Monti Pisani and Monti d'Oltreserchio, the Colline Metallifere. Stable isotopes ($\delta^{18}O$-H_2O, $\delta^{2}H$-H_2O, $\delta^{18}O$-SO_4, $\delta^{34}S$-SO_4) were measured on collected samples, in addition to chemical (major and trace elements) analysis. Pyrite and Fe-Al-K secondary sulphates were also collected from mineralization in the Apuan Alps and analyzed for sulfur isotopes. The isotope ratios of oxygen and sulfur of dissolved sulphates reveal multiple sources of sulfates. Two distinct water groups may be recognized. The first one includes water samples with lower $\delta^{18}O$-SO_4 and $\delta^{34}S$-SO_4 values spanning from 0.3‰ and -9.6‰ to 2.9‰ and -2.2‰, respectively. These samples were from springs, stream, and mine drainage in a catchment of the southern Apuan Alps heavily impacted by past mining activities (Doveri et al., 2021). Accordingly, they fall in the field defined by the isotopic ranges of pyrite and secondary sulphates found in the mines upstream, indicating that groundwater sulfate is mostly controlled by sulfide oxidation. The second group of water includes samples with higher $\delta18O$-SO_4 and $\delta34S$-SO_4 values ranging from 8.4‰ and 10.6‰ to 11.7‰ and 15.8‰, respectively. These values indicate a sulfate origin from the dissolution of gypsum/anhydrite, suggesting groundwater is deep enough to interact with the Triassic evaporitic formations (e.g., Boschetti et al., 2011) at the regional scale. However, a few samples fall along a mixing line between two water groups, suggesting possible mixing between sulfide and evaporitic components.

Hydrothermal hydrocarbons generation and migration into the basement rocks of Southern Tuscany

Schito A.*[1-2], Muirhead D.[2], Bowden S.[2] & Parnell J.[2]

[1] Departament de Mineralogia, Petrologia i Geologia Aplicada, Universitat de Barcelona, Spain.

Corresponding author email: andrea.schito@ub.edu

Keywords: hydrothermal hydrocarbons, hydrothermal fluids, biodegradation.

The occurrence of hydrocarbons (HC) in geothermal settings as a consequence of the interaction of organic-rich rocks with elevated temperature and/or hydrothermal fluids, is often overlooked or underestimated in the geological record despite ther importance in the uptake or reduction of metals during interaction with hydrothermal fluids to form ore deposits (Parnell, 1988).

Some of the most important ore mineralization in Italy is hosted in Southern Tuscany where the presence of hydrocarbons (mainly bitumen) associated with mineralization has been noted since the 70ies (Arisi-Rota & Vighi, 1971), but whose origin has been never fully explained.

In the metamorphic rocks of Monti Romani in Southern Tuscany, carbonaceous material in the form of graphitic carbon, amorphous carbon and liquid hydrocarbons have been studied togheter with paleo-fluids temperatures. Raman spectroscopic analyses show a contrast in structural ordering between carbon in the host rocks and carbon films and nodules at the contact with high temperature mineralized veins. Microscopy and gas chromatography additionally indicate liquid hydrocarbons, with a thermal maturity at the peak of the oil window and biodegradation in the depth interval between about 100 and 1500 m. Fluid inclusions analyses suggest temperatures moslty higher than 200°C in the veins hosting hydrocarbons and low-ordered carbonaceous material.

The association of hydrocarbons with high temperature fluids together with gas chromatographic and spectroscopic data indicate a probable hydrothermal origin of the oils, from the late Miocenic sediments that fill the Tafone Graben. A model is proposed in which hydrocarbons were generated along the fault that borders the Tafone Graben and then migrated toward the basements rocks at the footwall.

Variations in elemental sulfur viscosity and volcanic hazard assessment implications

Scolamacchia T.*

Agenzia regionale Strategica per lo Sviluppo Ecosostenibile del Territorio (A.S.S.E.T.), Regione Puglia.

Corresponding author email: t.scolamacchia@asset.regione.puglia.it

Keywords: sulfur viscosity, hydrothermal systems, volcanic hazard.

Several volcanic eruptions unheralded by precursory signals occurred in historical times causing casualties (e.g. Lewis, 2021). Deciphering the causes behind these unpredicted eruptions are important to improve volcanic hazard assessment.

Evidences of layers of elemental sulfur accumulated by magmatic degassing, have been discovered below water at volcanoes hosting crater-lakes. In these settings, the variations in sulfur viscosity, as pure element, were considered responsible to cause both lake water temperatures' cycling, and temporary sealing of the vent system, causing eruptions (Christenson et al., 2010). Pure sulfur viscosity is highly temperature dependent, because of its complex polymerization behavior: a four-orders-of-magnitude increase in viscosity occurs at ~160°C, up to a maximum of 93.2 Pa·s between 186 and 188ºC (Bacon & Fanelli, 1942). Besides viscosity, also step-changes in density, compressibility, and electrical conduction, occur in pure sulfur at temperatures ~160ºC. However, sulfur is also extremely sensitive to the presence of impurities, as noticed since the 1940s. In the presence of hydrogen sulfide, organic material, hydrocarbons, ammonia, or halogens significant different viscosity-temperature relationships occurs with respect to the pure S case. This behavior is critical in volcanic settings, where these components are common, and sulfur is not pure. Several volcanoes have shown transitions between periods of dome growth and periods with crater lakes, and sulfur melts have been reported at volcanoes with no records of historical eruptions, and no crater lakes; sulfur presence has been recently reported at submarine calderas. These evidences suggest that elemental sulfur accumulation within hydrothermal systems is indeed a common process, not restricted to crater lakes (Scolamacchia, 2024). Both emission types, and amounts, of gas species released at the surface, critical for volcano monitoring, would be altered, following chemical reactions within impure S, invalidating signals to issue alerts. Chemical reactions within impure sulfur, and viscosity variations can explain contrasting signals reported at volcanoes, and restless calderas, worldwide (Scolamacchia 2024). Implications for volcanic-risk-mitigation strategies are envisaged.

Decoding the processes that lead to the extraordinary enrichment of lithium in the Salar de Atacama (northern Chile): new insights from Li, B and Sr isotopes in surface and groundwater

Tardani D.*[1], Álvarez-Amado F.[2], Poblete-González C.[2], Godfrey L.[3] & Matte-Estrada D.[2]

[1] Instituto de Ciencias de la Ingeniería, Universidad de O'Higgins, Rancagua, Chile. [2] Departamento de Ciencias de la Tierra, Universidad de Concepción, Concepción, Chile. [3] Department of Earth and Planetary Sciences, Rutgers University, Piscataway, New Jersey.

Corresponding author email: daniele.tardani@uoh.cl

Keywords: lithium, stable isotopes, Salar de Atacama.

Northern Chile, northwest Argentina, and southwest Bolivia represent a world-class lithium deposit. However, this extraordinary enrichment remains controversial, and different processes have been invoked over the years, including active volcanism, leaching of soluble salts from volcanic rocks, and leaching of lithium-rich clays. The Salar de Atacama (SDA) represents one of the wealthiest Li reservoirs in northern Chile and has been widely studied in recent years. Most studies have focused on the southern and southeastern parts, where the highest lithium concentrations have been reported. However, a comprehensive model of water recharge in SDA still needs to be more precise. In this study, by combining isotopic ($\delta^{7}Li$, $\delta^{11}B$, and $^{87}Sr/^{86}Sr$) and chemical composition of a set of water samples from salt lakes, geothermal manifestations, groundwater, and diluted surface waters (rivers and streams with low salinity), we explore the hydrogeochemical processes that control SDA solute distribution. Our data confirm that ignimbrite weathering constitutes one of the most critical processes of solutes origin in the region, where deep water-rock interactions operate at high temperatures, enhancing the leaching of Li and other solutes. We determined that the groundwater flow entering the SDA has undergone pre-enrichment processes (e.g., leakage of salt pans from the Altiplano and dissolution of evaporites, among others) associated with salt contributions from the Western Cordillera. Our results provide a step towards a comprehensive understanding of the processes governing brine formation and lithium enrichment in a hyperarid environment, contributing to sustainable lithium exploration and exploitation in these environments.

The effect of anthropogenic pressure on the coastal groundwater resources: the case of Toro Bayo aquifer, Southern Chile

Tardani D.*[1], Álvarez-Amado F.[2], Taucare M.[3], Sánchez J.[2], Taussi M.[4] & Daniele L.[3]

[1] Instituto de Ciencias de la Ingeniería, Universidad de O'Higgins, Rancagua, Chile. [2] Departamento de Ciencias de la Tierra, Universidad de Concepción, Concepción, Chile. Keywords: hydrogeology, stable isotopes, saline intrusion.

Over recent decades, population growth, urbanization, and climate change have intensified water demand. Under current scenarios, surface water storage declines along with widespread depletion of water quality, increasing human activity dependence on groundwater. In particular, coastal aquifers represent strategic groundwater reservoirs, providing a secure water source for more than one billion people living in coastal regions. Coastal areas are generally more densely populated than the interior and have been found to exhibit higher rates of population growth and urbanization. For this reason, coastal aquifers require a great management effort since they present a high degree of vulnerability due to overexploitation, which can lead to irreversible damage such as saline intrusion. In Chile, a country with a coastline of 6,435 km, most of the largest cities are located in coastal areas (for example, Viña del Mar, Concepción, and Valdivia, among others). More than two million Chileans live in coastal areas, and agricultural use, industrial activities, and urban use overstretch water reserves. The study area is located on the south-central coast of Chile, in the district of Toro Bayo, in the estuary of the Valdivia River, 5 km southwest of Valdivia. This sector has been subject to a significant population increase in recent years, and the lack of a municipal water network has determined the consequent increase in groundwater extraction by private wells. In addition, industrial and agricultural activities are present in the area, which supply the entire water demand with groundwater.

By analyzing the chemical and isotopic composition ($^{87}Sr/^{86}Sr$, $d^{11}B$, and $d^{7}Li$) of groundwater, as well as hydrogeological and physicochemical data (water level, transmissivity, T, and conductivity), this study has successfully determined the vulnerability of the Toro Bayo aquifer to saline intrusion, as a direct result of overexploitation. The implications of these findings extend beyond the local context, representing a significant advancement in the sustainable management of water resources globally.

Synergic application of stable isotopes (N-O, B, C) to recognize nitrates sources and processes in the shallow phreatic aquifer of the Metauro River Basin (Central Italy)

Taussi M.*[1], Vespasiano G.[2-3], Tardani D.[4], Chemeri L.[1-5], Nisi B.[6], Vaselli O.[5-6], Gozzi C.[5], Delgado-Huertas A.[7], Agostini S.[6], Apollaro C.[2] & Renzulli A.[1]

Corresponding author email: marco.taussi@uniurb.it

Keywords: stable isotopes, hydrogeochemistry, nitrate contamination.

The shallow coastal aquifer of the lower Metauro River valley has been experiencing a long-lasting story of nitrate contamination since the 1970s when the increase in the use of agricultural fertilizers contributed to very high levels of pollution (NO_3 up to >300 mg/L). The waters of the Metauro area represent a fundamental resource exploited daily for drinking, agricultural, and industrial uses. This anthropic pressure exposes the water resources to depletion and quality degradation risks, making the area of high social and scientific interest. Previous studies on the shallow coastal aquifer focused on the chemical characteristics of this water resource, preliminarily highlighting the importance of anthropogenic and natural inputs in modifying the pristine composition of the waters, strongly increasing NO_3 and, though at a lower extent, chloride, sodium, and sulphates.

In this work, the different sources of nitrates and processes occurring in the shallow phreatic aquifer were defined by applying a multi-isotopic approach involving $\delta^{15}N\text{-}NO_3$ and $\delta^{18}O\text{-}NO_3$, $\delta^{11}B$, and $\delta^{13}C$-TDIC on sixteen samples collected twice during April and October 2023. The $\delta^{13}C$-TDIC values were relatively homogeneous throughout the surveys, varying between -14.2 and -7.1‰ vs. V-PDB, with the higher values related to the surface water samples and likely recording a higher degree of interaction with carbonates in the river basin with respect to groundwater. Isotopic results on NO_3 indicate different biogeochemical processes and sources. Values of $\delta^{15}N\text{-}NO_3$ were indeed between +2.3 and +23.2‰ vs. AIR, while those of $\delta^{18}O\text{-}NO_3$ ranged from -3.9 up to +20.2‰ vs. V-SMOW. In both cases, no markedly high differences were recorded among the two surveys. Most samples fall in the overlapping fields of organic pollution (sewage and manure) and soil nitrogen. However, the latter can be discarded as a primary nitrate source, being NO_3 always >30 mg/L. On the contrary, the five samples showing the lowest NO_3 concentrations (<10 mg/L) have heavier isotopic content of both N and O (i.e., >10‰ in both cases), suggesting the possible occurrence of denitrification processes. By coupling the $\delta^{15}N$ values with those of $\delta^{11}B$, the latter ranging from +2.9 up to +34.7‰ vs. NIST-SRM 951, the primary sources of nitrates were better constrained, suggesting that they are mostly related to sewage and septic tanks and, secondly, to swine manure inputs.

Eventually, to have an ultimate and more comprehensive view of the nitrate pollution issue in the area and give the local environmental agency robust and reliable information on where to intervene with remediation actions, the proportional contributions of the different NO3 pollution sources will be evaluated by applying the Bayesian stable isotope mixing model MixSIAR.

Keywords: Northern Apennines, Roberto Signorini, Carlo Ippolito Migliorini.

Roberto Signorini (1901-1980) was born in Florence into a family of artists. His uncle was the famous painter Telemaco, exponent of the "Macchiaioli" current. Since the establishment of the AGIP national oil company in 1926, Signorini was employed as a geologist and entrusted with various assignments throughout the country. He studied in Belgium, graduating from the Mining Engineering School of Liege in 1929 and a year later in Engineering at the University of Rome. In 1936, he was appointed Chief of the Geological Section of AGIP, position held until 1946. He made great efforts during the World War II to keep alive the Italian Geological Society, serving as Secretary (Alvarez, 2009). After the war, having obtained professorship in 1942, he worked as adjunct professor of Physical Geography from 1947 and of Engineering Geology from the subsequent year. In 1968, he moved to Siena, as lecturer of Engineering Geology, in the newly established degree course in Geology, held until his retirement in 1971. Despite his great experience and eclectic attitude, Roberto was never permanently hired in an academic position (Moretti, 1980).

Signorini had a productive relationship with another Tuscan petroleum geologist: Carlo Ippolito Migliorini (1891-1953), born in Bibbiena, in the Casentino area (Trevisan, 1953). After the bachelor in Florence, Migliorini studied in England, his mother's homeland, at the Camborne School of Metalliferous Mining. His early passion for geology led him to join the Italian Geological Society already at the age of fifteen. Hired by AGIP in 1934, Migliorini led missions in Somalia between 1936 and 1939. He was in charge of the company's Exploration Section until 1943, when the employment relationship ended. Overcoming the difficulties of the post-war period, he took advantage of his experience as a consultant of national and foreign oil companies in Italy and abroad (Africa, Middle East).

The applied research for hydrocarbon in the Po Plain and Peninsular Italy led progressively the two colleagues to develop, with integrated approach, an innovative vision of the stratigraphy, structure and tectonic evolution of the Northern Apennines (Merla, 1984). It happened long time before alloctonistic theories were applied to the Apennine orogeny, and the global tectonics theory had not yet been developed. As usual in the history of scientific thought, their paradigms have been overcome in the following decades, and the memory of their work progressively faded over time. This paper aims at remembering Migliorini and Signorini, paying due credit to these forerunners of modern sedimentology and Apennine tectonics for their innovative contribution to the progress of the Italian geology in the middle 20th century.

Keywords: history of geosciences, Ivanoe Bonomi, Tommaso Tittoni.

In the early stages of the Kingdom of Italy, geology was highly considered in the national culture; the economic development of the newborn State depended in fact mostly on the research of natural resources and on great engineering works, based on updated geological maps. At that time, geological knowledge was the prerogative both of mining engineers and naturalists, although with some conflicts between them. Consequently, eminent scientists and technicians filled relevant public positions between late 19th and early 20th century, because of their competence and authoritativeness. Among them, four Earth scientists or engineering geologists achieved (or barely touched) even the role of Prime Minister of the Kingdom of Italy. First, we must cite Luigi Federico Menabrea (1809-1896), hydraulic engineer, General of the Savoy Army and politician, Prime Minister between 1867 and 1869. The SGI founder Quintino Sella (1827-1884), Member of Parliament and thrice Minister of Finance, in 1881 was entrusted by the King with the formation of a new government, unfortunately without success. A third relevant personality was Ivanoe Bonomi (1873-1951), graduated in 1896 in Natural Sciences at the University of Parma, with a thesis in palaeontology, concerning the ichtiofauna of Mondaino, near Rimini (Baraldi, 2014); after a second graduation in law (1900), he early quitted the scientific activity and became lawyer, journalist and politician (thrice Prime Minister, but also Member of Parliament, Senator, Home Secretary, Minister of War and of Public Works, member of the Constituent Assembly, first President of the Senate of the Republic). This contribution focuses though on Tommaso Tittoni (1855-1931), which was Prime Minister in 1905 for only 13 days, until now the record of shortest period in charge (Tassani, 2019). Tittoni has been jurist, diplomat and politician (Member of Parliament, Senator and President of the Senate from 1919 to 1929, President of the Provincial Council of Rome). Beside his several political writings, he produced also a few geological papers and maps of the volcanic areas surrounding Rome. After his graduation in law, Tommaso became also student of Giuseppe Ponzi, the founder of the Roman geological school, at the Sapienza University; later he studied also in Oxford and Liege (Novarese, 1931). His father Vincenzo Tittoni, politician and member of the *Destra Storica*, introduced him to Sella, which became his mentor in geology. Therefore, Tittoni was among the founders of the Italian Geological Society in 1881, being appointed first Treasurer. Nowadays, the growing awareness about our changing Planet urgently requires a global revision of the relationship between humanity and Earth. In such a framework, the history of influence of geological culture on Italian society and politics could provide useful insights to find strategies for a sustainable future.

The problem of the age of "greenstones" in the Western Alps: the perspective of Carlo Bruno (1831-1916)

Barale L.[1], Console F.[2], Mosca P.*[1] & Pantaloni M.[2]

[1] Istituto di Geoscienze e Georisorse, CNR. [2] ISPRA, Roma.

Corresponding author email: pietro.mosca@cnr.it

Keywords: Carlo Bruno, Western Alps, history of geology.

In the history of the geological studies of the Western Alps, one the most debated topic in the 19th century was the chrono-stratigraphy of the vast mass of predominant carbonate micaschist (calcschist) associated to distinctive "greenstones" (including serpentinite and metabasite), quartzite and limestone. This group of rocks was identified by Bartolomeo Gastaldi (1818-1879) as the "Zona delle Pietre Verdi", believed to be of Paleozoic age. It was mapped in the "Carta Geologica delle Alpi Piemontesi" based on field studies conducted between 1860 and 1879 by Gastaldi himself, Martino Baretti, Heinrich Gerlach, Giovanni Michelotti, Carlo Bruno and Luigi Bruno. A Mesozoic age for this zone was definitely imposed later by the studies of Secondo Franchi (1898).

In this contribution, we present previously unpublished material from the ISPRA Library, showcasing ideas about the lithostratigraphy of the Maritime and Ligurian Alps developed at the end of the 1870's by Carlo Bruno (1831-1916), priest and natural history teacher and one of the collaborators of Gastaldi. In these sectors of the Western Alps, in particular, he was able to date the dolomitic limestones to the Triassic based on abundant fossils he had found. In his last writing, Gastaldi gave credit to Bruno, acknowledging that his previous chronostratigraphic interpretation was mistaken (Gastaldi, 1878). In addition, Bruno had observed the superposition of "greenstone" masses to Triassic dolomitic limestones in some localities and then he also asserted a Triassic age for the "greenstones". At the beginning of 1880, Bruno conveyed his significant conclusions in two letters to Felice Giordano, then Chief Inspector of the Regio Corpo delle Miniere and employed in the planning of the studies of the Italian Western Alps for the geological cartography project of Italy. In these letters, Bruno also expressed the intention to prepare a paper on the subject to be submitted to the Accademia dei Lincei, and requested Giordano to send "a commission of geologists" to verify his claims with him in the field. The letters are accompanied by a hand-drawn watercolour plate containing two geological sections across the Maritime and Ligurian Alps, which show the relationships among the different rocks, and in particular the supposed stratigraphic superposition of "greenstones" to the Triassic carbonates.

Keywords: ecomuseum, Agro romano, geosites.

In Greco-Roman mythology, the Genius Loci was a minor deity, sometimes quite mischievous, who did not reside on Mount Olympus but dwelled in places, among houses, woods, springs, and in the spirit of people. It was a metaphorical representation of the collective memory linked to the world in which a community physically and spiritually resided. The Spinaceto-Tor de' Cenci neighborhood, located in the southwest quadrant of Rome, was created within the framework of Law 167/62. During that period of economic boom, the progressive abandonment of the countryside had led to a sudden and massive migration to cities, creating an urgent housing need. The neighborhood, the largest project of public and residential housing ever built in the world, was born with the intention of creating a New Town, following the model of those in Northern Europe where the preservation of the Roman countryside landscape and sense of place was a priority. The Roman countryside had an anonymous but indispensable history for the evolution of the city for the production of foodstuffs (agriculture and animal husbandry) and building materials. The landscape is marked by farmhouses, hydraulic works for land reclamation, quarries of leucitic lava (used for the production of cobblestones), pozzolana, sand, and gravel. Among the inhabitants, the memory of its "Arcadian past" is still preserved, harmonizing within a distinctly multi-ethnic population. A territory museum is being created within the school to collect, study, and archive testimonies and experiences in order to enhance the material, natural, and immaterial heritage of the Tor de' Cenci Spinaceto area. The territory, viewed through the lens of Earth Sciences, becomes a place of adventure and experience starting from the history of the first geological explorers. The numerous outcrops, mainly related to the Tor de' Cenci Unit but also to the Ponte Galeria Formation, the Pozzolane Rosse, and the Lave di Vallerano, are remnants of past mining activities discontinued in the 1950s, which remain, as monuments of industrial architecture, among the buildings or paths of the parks. A section of the museum is dedicated to the history of geology and to the authors who, over time, have studied this territory. Fifty years have passed since the neighborhood was built, and in this span of time, the community has acquired its own identity, which is recognized in the territory, steeped in a shared history. The territory itself then acquires the dimension of a place of shared memory, a backdrop for the events experienced by the inhabitants. The transformation of a place of memory, shared by the experiences of many people, into a monument, that is, into a symbol with which to identify, requires an educational process of transforming memory into history, through a process of critical and orderly reconstruction of past events and occurrences, both human and natural, starting from geology. The museum activity, carried out within the Ottorino Respighi Complex, is part of the "Open Schools" project funded by the Municipality of Rome, which offers students activities to be carried out within the school outside of school hours.

Historical data revision of the 1688 Sannio-Matese earthquake: dataset of environmental effects for constraining the seismogenic source

Capozzoli A.*[1], Paoletti V.[1-2], Porfido S.[2] & Nappi R.[2]

[1] Dipartimento di Scienze della Terra, dell'Ambiente e delle Risorse, Università di Napoli «Federico II».
[2] Istituto Nazionale Geofisica e Vulcanologia, Osservatorio Vesuviano, Napoli.

Corresponding author email: angelica.capozzoli@unina.it

Keywords: 1688 earthquake, historical data revision, ESI-07 scale.

The Sannio earthquake of 5 June 1688, with a magnitude of Mw=7 and epicentral intensity I=XI, had a devastating impact on Southern Italy, causing significant damage to the economy and the natural environment. The earthquake induced both primary, superficial faulting, and secondary effects, including gravitational phenomena, ground fractures, liquefaction and extensive hydrological alterations linked to the flow of springs and rivers. Despite being a well-known earthquake, the seismogenic source and the environmental effects induced by it are still subjects of scientific debate. Currently there is little knowledge about the environmental effects induced by this earthquake and a vision accounting for all the available data is still missing. In this context, we aim at collecting all available data and build a complete geodatabase, including information on the spatial location the above mentioned phenomena, with the best possible accuracy.

We present preliminary results deriving from the study of historical data revision. Data on the environmental effects of earthquakes (EEE) are collected from various sources, such as scientific articles, historical information, original archival sources and geological reports, will be integrated with subsequent field investigations. The EEE are then catalogued according to the guidelines of the ESI-07 scale. The final objective is to create a homogeneous and accurate dataset containing all the EEE induced by the 1688 Sannio-Matese earthquake. Moreover, this dataset will be used along with geological and geophysical data for constraining the 1688 Sannio-Matese seismogenic source through a multidisciplinary approach. Our preliminary results highlight the importance of collecting and analyzing data on environmental effects of earthquakes to better understand local seismic hazard of the Sannio-Matese area and the potential impact of earthquakes on natural environment.

The "Signora" of limnology. Rina Monti: geological experience, ecosystem protection and the impact of human activity

Cofano A.* & De Ceglie R.

Dipartimento di Ricerca e Innovazione Umanistica, Università di Bari "Aldo Moro".

Corresponding author email: cofanotonia099@gmail.com

Keywords: limnology, environmental impact, ecology.

After receiving her degree in Natural Sciences in 1892, Rina Monti (1871-1937) carefully took care of her education and, in the academic year 1892-93, she decided to assist the mineralogist Francesco Sansoni in his research activity at the University of Studies of Pavia. It was a short but crucial period for Monti's professional growth as it allowed her to come into direct contact with geology for the first time; on the other hand, Sansoni himself, to increase the young woman's knowledge, decided to pair her up with the engineer and geologist Arturo Cozzaglio who was conducting field studies in Val Camonica at that time. After months of work, Monti produced and published some articles (Monti, 1894) which were published in the Journal of Mineralogy, Crystallography and Petrography directed by Sansoni. Rina's contributions, completed by those of Cozzaglio (Cozzaglio, 1894), represented the culmination of a study path aimed at learning geology techniques and tools, which proved to be of great importance and effectiveness for her mature studies. Participation in 1906 at the Congress of Italian Naturalists in Milan, promoted by the Italian Society of Natural Sciences, and her marriage to Augusto Stella, an important Italian geologist, sealed the living and ever-constant bond between Rina and Earth science. For Rina, however, the geological description represented the first step to truly understand the history and present of the lakes and the complex and very delicate ecosystems that they protected. Rediscovering the origins of these places pushed the researcher to ask herself what the modifications had been that had altered their natural harmony. Her studies are more relevant than ever because they focus on the conservation, protection and promotion of the environment. For this reason they are capable of making us reflect on fundamental issues of our era (Monti, 1929a, b).

Microhistory of the civilization of mines: from the golden fleece to the critical raw material act

De Caterini G.*[1-4], Ferranti N.[2], Finocchiaro G.[1], Fumanti F.[1], Giarda M.[3], Guerrieri L.[1], Leoni G.[1], Mestriner T.[3], Roggero F.[4], Savoca D.[2], Spizzichino D.[1] & Tria N.G.[1]

[1] ISPRA, Roma. [2] ANIM – Associazione Nazionale Ingegneri Minerari. [3] Assorisorse. [4] Dipartimento di Scienze Giuridiche, Sapienza Università di Roma. [5] Società Geologica Italiana, Sezione di Storia delle Geoscienze.

Corresponding author email: giovanni.decaterini@isprambiente.it

Keywords: mining industry, sustainability, history of technology.

In 2024, the EU unveils the Critical Raw Material Act, a legislation embedding the mining sector within the framework of the "Green Deal" strategy. This act aims to address the issue of global warming by promoting policies supporting a new economy based on sustainability, energy transition, and the establishment of a new relationship between humans and nature.

The history of civilization is marked by epochs that begin and end with events which over time generate radical cultural revolutions economically, socially, culturally, technologically, and consequently environmentally. The first major techno-economic revolution was the agricultural one. In a few millennia, the spread of technical knowledge extended across the then-known world, creating an initial "global market". However, nature is certainly stronger than technology.

The second major revolution occurs in the mid-1700s, symbolically marked by the steam engine, powered by coal and produced in iron. Humanity begins massively altering nature. In the 19th century, industry spreads throughout Europe and the Americas, ushering in the age of gas, oil, and the internal combustion engine. This period is characterized by steel, new metals such as aluminum, and reinforced concrete. However, the environmental impact of industry is high, with a total lack of environmental awareness.

The 20th century heralds the atomic age, with humanity convinced that technology could lead to its demise. The age of plastic develops, and environmental issues become increasingly relevant in the consciousness and regulations of Western states.

In the 1970s, the explosion of the electronic revolution occurs, dominated by information technology. The global market spreads, and humanity begins to realize its destructive impact on the environment and climate. This marks the beginning of the third industrial revolution, leading to the energy transition from coal to cleaner energy sources. Nature becomes a moral category, and articulated environmental regulations develop. Western countries begin to gradually phase out the most impactful industries. The global market triumphs, rendering some sectors, including mining, non-competitive.

Today, we are experiencing the fourth industrial revolution, the era of intelligent machines managed by cyber-physical systems via Cloud computing. Science has demonstrated that human activity alters the climate. The new electronic industry demands rare materials, such as rare earths, essential for the electronics industry. Changes in the global geopolitical context and the closure of the global market challenge European strategic production.

However, we are on the brink of a new industrial revolution outlined by the EU's Green Deal. It proposes a more ethical vision of industry and the economy, integrating factors such as sustainability. Crucial is the environmental issue and policies for mitigating global warming and ensuring the supply of materials without which the energy transition will be difficult to achieve. The future involves new methods of waste recovery, the use of renewable energies, and the integration of sensors to reduce energy consumption. This revolution will only be possible through the use of rare and strategic materials outlined in the Critical Raw Material Act.

The relevance of the 1973 mining map of Italy: its revamping in the GeoSciencesIR project

De Caterini G.[1], Leoni G.*[1], Andrisani M.G.[1], Carta R.[1], De Benedetti A.A.[1], De Corso S.[1], Ferrigno F.[1], Fumanti F.[1], Guerra M.[1], Guerrieri L.[1], Lucarini M.[1], Naitza S.[2], Olivetta L.[1], Pantaloni M.[1], Patanè R.A.[1], Serra M.[1], Spizzichino D.[1] & Amanti M.[1]

Corresponding author email: gabriele.leoni@isprambiente.it

Keywords: mining map, georesources.

In 1973, the Geological Survey of Italy published the Mining Map (scale of 1:1,000,000), followed in 1975 by a rich analytic description (Castaldo & Stampanoni, 1975). The release was promoted by the Director Jacobacci who, approaching the 100th anniversary of the Royal Geological Survey, prompted the Mining Corps to complete the knowledge of the Italian mining heritage. In fact, since the early years of the Geological Survey's activity, there was a need to produce a technical-administrative tool that, through coordinated cartographic research and documentation, would frame the knowledge about the national mining heritage. Therefore, Jacobacci, in the endeavour to fulfil the initial institutional mandate, renewed efforts by recruiting top experts on mining issues from the Geological Survey, the academia, the industry and the mining districts. Since, until then, knowledge of the mining heritage was only derived from information and memories of the past or from a multitude of random, unplanned discoveries, the introduction, emphasised the importance of collecting homogenous information.

The mining map showed the distribution of mineral deposits and of active and inactive mines, at the time of its drafting. The map's legend and the associated text proposed an exhaustive state-of-the-art of the national mineral deposits, laying a valid premise for further development of more detailed mining knowledge. The graphic content displayed the properties of deposits ("corpi minerari") relative to genetic, depositional and composition parameters of the resources. This work advanced synthetic standards for depositional and mining terminologies, providing also an in-depth literature analysis. To this aim, the 1973 Mining Map was planned and structured analytically as a geodatabase consisting of 350 georeferenced points, locating areas of interest of mineral bodies (Servizio Geologico d'Italia, 1973). The deposits were characterized through scientific research and mining activity data, analytically describing the following characteristics: name of mineral body, nature of mineral/s, morphology of deposits, type and age of host rocks, genetic process, relevance and estimated dimension of deposit and mining activity status.

The valuable content and the method with which the 1973 Mining Map was created is still appreciated. It constituted the cornerstone for the RIMIN project (1986-1998) aimed at laying the scientific basis for private operational research, in order to expand the potential of existing mines and to discover new deposits. Then, mining research products, through different national and European projects, were collected by the GeMMA database. Finally, in the framework of the GeoSciencesIR project, it was deemed convenient to digitise the map and the text data, to revamp this knowledge and to integrate it with last 50 years of data. In fact, the deposit-based interpretation and synthesis of analytical mining data can still offer a complete and updated insight of mineral resources in Italy.

On the burning earth: the fascination of Vesuvius and the origins of modern geology

De Ceglie R.* & Petrocelli C.

Dipartimento di Ricerca e Innovazione Umanistica, Università di Bari "Aldo Moro".

Keywords: Vesuvius, Gimbernat, Babbage.

Between the end of the 18th century and the first decades of the 19th century, at a time when the foundations of modern geology were being laid, Vesuvius and the entire volcanic area around Naples became a compulsory destination for the observations of local and foreign scholars. The uniqueness of the Neapolitan landscape and the majesty of the irascible volcano became a classic in geological literature, and two very different scholars, Carlos de Gimbernat (1768-1834) and Charles Babbage (1791-1871), could not help but write about it (Gimbernat, 1819; Babbage, 1847, 1864). Fascinated by Vesuvius, they both travelled the same routes, risking burning themselves in the 'frightful furnace', but their paths would never cross.

Carlos de Gimbernat is an original and fascinating figure of a scholar, well known and included in the scientific community of the early nineteenth century. His life is almost the plot of an adventure novel that sees him travelling around a Europe tormented by wars and revolutions. A cosmopolitan scientist with multiple interests, his arrival in Naples in 1818 coincided with a spectacular and long eruption of Vesuvius: an event with a strong symbolic value that would condition his future. His stay would be devoted to geological and volcanological excursions and observations, which he would combine with libertarian ideals a highly symbolic blend of new scientific and political ideas.

A farsighted mind, mathematician, physicist, scientific reformer, Charles Babbage was also a tireless traveller. Bewitched by Vesuvius and the geological riches of the Campi Flegrei, he arrived in Naples in 1828 and was enraptured by the mountain that 'ejected red-hot fragments of lava'. Visiting the Serapeo, he lingered over the singular circular marks and mysterious holes left by shellfish on the marble of the 'most remarkable building on the face of the earth', clear proof that the Temple of Serapis was not always at the same level with respect to the sea. With the help of his calculating machine, the Difference Engine, he proposed an interpretation of the observed phenomena that would be accepted by the most talented geologists of the time

Keywords: Karakoram, Italian Expedition, Cretaceous stratigraphy.

Between the years 1913 to 1914 the De Filippi Expedition, led by the Italian explorer and mountaineer Filippo De Filippi (1869–1938), traversed the Himalayan Range from Kashmir to Baltistan and Xinjiang. Exploring mostly unknown territories, traveling more than 2000 kilometers, and equipped with advanced instruments for geodetic and meteorological measurements, the expedition members surveyed, mapped and collected a large number of rocks and fossils samples. Members of the expedition included physicists, meteorologists, alpine guides, military men from Italy and the British Empire, along with several local carriers. Prominent figures were the geologist Giotto Dainelli and the geographer Olinto Marinelli who surveyed the topography and geology of the area. In June 1914, leaving from the base camp south of the Karakoram Pass, they led the exploration of the remote Aksai Chin region, characterized by mountains and highlands located at more than 5000 m asl, while the rest of the group was employed elsewhere (Fabbi et al., 2024). They realized geological maps and collected hundreds of well-preserved fossils, mostly referred to the Cretaceous, which was documented for the first time in the whole Trans-Himalayan Range by the De Filippi expedition (Sha et al., 2020). After almost two years, the expedition returned to Italy via a long route through Central Asia and Russia, however, publication of the findings was delayed due to the outbreak of the First World War.

Due to the enduring geopolitical tensions between India and China over territorial borders since the late 1950s, the Aksai Chin region has remained a nearly inaccessible area. Thus, the paleontological material collected by Dainelli and Marinelli and their syntheses of the geology and stratigraphy of the area represent unique documents for reconstructing the stratigraphy and geology of this sector of Western Tibet (Gaetani 2011; Sha et al., 2020). The De Filippi collection is housed in the Natural History Museum of the University of Florence and constitutes still today a valuable resource regarding the history of the scientific exploration and understanding of the geology of the region, providing a unique window into a very remote and fascinating part of the World.

Military geology and historical archives: from De Ambrosis' monographs to Bulow-Krantz-Sonne's Wehrgeologie, the role of geology in the Second World War

Garzarella A.*

Dipartimento per il Servizio Geologico d'Italia, ISPRA, Roma.

Corresponding author email: adele.garzarella@isprambiente.it

Keywords: history of geoscience, military, geology.

In recent decades, the study of the impact of the battlefield terrains on military strategy and tactics has greatly expanded. The strong climate conditions during the winter 1943-1944 and the influence of huge rain and snowfall was first described by Cori (1994) giving a first attempt to define the environmental conditions during the Sangro River battle, 28th-30th November 1943.

The Central Appennines Meso-Cenozoic carbonate stratigraphic sequences, sorrounded by mainly clayey-sandy hilly foothills played an important role for military strategy (Narebski, 2011). The German Todt Organization planned the defense lines months before the starting of the battles and located them in the narrowest points (isthmuses) of the Central Apennine, i.e. the Gustav line running from Garigliano river mouth in Lazio country to Ortona on the Adriatic coastline, and the Gothic Line, from La Spezia (Tyrrhenian Sea) to Pesaro (Adriatic Sea). The German strategy to choose the mountainous carbonate massifs for their defense lines, using the available lithoid material, managed to slow down the progress of the allies, forced to operate on landslides and easily erodible hilly area (slopes> 30 °, alternation of gorges and ditches), aided by the harsh climate and hydrography, with rivers that served as natural trenches. The German defensive lines were the emblem of how a deep knowledge of natural element can be a multiplier of forces for an army (Chasseaud & Doyle, 2005).

The serendipiteous findings of the General Delfino De Ambrosis monographies regarding the military geography of Italy, printed for the official cadets training in the Italian School of War, had open new questions on the previous knowledge of the German-Italian Army in preparation of the line positions, as the countries were allied till the September 8th. Prior the Italian Campaign, during the Fascism Period, De Ambrosis surveied the whole Italian landscape, from North to South and the Libic Italian, too, giving the first complete decription of geology, georesources, climate and idrology of Italy at the time for war purposes (De Ambrosis, 1924).

The Wehrgeologie Handbook published by Bulow-Krantz-Sonne in 1938 is also here presented to better understand the importance of the geology in the warfare strategy planning, and how the application of principles and knowledge of Geology is a truly force multiplier for an Army.

One against all: fifty years after the geological scheme of Calabria by Leo Ogniben (1973)

Innamorati G.*[1], Fabbi S.[1], Romano M.[1] & Argentieri A.[2]

Keywords: Leone Ogniben, Calabria.

The academic world of geology in the 1960s and 1970s in Italy has been undoubtedly affected by radical changes: a true revolution, on the wave of the advent of plate tectonics (Praturlon, 2012). This transformation completely redefined the mechanisms and behaviors governing both intra- and extra-departmental relationships, as well as the rules of engagement and power dynamics. At the same time, there was a shift towards a new way of conducting research, based, consistently on the international trend, on quantitative rather than qualitative methods.

Many factors contributed to this revolution: legislative reforms (in particular the law on national geological mapping of 1960, due to the politician Fiorentino Sullo); reforms of University and of the National Research Council (CNR); funding of "big science" projects (above all, the "Progetto Finalizzato Geodinamica"). The new scenario forced academic research to break out of its shell and to collaborate with other institutions and energy industry. These changes were also fostered by the emergence of a new generation of scholars, ready to break free from the constraints imposed by established conventions and sustained by their mentors.

In this period of intellectual and scientific ferment, Leone Ogniben was a controversial figure who followed a completely different path with respect to most academics. Before becoming professor at the University of Catania, he spent a nearly 20 years post-graduate career in the industrial sector, acquiring a different mindset with respect to the majority of his colleagues (Roda, 1991). On one hand, this background had led him to be a modern, independent, and unconventional academic, anchored in a strong quantitative scientific approach, but, on the other hand, it had also made him a rigid man, closed in his convictions and little inclined towards dialogue and intellectual exchange. Furthermore, despite the severity with which he proclaimed his idea of conducting good research, Ogniben ended up betraying these paradigms in order to demonstrate and apply his geological schemes.

Leone Ogniben is known for his studies concerning Eastern Sicily, the Calabrian-Lucanian Border, and especially his monography on the Calabria-Peloritani Arc (Ogniben, 1973), which sparked a harsh response from a sizable group of researchers (Amodio Morelli et al., 1976). This famous discord should not be interpreted solely as a skirmish or animosity between geologists with different views and temperaments, but rather as paradigmatic of that period of great change mentioned earlier, with young researchers who struggled to stay within the rigid academic logics with which Ogniben identified.

Geosciences and engineering of Lungro rock salt: unveiling Italy's longest-lived underground mining site in Calabria

Macini P.*[1] & Pantaloni M.[2]

[1] Dipartimento di Ingegneria Civile, Chimica, Ambientale e dei Materiali, Università di Bologna.
[2] ISPRA, Roma.

Corresponding author email: paolo.macini@unibo.it

Keywords: rock salt, mining history, solution mining.

The Lungro area is renowned for the presence of the longest-lived Italian underground rock salt mine, exploited almost continuously from ancient times until 1978. The history of mining activity is documented since the Middle Ages, although evidence suggests that salt production by near-surface excavation dates to the Greek and Roman civilization or even to prehistoric times. During the Middle Ages, mining methods were aimed to the maximum profit, and the mine, rather than being rationally developed, was deepened along the vertical, following the winding path of higher quality salt layers. This approach led to problems such as of rock instability, inadequate ventilation and water infiltration arose (Galli, 1828), that characterized this mine up to its recent abandonment.

Following the Napoleonic invasion of the Kingdom of Naples (1806-1815), the modernizing spirit of the new rulers was aimed to reorganize the feudal administration and diminish most of the rights and privileges of the old nobility. As part of this process, mines were nationalized, and the mineral resources of Calabria attracted the interest of the French government. In 1811 the naturalist and geologist Giuseppe Melograni published a comprehensive report on the site, rich in geological considerations, technical descriptions, geometrical surveys, and practical recommendations for a modern and rational mining operations (Melograni, 1822). Concurrently, Pietro Pulli, Inspector General of the Kingdom, was commissioned to provide information on the economic and social conditions existing in Lungro (Pulli, 1813). By the mid-19th century, the mine, with its four production levels, a ventilation shaft and a complex tunneling network, was an important industrial enterprise, with over 400 miners, alongside a technical and administrative staff, a number comparable only to the steam spinning mills of Villa San Giovanni (Reggio di Calabria). In 1879, Torquato Taramelli visited Lungro and the surrounding area during a field trip to Calabria, and provided invaluable stratigraphic and paleontological observations, both still very unknown at the time (Taramelli, 1880). His report contains also a precious first-hand description of the bad working conditions he experienced inside the mine.

Although partially renovated at the end of the 19th century, both in its internal structure and in work organization, the mine decline began in the early 1900s. This decline accelerated as the Italian government estimated that sea salt produced in Sicily was cheaper than rock salt from Lungro. Consequently, a "slow death" approach was used, gradually decreasing exploitation of the deposit until all workers retired, without layoffs but also without new hires. Miners access to the underground was never solved: still in the 1970's, two of the eight working hours of the daily shift were lost to descend into and ascend from the mine, as there were over 2000 steps to walk. Poor mining methods persisted throughout the 20th century, culminating in its final abandonment in 1978.

Reflection vs. refraction seismic: Tiziano Rocco and the development of applied geophysics in Italy

Macini P.*[1], Mesini E.[1] & Argentieri A.[2]

[1] Dipartimento di Ingegneria Civile, Chimica, Ambientale e dei Materiali, Università di Bologna.

Keywords: seismic reflection, history of geosciences, exploration geology.

Tiziano Rocco (Motta di Livenza, 12/2/1908 – Milan, 02/07/1984) was a mining engineer involved since his early career in a key and new activity for oil companies around the world in the 1930s: applied geophysics. Hired in 1929 by the Italian state-owned company AGIP (founded in 1926) under the guidance of Guido Bonarelli and Arnaldo Belluigi, then manager of the geophysical section, after a short period of training he led gravimetric, magnetic and electrical survey teams in Italy, during the 1934 campaign in eastern Sicily. Rocco eagerly studied the scientific literature and soon learned that a new geophysical method for oil exploration, seismic reflection, had been successfully tested in the USA since the early 1930s (Guidi, 1998).

In 1937, after some trials with German equipment and the in-house construction of rudimentary seismic units, AGIP asked Francesco Vercelli (Trieste Institute of Geophysics) to visit Berlin to verify the state of the art of the German allies, and look for a more convenient alternative than that of the American Western Geophysical, already contacted by Rocco. Vercelli and Rocco visited Berlin, and they verified the lack of satisfactory technical standards, which instead they found in the USA in another joint visit (1938). Upon their return, the Board of AGIP approved Western's offer (although with great political worries), and in 1939 two seismic groups arrived in Italy. The first survey was carried out on 10 June 1940, the very day Italy entered WW2, in the Po Valley basin (Pozzi, 2009). Good results arrived quickly: in late 1940, the structures of Ripalta, Caviaga, Cortemaggiore and Piadena had already been outlined. Rocco located the first exploratory wells, which led to the first success in 1944, the discovery of Caviaga gas field. Rocco foresaw the potential of geophysics, and in particular of reflection seismic, at least a decade in advance in Europe, in times of poor collaboration between Companies, Universities and Research Institutes, when scientific and technological advances were shared with difficulty.

Rocco left AGIP in 1943, due to the turbulent events of the armistice and the German occupation of Italy; from 1945 he worked with SPI (Società Petrolifera Italiana) and from 1948 with Western Geophysical. He returned to AGIP in 1951, as Director of exploration. In the 1950s and '60s he significantly contributed on the company's successes in Italy and foreign countries (Iran, Egypt, Nigeria, Tunisia and Libya), as well as for the detailed definition of the geological structures of the Po Valley basin (Rocco, 1942, 1949). He retired in 1968, and in the same year he was elected President of the Italian Geological Society (SGI) for the two-year period 1968-69. Rocco had been SGI member since 1940, and held the position of Vice President under the chairmanship of Roberto Malaroda (1966-67). With his appointment, SGI intended to open up to the applicative aspects of geosciences and intensify the relationships with the industrial sector, and particularly with AGIP.

Antonio Stoppani: a pioneer of petroleum geology and his activity in the Italian oil production industry

Macini P.[1], Pantaloni M.*[2] & Console F.[2]

[1] Dipartimento di Ingegneria Civile, Chimica, Ambientale e dei Materiali, Università di Bologna.

Corresponding author email: marco.pantaloni@isprambiente.it

Keywords: petroleum geology, history of geology.

This work deepens into the significant advancements made in petroleum geology, geosciences, and technology within Italy during the mid-19th to early 20th centuries. These advancements laid the groundwork for the emergence of the national petroleum industry. Specifically, it scrutinizes the pivotal role played by Antonio Stoppani, who catalyzed the inception of modern petroleum geology studies in Italy. Following E.L. Drake's landmark discovery in Pennsylvania in 1859, a flurry of activity in petroleum production, refining, and export burgeoned in North America—a phenomenon named the "oil rush," which stands as one of the earliest instances of commercial globalization (Novelli & Sella, 2009). Within a brief span, a multitude of companies engaged in oil and gas exploration emerged in Italy, drawing upon the nation's rich historical and scientific heritage, as well as centuries-old artisanal practices of harvesting and trading olio di sasso (rock oil) (Stoppani, 1864).

Initially concentrated in the Emilia region (including the provinces of Piacenza, Parma, and Modena) (Macini et al., 2018), this activity soon expanded into Abruzzi (particularly the Pescara Valley, between Tocco da Casauria and Lettomanoppello), Lazio (former region of Terra di Lavoro, between Ripi and San Giovanni Incarico) and Sicily.

Since 1864, Antonio Stoppani embarked on the development of various aspects encompassed by contemporary "petroleum geosciences." Notably, in a seminal article, he comprehensively addressed the distribution, characteristics, and origins of oil and gas from a global perspective, surpassing the confines of Italian geography. This approach, unprecedented for its time, underscored Stoppani's profound familiarity with recent American scholarship, particularly that of T.S. Hunt, whose work elucidated the theory of anticlines.

In 1866, Stoppani further augmented his contributions by publishing a map delineating the petroleum-rich zones of the Emilia Region (Stoppani, 1866). This endeavor coincided with the initiation of an ambitious cartographic project aimed at crafting a geological map of Italy.

Stoppani's endeavors extended beyond scholarly discourse; he meticulously analyzed the scientific underpinnings of oil exploration in Italy, pinpointing the most promising locales, formulating hypotheses regarding hydrocarbon origins, and delineating the technical and economic constraints inherent in domestic oil management. His commitment was exemplified by extensive visits, studies, and advisory roles at virtually all Italian petroleum production sites.

Ultimately, Stoppani assumed the presidency of the "Società Italiana delle Miniere Petrolifere di Terra di Lavoro," overseeing oil extraction operations at S. Giovanni Incarico, situated in present-day in Frosinone province. However, in 1881, disillusioned perhaps by the profit-driven motives of his partners, who prioritized immediate gains over the broader scientific, technological, and societal benefits of sustained endeavors, Stoppani disengaged from all involvement in the petroleum production industry.

Keywords: marine geology, submarine geomorphology, oceans.

Underwater topography is modelled by physical, chemical and biological processes operating at depth on rocks and bottom sediments. The study of underwater topography began in the mid-19th century and before then bathymetric data were practically absent. Kant, in 1802, in 'Physical Geography', reported of a captain who, on a voyage to the North Pole, failed to find the bottom at 4680 feet, the greatest depth ever measured. Kant, however, suggested that the greatest depths of the sea must be in proportion to the highest mountains. Lieutenant Maury in 1854 published the first map of the seabed of the Atlantic Ocean in which the mid-Atlantic ridge was completely unknown. In 1912, the map of the aforementioned Ocean by the German oceanographer Gerhard Schott showed the aforementioned ridge for the first time. So until the 20th century, almost nothing was known about the ocean floor. It was only in the 1960s, thanks to geophysical campaigns and the great work on the interpretation of bathymetric data by Barren et al., which were published in 1977 (Beran et al., 1977), that a map with the main landforms of the ocean floor was produced. Even today, the ocean depths are inaccessible, poorly known and largely yet to be surveyed and measured.

Keywords: history of cartography, geological map, history of volcanology.

A detailed reading of the second volume of Der Aetna clearly shows that the comprehensive work of Sartorius and his collaborators constitutes the most important scientific work in the field of geological and mineralogical studies carried out on Etna. The work began with the drafting of the topographic and geological map of the volcano published in 1838, and concluded with the posthumous publication of Der Aetna, revised and completed by Lasaulx in 1880. Noteworthy, Der Aetna treats the topics with a detail and completeness never addressed before in a single work, as well it includes of the only map at scale 1:15.000 existing to date of the Valle del Bove. At the same time, it has been the least read work ever, mainly due to the complexity of German language and, above all, it has been cited as mere bibliographic reference. These reasons led to diminish the impressiveness and importance of Der Aetna, which has frequently been compared to the outdated monograph on the volcanology of Etna by Carlo Gemmellaro of 1858 and to the short work by Charles Lyell published in the Philosophical Transactions of the Royal Society of London in 1858. In this context of oblivion, most of the findings and conclusions of Sartorius and Lasaulx have been reproposed during the 20th century as new hypotheses on the evolution and structure of Etna, ignoring that they had already been formulated.

Today, more than 140 years later the publication of the second volume of Der Aetna, the map of the Valle del Bove, and the previous geological cartography of the Atlas des Aetna, constitute a unique collection of geological and volcanological data of a historical nature for Etna, most of which have been erased by the volcano's eruptive activity. Among all the volcanological works carried out on Etna during the 19th century, Der Aetna and the associated cartography are the only ones still used in the 21st century by researchers, who extract the volcanological parameters of historical eruptions, which are fundamental for the implementation of volcanic hazard studies.

The geological map of the western side of the high Agri Valley

Palladino G.*[1], Prosser G.[2], Grimaldi S.[2], Olita F.[2], Cascini L.[2] & Dello Iacovo B.[3]

[1] Akkodis s.r.l. [2] Dipartimento di Scienze, Università degli Studi della Basilicata. [3] Eni.

Corresponding author email: giuseppe.palladino@akkodis.com

Keywords: hydrogeological complexes, Agri Valley, southern Apennines.

Geological maps provide a fundamental support for engineering/land use decisions and for locating natural resources. In particular, they greatly help in assessing groundwater distribution and in the definition of the main hydrogeological complexes. In this context a new geological map of the western side of the Agri Valley area (axial sector of the southern Apennines), has been carried out to better define the complex carbonate hydrostructure of the Monti della Maddalena (Grimaldi & Summa, 2005). The intense deformation recorded in the study area, combined with a complex tectono-stratigraphic setting, produces a significant compartimentalization of the aquifers, that requires detailed geological mapping to be reliably described. Available geological maps in the study area (505 "Moliterno" and 521 "Lauria" sheets 1:50000, ISPRA) do not provide the necessary level of detail to correctly define the complex hydrostructure and need to be updated with the newly investigated stratigraphic and tectonic units.

We have carried out a geological mapping at 1:25.000 scale, using a new scheme of the tectonic units, and applying a finer stratigraphic subdivision, which includes members or beds. As a result, we provide a formation to member-detailed geological map of the western side of the high Agri Valley with sufficient resolution for defining the tectonic structures that influence the circulation groundwaters in the study area. The area displays a stack of tectonic units consisting of Mesozoic to Cenozoic rocks represented from top to bottom by: i) the ocean-derived Liguride Units; ii) the carbonates of the Apennine Platform; iii) the pelagic successions of the Lagonegro Basin. The tectonic units, piled up during Miocene to Pliocene contractional tectonics, are offset by low- to medium-angle normal faults and by different sets of high-angle transtensional to normal faults, developed during the Late Pliocene to the Pleistocene. Some of these faults controlled the formation of the NW-trending Agri valley basin, filled by Middle Pleistocene lacustrine and alluvial deposits.

The main results are:

1. a third Lagonegro tectonic unit besides the Lagonegro I and II ones. The new unit is located in between the Lagonegro and the Apennine Platform units at bottom and at top, respectively. It shares many stratigraphic features with the Lagonegro II Unit so that it is believed to results from the tectonic doubling of this latter unit;
2. the definitive dismission of the Moliterno Formation, formerly interpreted as the base of the Apennine Platform (Sheet 505 "Moliterno"-ISPRA). The formation has been either reconducted to the Monte Facito Formation or to thin slices of the Apennine Platform;
3. the tectonic nature of the basal contact of the Albidona Formation, which has been framed within the Liguride Units.

These results allowed to better define tectonic multilayer of the southern Apennines, greatly improving the knowledge of the groundwater circulation in the area.

The woman who painted the ocean floor: celebrating Marie Tharp's legacy

Romano M.* & Chiocci F.L.

Dipartimento Scienze della Terra, Sapienza Università di Roma.

Corresponding author email: marco.romano@uniroma1.it

Keywords: women in geology, marine geology, Mid-Atlantic Ridge.

Marie Tharp was a pivotal figure in the advancement of Earth Sciences, particularly in marine geology and ocean floor cartography. Her groundbreaking work played a significant role in reforming the concept of continental drift and laying the groundwork for the plate tectonics revolution of the early 1960s (Barton, 2002; Romano & Chiocci, 2020). Initially met with skepticism, the theory of continental drift proposed by Alfred Wegener in 1912 faced opposition from the scientific community, including prominent paleontologists and geophysicists, who denied the mechanism proposed by Wegener for the movement of rigid sial continental crust above sima basaltic oceanic crust. Tharp's contributions became crucial in bridging this gap in understanding. Prior to her work, knowledge of the ocean floor, covering over 70% of the Earth's surface, was very limited. Tharp's meticulous analysis of bathymetric data, the discovery of the Mid-Atlantic Ridge and somital axial valley, challenged existing scientific paradigms. Despite initial resistance, her findings, alongside those of her colleague Bruce Heezen, provided essential data supporting the theory of seafloor expansion that may account for the drifting of crustal fragments on Earth surface favoring the floor to the modern plate tectonics paradigm. Tharp's interdisciplinary expertise in geology and mathematics was instrumental in transforming raw bathymetric data into comprehensive maps and profiles, utilizing early computer technology to aid in data analysis. The graphical representation of ocean floor data pioneered by Tharp and Heezen revolutionized scientific communication, facilitating the visualization of complex geological structures and fostering the development of new hypotheses. Their publication of the first complete world map of ocean floors in 1977 provided a comprehensive overview of the Earth's geodynamic processes, highlighting the interconnectedness of ocean ridges, transform faults, fracture zones, seamounts, and trenches. Despite facing gender-based discrimination early in her career, Tharp's pioneering work ultimately earned recognition for its significant contributions to the advancement of science. Her story echoes those of other overlooked figures in scientific history, underscoring the importance of acknowledging and valuing the diverse contributions of women in shaping our understanding of the natural world.

Early interpretations of the Eocene Bolca Fossil-Lagerstätte (Italy): three centuries of debates for the emerging Earth Sciences

Romano M.*[1] & Carnevale G.[2]

[1] Dipartimento Scienze della Terra, Sapienza Università di Roma.
[2] Dipartimento di Scienze della Terra, Università degli Studi di Torino.

Corresponding author email: marco.romano@uniroma1.it

Keywords: history of paleontology, Bolca Fossil-Lagerstätte, Eocene.

The well-known Eocene Bolca Fossil-Lagerstätte is a prominent and influential fossil site of the Cenozoic Era, renowned for its exceptional completeness, diversity, and preservation of vertebrate, invertebrate, and plant fossils (Carnevale, 2020). Centuries of excavation at primary sites like the Pesciara, Monte Postale, Purga di Bolca, and Monte Vegroni have yielded over 500 described species, facilitating nuanced interpretations of the lower Eocene western Tethys tropical marine ecosystems. These specimens are revered as iconic representations of Italian paleontology and have graced collections across Europe and North America for centuries. Bolca's fossils have not only contributed to scientific discourse but also shaped the early trajectories of paleontology and geology. This contribution offers a historical overview of Italian scientists' initial contributions to Bolca's fossil sites from the sixteenth to the eighteenth centuries, amidst fervent debates within the emerging field of Earth Sciences (Romano & Carnevale, 2023). Despite varying hypotheses about the origins of Bolca's fossil fish deposits, Italian scholars pioneered concepts rooted in empirical field data. Key controversies, including the organic versus inorganic origin of fossils, underscore the contributions of Italian scholars like Fracastoro, Scilla, Colonna, and Vallisneri. Debates regarding the presence of marine fossils in in areas now emerged up to the highest mountains sparked controversies between diluvialists and antediluvialists, reflecting broader scientific discourse in Earth Sciences. These seminal debates, entrenched in the early works on Bolca's deposits and fossils, underscore Bolca's enduring significance in geological history, examined chronologically from the sixteenth century onward.

Keywords: dinosaurs, Oviraptor, Cretaceous.

In this contribution, we commemorate the bicentenary of the first scientific description of the theropod *Oviraptor* by American paleontologist Henry Fairfield Osborn. We delve into the history of its discovery in Mongolia and the initial interpretations surrounding this iconic dinosaur. *Oviraptor philoceratops*, a small bird-like dinosaur from the late Cretaceous period, was first discovered in 1923 by George Olsen of the American Museum of Natural History (AMNH) during a Central Asiatic Expedition led by Roy Chapman Andrews. The discovery, made atop a dinosaur egg nest in the Gobi Desert, initially led Osborn to speculate that *Oviraptor* was an egg thief, an interpretation that provided the name for the new genus (Osborn, 1924). Osborn formally named the species *Oviraptor philoceratops*, suggesting a preference for ceratopsian eggs. Despite Osborn's initial hypothesis, subsequent discoveries of nesting oviraptorids demonstrated their role as nurturing parents rather than egg thieves. Our contribution sheds light on the historical context of *Oviraptor*'s discovery and the evolution of scientific interpretations over the past two centuries. By commemorating this milestone, we honor the legacy of the legendary Central Asiatic Expedition and the ongoing advancements in our understanding of dinosaur behavior and evolution.

Keywords: deep time, epistemology.

The human mind is not used to the cognitive exercise of comprehending the vastness of the concept of deep time. Yet geoscientists have been able to measure it: something that transcends and far exceeds the human scale. From the rejection of anti-scientific biblical limitations, to the term *arche-fossil* coined in 2008 by Meillassoux (2014) to express the staggering realisation that science can now report events that predate human consciousness, even the advent of life itself, the idea of geologic time was given this new name, "deep time", by McPhee (1981; Gee, 1999) – hinting at how all of human history is just scratching the surface of Earth history.

In order to discern the mind-widening scope of deep time, the aim of this contribution is to engage in an epistemological reflection on the representations of the concept, as well as the implications of this evolution as time goes by. It begins with an analysis of how and to what extent James Hutton's findings at Siccar Point (Berwickshire, Scotland) (in: Gould, 1983) impacted the notion of the world's origins, and it looks at ways to make sense of the intimidating, astonishing thought of deep time in the present.

Besides offering musings upon the difference between geological time and everyday time, we suggest travelling back and forth in time well beyond the temporal constraints imposed by human nature, in an effort to demonstrate how geological time admits no narrative until some other means emerge to favour a different view that recognizes the true magnitude of Deep Time.

Maria Matilda Ogilvie Gordon: the "Lady of Dolomite", a pioneer of geological surveying and more…

Sabato L.*

Dipartimento di Scienze della Terra e Geoambientali, Università di Bari "Aldo Moro".

Corresponding author email: luisa.sabato@uniba.it

Keywords: gender bias, pioneer female geologist.

Maria Matilda Ogilvie Gordon, or May as she was known, was born in 1864 in Scotland. Her passion for geology began with a holiday in the Scottish Highlands. May graduated in 1890 as a Bachelor of Science specializing in geology, botany, and zoology, but when she wanted to attend University in Berlin, she was denied entry because was a woman. Despite this, May attended the University of Munich, even though was not officially enrolled: to listen to lectures she had to sit in a separate room with the doors half open. In the summer of 1891, following a stay in various locations in the Dolomites, May was so fascinated and attracted by them that decided to stay at Corvara, in Alta Badia, to study those mountains. At that time those places were inhospitable, there were no roads or inns; she had to leave before dawn and returned in the evening exhausted, with a backpack full of samples and fossils, but her passion and stubbornness got the better of her tiredness. Of course, a woman alone attracted attention at that time, but the mountain guides respected her, and taught her to climb. May produced detailed geological maps and identified and studied over 300 species of corals, sponges, and crustaceans, without any guide or control of a supervisor. She was the first woman in the United Kingdom to receive the DSc degree of Science in 1893 from the University of London and the first woman to obtain the PhD in 1900 from the University of Munich (Wachtler & Burek, 2007). May was also the first woman to publish scientific articles concerning the structural geology of the Italian territory and published many other articles and books, including some geological guides also aimed at a non-expert audience (Argentieri, 2020). Despite this, only very late some merits were recognized, such as the prestigious Lyell medal of the Geological Society of London received in 1932, and more than 60 years after her death, her name was given to a new genus of Triassic fern found in the Dolomites. May also became an activist of the Liberal Party and leader of various associations created for the cause of women's emancipation and was the first woman to preside over a district court of Justice, and much more. For all this she was awarded the honor of "Dame Commander of the Most Excellent order of the British empire" conferred by King George V in 1935 (Burek, 2005). It was not easy to reconcile her scientific interests with family duties (she was married and had 4 children) and commitment to social life, and above all it was difficult to fight the prejudices according to which being interested in Science was an exclusively male prerogative.

To introduce Italian girls to this geoscience pioneer and encourage them to undertake scientific studies, overcoming the unfortunately still widespread stereotype that Sciences are "men's stuff", a short video was produced (by: Perrini, Billotta, De Giorgio, Sportelli), and shown on numerous occasions dedicated to University orientation for high secondary school classes.

Seismic maps between historical approach and scientific research. A contribution from the history of science to risk reduction

Saltarelli C.*

DiSPeA - Dipartimento di Scienze Pure e Applicate, Università di Urbino.

Corresponding author email: c.saltarelli1@campus.uniurb.it

Keywords: seismic maps, history of science, territory and risk management.

The presentation will highlight one of the crucial moments for the evolution of scientific knowledge on seismic phenomena and their dissemination: the drafting of a seismic map of the national territory between the end of the 19th and the beginning of the 20th century, in conjunction with the creation of the Italian geological map. As the scientific and public debate demonstrates to date, the construction and adoption of seismic maps can be configured as tools for a more or less functional and ethical approach for land management planning, as well as for the prevention and mitigation of risks. The history of emergency management by the various Italian governments has recently been reconstructed (Botta, 2013, 2020), and the different stages of the cultural development of earthquakes in Italy (Guidoboni & Pourier 2019).

However, the history of seismic maps has not yet been addressed through a long-term perspective, useful for detecting significant passages in the protection of the territory and the mitigation of natural risks in Italian scientific and cultural history. Since the 1970s, Italian scientific research has analyzed, under the impetus of industrial needs, a considerable amount of data aimed at creating seismic maps and databases which have been decisive for the evolution of the in-depth knowledge of seismic structures of our country and, at the same time, have provided decision-makers and public opinion with important tools for knowledge of the territory and risk management (CFTI15MED and DBMI15).

The first part of the talk will be dedicated to the reconstruction of the scientific context that allowed the development of the first Italian seismic map, with particular reference to the innovative interdisciplinary methodology developed by M.S. De Rossi, T. Taramelli, and M. Baratta. The convergence of several disciplinary instances (geological, geographical, historical, physical, archaeological, and paleontological) was decisive for the appearance of a work, and at the same time of a scientific research tool, useful for the seismic knowledge of the national territory and for the implementation of risk mitigation policies to reduce vulnerability. Subsequently, the contribution of historical seismology will be analyzed which, recovering the experience of the early twentieth century, has been able to develop, also thanks to the evolution of computer applications, seismic maps that are increasingly advanced and accessible to public opinion and politics. Finally, the current public debate on adopting the national seismic map, especially on the methodological side, highlights the double character of seismic maps: scientific and cultural. The neglect of this last point contributes to the increase in the vulnerability of our territory, therefore an appropriate dissemination of seismic maps to public opinion becomes strategic for improving the management of the territory and the associated risks.

The ancient mine of Poggio Mozzeto in the Bai Valley (Roccastrada, Grosseto)

Sammuri P.*

Società Geologica Italiana, Sezione di Storia delle Geoscienze.

Corresponding author email: science.sam@tiscali.it

Keywords: Copper mine, Southern Tuscany, Middle Age.

The copper-silver deposit of Poggio Mozzeto is located in the valley of the river Bai about 3 km from Roccastrada. The area, consisting mainly of Triassic formations, is in the western margin of the Monticiano-Roccastrada Paleozoic ridge. At Poggio Mozzeto in the Middle Ages (Sienese documents of the 14th -15th centuries), and perhaps even earlier in the Classical Age, was active a substantial extraction of copper, silver and lead minerals, witnessed still today by numerous tunnels, trenches and little shafts. On these mining remains there are testimonies of 18th century scholars (Pecci, Bartoloni) and 19th century (Simonin, Caillaux). During some mineral prospecting conducted in the last century were reported sporadic findings of concentrations of iron hydroxides ("*brucioni"* consisting of goethite, limonite and sporadic hematite) containing traces of copper minerals: chalcocite, azurite, malachite. Currently, due to erosion and dense vegetation cover, it is very difficult to detect traces of mineralization. All existing geological studies on the deposit and the characteristics of mineralisation are examined and discussed in this paper.

Keywords: Quaternary geology, chronostratigraphy, intermountain basins.

Piedimonte M., Isernia and C. di Sangro 1:50.000 geological sheets host several intermountain basins and alluvial plains. They are filled by very thick quaternary sedimentary successions made of fluvial, alluvial fan, slope, fluvial-marshy and palustrine-lacustrine lithofacies assemblages. Field and boreholes geology, supported by tephro-stratigraphical and geochronological (14C, Ar/Ar, U/Th and OSL-TL), highlights that the infilling successions were constrained between Lower Pleistocene and Holocene. A great part of the infilling was deposited during Middle Pleistocene, probably due to the strong activity of extensional faults bordering and intersecting tectono-sedimentary basins. Faultings and long-term climatic changes caused the terracing and/or entrenching of the quaternary geological units, allowing us to distinguish and group them in synthems and subsynthems.

Piedimonte M. sheet. In the Volturno and Calore R. alluvial plains, more generations of alluvial fans, slope, travertine and fluvial deposits were recognized. Five boreholes were carried out in order to estimate the thickness and lithofacies assemblage of the not outcropping deposits. Based on geochronological data and morpho-stratigraphical constraints, they were grouped in 3 synthems: 1) Lower Pleistocene p.p.-Middle Pleistocene synthem presenting intercalated Roccamonfina tephra layers (c. 600 ka, Rio Rava, B and WTT); 2) Late Pleistocene synthem containing CI (39 ka) and NYT (15 ka) tephra layers. Also U/Th datings on travertine deposits and OSL-TL datings on fluvial sandy layers support this grouping; 3) Late Pleistocene and Holocene synthem thank to the presence of archaeological remains and 14C datings.

Isernia and C. di Sangro sheets. In the Isernia and Venafro basins, quaternary deposits were grouped in 3 synthems. 1) Lower Pleistocene-Middle Pleistocene p.p. synthem (> 600 ka) thank to morpho-stratigraphical constraints and paleomagnetic data; 2) Middle Pleistocene synthem thank to Ar/Ar datings on intercalated tephra layers, U/Th datings on travertine deposits and OSL datings on fluvial sandy layers; 3) Late Pleistocene-Holocene synthem. In the Isernia le Piane basin, a deep borehole (80 m) reaching carbonatic bedrock was carried out. The whole investigated quaternary succession, from the bottom to the top, shows lithofacies of: a) lacustrine-palustrine environments of Lower Pleistocene age based on paleomagnetic data; b) fluvial marshy, fluvial and travertine deposits of Middle Pleistocene age based on Ar/Ar datings from intercalated tephra layers (between ca. 540 and 460 ka); c) fluvial-marshy deposits of Late Pleistocene-Holocene age. Also in the Sessano basin, quaternary infilling shows fluvial marshy deposits constrained between Middle Pleistocene and Holocene age based on Ar/Ar datings on intercalated tephra layers, as well as in the Rocchetta and C. S. Vincenzo area travertine deposits were constrained to Middle-Late Pleistocene based on U/Th datings.

The Jurassic-Miocene Apenninic limestones in southern Matese: biostratigraphy and sedimentary evolution from geological mapping of the Sheet 418 Piedimonte Matese

Amodio S.*[1], Barattolo F.[2], Bravi S. [2], Cesarano M.[1-3], Angiolilli D.[1-4], Auciello E.[1-4], Boscaino M.[1-4], Girardi G.[2], Randisi A.[1] & Pappone G.[1]

Keywords: lithostratigraphy, shallow-marine carbonates, biotic events.

This work depicts the present status of a revisiting and updating based on the biostratigraphy and facies analysis of carbonate platform successions, Jurassic-Miocene in age and cropping out in the southern sector of the Matese Massif, southern Apennines of Italy. This sector of the Apenninic chain, that is going to be included in the Sheet 418 "Piedimonte Matese", CARG project, is characterized by the substantially persistence in these areas of carbonate platform and ramp settings during the Mesozoic until to the Miocene (Parente et al., 2022).

New and old peculiar evidences are here presented by geological mapping, coupled with the measurement and correlation of the Monaco di Gioia-La Pizzuta-Mt. Acero-Monticello (for the older units) and Pietraroia-Regiapiana (for the younger ones) stratigraphic sections. Calcareous algae and benthic foraminifera biostratigraphy, integrated with a sedimentological and facies analysis, allows reconstructing the main bioevents as well as the sedimentary evolution of the Matese area.

The first noteworthy event in the *calcari con requienie e gasteropodi* Fm. (CRQ) of the Monte Acero section (570m thick, Kimmeridgian *p.p.*-Aptian *p.p.*) is the presence, few meters after the LO of *Campbelliella striata*, of *Pseudoclypeina*? *crnogorica* Radoičić, large dasycladalean alga considered an additional tool for dating the Berrasian in the field.

Following, at Monaco di Gioia-La Pizzuta, *Selliporella johnsonii* (Praturlon, 1964) nov.comb. appears at the end of the Weissert event (late Valanginian) and disappears at the Valanginian-Hauterivian boundary (Barattolo et al., 2021); the LO of *Salpingoporella annulata* marks the Hauterivian-Barremian transition; the LO of *Clypeina solkani*, *Clypeina parasolka* and *Campanellula capuensis* coincide with the early-late Barremian (Amodio et al., 2020).

Last but not least, three Plattenkalk horizons, at "La Peschera" Cusano Mutri, M.te Cigno and at "Le Cavere" Pietraroja, bearing fishes, amphibians, reptiles, invertebrates and plants (gymnosperms angiosperms) characterize the lithofacies of *calcari ad ittioliti* (CRQa). These dolomitic and marly limestones, which at Pietraroja contain the notorious small dinosaur *Scipionyx samniticus*, accumulated in a restricted lagoon (Pietraroja) as also in more distal environments and were included between the *Salpingoporella dinarica* and *Sabaudia minuta* (*Akcaya minuta)* biozones (upper Aptian-lower Albian).

Starting from the late Aptian, a synsedimentary tectonics induced emersion the platform as testified by the bauxite deposits embodying the Albian *p.p.*-Turonian *p.p.* During the Coniacian to Campanian, rudist dominated bioclastic associations developed but in open ramp settings. After the Palaeogene hiatus, only interrupted by the Eocene discontinuous shallow-water limestones discovered at the Monticello section, the sedimentation was resumed in the Early Miocene and ended in the late Serravallian-Tortonian when chain building started.

Keywords: Apulian foreland, Manfredonia, CARG.

The Gargano Promontory has received in the last decades a renewed attention by the scientific community due to the peculiar geological features of this sector of the Apulian foreland, which is considered seismically active. Furthermore, the outcropping Mesozoic carbonate units represent potential field analogues for the petroleum reservoirs discovered in the southern Adriatic Sea. Although the high number of scientific papers published on the aforementioned topics has given a notable contribution to the geological knowledge of the Gargano Promontory, the southern sector still remains quite underexplored due to the lesser availability of well-exposed outcrops. The geological survey of 397 Sheet "Manfredonia", as part of the CARG project, have contributed to filling this gap by proposing new stratigraphic and structural constraints for the interpretation of the tectonic evolution of the Gargano Promontory. The aim of this study is to illustrate the main structural elements that have deformed the Mesozoic-Cenozoic carbonate units in this sector of the Apulian foreland. Detailed lithostratigraphic analysis played a pivotal role in the geological survey because, under certain conditions (such as limited exposure and well-exposed outcrops), it has been the only usable tool to identify the occurrence of tectonic features otherwise unrecognisable. The following lithostratigraphic units have been recognised: Calcare di Bari Fm. (Callovian *p.p.*- Cenomanian *p.p.*), Calcare di Altamura Fm. (Coniacian *p.p.*-Santonian *p.p.*); Calcarenite di Gravina Fm. (Middle-Late Pliocene). In addition, the informal units of Masseria Belvedere fm. (late Serravallian), Masseria Spagnoli fm. (late Tortonian); Masseria Pezza Nuova fm (Messinian ?) and Valle di Vituro fm. (late Messinian?). Most of the tectonic structures mapped in the studied area as the Mattinata and Rignano faults along with their wrench related structures, NW-SE oriented faults and folds systems formed after distinct tectonic phases showing a common deformation style. In the southern Gargano three tectonic phases have been recognised due to the stratigraphic constraints provided by the Neogene units: a) the Masseria Spagnoli fm. onlaps both the Masseria Belvedere fm. and the Mesozoic substrate along the southern limb of a major anticline developed on the footwall of the Rignano Fault. This relationship suggests that the early phase of formation of this structure occurred during early/middle Turonian times; b) a later tectonic tilting (about 20°) recorded by the Masseria Spagnoli fm. reveals a reactivation of this structure after late Tortonian times; c) the Calcarenite di Gravina Fm. crops out at the footwall of the reverse Monte Granata fault and close to Manfredonia town, where it is partly deformed by the strike slipe Ortolino fault. This enabling to date the activity of these structures after Pliocene times.

Offshore geological map in south-eastern Sicily: the "Siracusa - 646" (CARG project)

Keywords: Siracusa, marine geology, geological mapping.

The south-eastern Sicilian coast has always been object of several studies to reconstruct the geological framework especially in terms of tectonic evolution and geohazards, due to its position between two important structures in the central Mediterranean region, the Hyblean Plateau and the Hyblean-Malta Escarpment. New data collected in the frame of the geological mapping of the sheet 646 "Siracusa" (CARG Project) implemented the knowledge of the continental shelf area, located from the Augusta Bay to the Maddalena Peninsula (offshore Siracusa), between the eastern Sicilian coast and the Malta Escarpment.

The new dataset, acquired during two different oceanographic campaigns in autumn 2023 and spring 2024, allowed the re-interpretation of the pre-existing data of this sector. We collected both multibeam data in the inner part of the continental shelf and a Side Scan Sonar mosaic, calibrated by 40 sediment samples from the seabed. The dataset was completed with existing CHIRP sub-bottom profiles and new Sparker seismic reflection profiles.

In the continental shelf we distinguished and mapped six depositional systems, from the inner shelf, characterized by several erosive channels up to 400 m wide, and the outer shelf, where there is a depositional basin with sediments up to 35 m thick, organized in 5 seismostratigraphic units pertaining to the Late Quaternary Depositional Sequence (LQDS), which has no relevant thickness in the inner shelf area.

In the upper continental slope zone, a complex system of canyons and gullies has been mapped. The absence of lowstand wedges suggests an ongoing erosional activity responsible for the retreat of the shelf break. Furthermore, two main sets of normal faults were distinguished with NNW-SSE and ENE-WSW trend respectively. The first system conforms with that detected on land and pertain to the Malta Escarpment regional fault system. This is responsible for the "fault-blocks structures" that characterize the whole area. Both systems produced different displacements of the pre-quaternary sequences thus defining the accommodation space for the LQDS. These results have ensured a step forward in the geological knowledge of this area of the Mediterranean and contribute to the assessment of the marine geohazards in a potentially exposed region.

Surface and subsurface geology of Gravina in Puglia, Southern Italy

Keywords: Apennine foreland-foredeep, surface geology, thickness map.

Gravina in Puglia, located at the southern margin of the Murge relief, is an ideal site to explore the stratigraphic and structural relationships between Southern Apennine foredeep and foreland geological units. The town, flaked to the west by a NS-oriented canyon, is prone to several geological hazards including rock falls, seismic amplification and sinkholes related to widespread cavities in the shallow subsurface. Despite this geological complexity, local geologists are called to face these challenges without an adequate official geological map. As the available geological map (sheet 188 of the Geological Map of Italy to scale 1:100.000) dates back to the 1966, a new geological map, at a higher resolution, is required for land management.

We present here two maps depicting surface and subsurface geology of the urban area of Gravina in Puglia. Surface geology is characterized by the following lithostratigraphic units. The Cretaceous Calcare di Altamura formation (ALT, in nearby sheets of the Geological Map of Italy to scale 1:50.000), is part of the Apulian foreland carbonate platform and is dominated by micritic limestones with occasional rudist-bearing horizons. This formation is exposed in the Gravina canyon and in the northern part of the town. The Plio-Pleistocene Calcarenite di Gravina formation (GRA), largely exposed in the urban area, includes two lithofacies: the first with prevalent lithoclasts from the ALT formation, the second dominated by nearshore bioclasts. The boundary between ALT and GRA is marked by an angular unconformity with truncation of ALT strata and locally by a conglomerate horizon. GRA is overlain by a Pleistocene sedimentary succession, with overall coarsening and shallowing-upward trend, exposed on the hills surrounding the town. This succession represents the upper Bradanic-Foredeep infill and is composed of silty clays, laterally correlative to the Argille Subappennine Formations (ASP), grading upwards into fossiliferous sands and calcarenites. The latter are locally overlain with erosive contact by etherolithic gravels and conglomerates. Gravina in Puglia historically developed onto the GRA formation, and subsequently expanded over ALT limestones and on the ASP muds.

The thickness of GRA, represented in the subsurface-geology map, increases southward from zero to approximately 50 m, controlled by a series of NW-SE trending normal faults and paleo-cliffs, with possible structural control. Locally thickness of GRA may increase northward of few meters in the hanging-wall of NE-dipping faults. The subsurface-geology map represents an important predictive tool because the boundaries between ALT and GRA, and GRA and ASP, characterized by markedly different mechanical properties, may represent important seismic reflectors which may cause local amplification of the seismic signal. Moreover, the knowledge of the depth of the ALT-GRA and GRA-ASP boundaries is crucial for the design of shallow-subsurface infrastructures.

Paleotectonics imprint on the southern edge of the M. Morrone structure (Central Apennines)

Capotorti F.* & Tomassetti L.

Dipartimento per il Servizio Geologico d'Italia, ISPRA, Roma.

Corresponding author email: franco.capotorti@isprambiente.it

Keywords: field mapping, paleotectonics, breccias.

Field mapping carried out for the new 1:50,000 scale 370 Guardiagrele sheet (CARG Project) showed along the southern edge of the M. Morrone thrust-related-anticline several large S-SW dipping tectonic normal faults with evidence of their pre-compressive activity. In particular:

- the faults are curvilinear and strike from NW-SE to about E-W, moving to the east and approaching the M. Morrone thrust front;
- where the faults can be detected, they always have a low immersion angle (maximum 40°), becoming a 'normal angle' when the footwall layers are brought back to the horizontal position;
- the extensional structures, despite their conspicuous downthrown (several hundred meters), do not displace the M. Morrone thrust front in a significant way; also, they do not form planes at the hangingwall;
- on the hangingwall of the normal faults, several generations of breccias and conglomerates are exposed, also highly tilted. Some of them are similar to the Rigopiano conglomerates (even with the occurrence of terrigenous clasts), found on the ridge of M. Morrone and classically attributed by literature to a wedge-top deposits due to the polygenic origin of their clasts, while other breccias are made up exclusively of clasts of local succession;
- in addition to the breccias, near the site of Colle Ardinghi, on the hangingwall of the large normal fault of the Fosso Vella, Upper Miocene deposits, both limestones and clayey, are exposed directly transgressive on Lower Cretaceous limestones, along what was probably a tectonically tilted and uplifted block, then down-sunk;
- on the hangingwall of the Il Rio fault, olistoliths of several hundred square metres, made of local carbonate succession, are exposed, apparently 'floating' onto the Upper Miocene flysch; they can be interpreted as large underwater rockslides occurred during Late Miocene interval.

New geological map at a 1:10.000 scale and tectono-stratigraphic review of the NW Campania-Basilicata boundary (Southern Apennines, Southern Italy)

Keywords: Southern Apennines, geological field mapping, litho-biostratigraphy.

A geological survey at a 1:10.000 scale and litho-biostratigraphic investigations have been recently undertaken in the Southern Apennines among the villages of Bella, Castelgrande, Muro Lucano, San Fele and Laviano (NW Campania-Basilicata boundary), within the framework of the CARG Project, sheet n.469 Muro Lucano. The data gathered during the survey allowed a careful revision of the exposed lithostratigraphic units and an improved definition of the tectonic structures. The results are summarised in a new geological map of the area at a 1:10.000 scale, where the following tectono-stratigraphic units are distinguished:

the Lagonegro Basin Unit, characterised by the Rhaetian-Jurassic Scisti Silicei of the S. Fele facies (Scandone, 1967), mostly made up of jaspers, with a sequence of 1 m-thick silicified calcirudite beds in the lower portion, and the Berriasian-Aptian *p.p.* Flysch Galestrino (Patacca & Scandone, 2007), made up of an alternation of marlstones and laminated calcarenites to calcilutites;

the Apennine Carbonate Platform Unit, consisting, from bottom to top, of: i) dolomitised limestones (Upper Triassic?); ii) well-bedded limestones with *Palaeodasycladus mediterraneus* and *Orbitopsella praecursor* (Hettangian?-Toarcian *p.p.*); iii) poorly-bedded oolithic limestones (Middle Jurassic?); iv) up-to-very-thick fine-grained limestone beds with thin green marly intercalations (Upper Jurassic?); v) limestones with acteonellids and requienids, stromatolitic laminae, green marly clasts and black clasts (Lower Cretaceous-Cenomanian *p.p.*); vi) biolithoclastic limestones with radiolitids and caprinids, and black pebbles (uppermost Cenomanian to Turonian);

Langhian-Serravallian thrust top/foredeep deposits of the Castelvetere Formation (Pescatore et al., 1969), lying unconformably on top of the Apennine Platform and consisting of two intervals. The lower, sandy-conglomeratic interval, includes a huge olistostrome consisting of Argille-Variegate-Group terrains containing 10 m-sized olistoliths deriving from the Apennine Platform. The upper marly interval includes centimetric siliciclastic siltstone-to-fine-grained-sandstone beds, metres-thick medium-to-coarse-grained sandstone beds, large slabs of Sicilide-affinity and thousands-of-cubic-metres olistoliths of the Apennine Platform;

sediments of the Pliocene Intra-apenninic Basins (e.g., Servizio Geologico d'Italia, 2013) consisting of pelitic-sandy to gravelly-sandy lithofacies with ichnofossils and bivalves.

Contractional structures, mostly affecting the Castelvetere Formation, consist of wide and rarely overturned folds, in some cases connected to fault propagation, with about E-trending hinge lines. Cenozoic East-directed contractional and transpressional faults and Miocene-Quaternary extensional fault sets with E-W, NW-NE and NE-SW orientations affect both the Castelvetere Formation and the Apennine Platform.

Keywords: carbonate platform, field mapping.

In the area of the Matese Mts falling within the CARG Project Geological Sheets 418 "Piedimonte Matese" and 404 "Isernia", the Meso-Cenozoic relationships between carbonate platform, slope and basin are well exposed. These relationships can be recognized in two different tectonic units, namely the Matese (MaU) and the Montagnola di Frosolone (MFU) units, which were issues of discussion by different Authors (e.g., Patacca & Scandone, 2007) for their structural relations. The results of the field mapping of these sheets, based on stratigraphic data and structural analysis, highlight the geometric relationships between the different sectors of the Matese Mts and the Montagnola di Frosolone. The Piedimonte Matese Sheet is characterized by a Triassic to Middle Miocene shallow-water carbonate platform succession, interrupted by a "mid" Cretaceous stratigraphic gaps marked by thick bauxitic levels, and by a wider Paleogene gap represented by a discontinuity surface between the Miocene and Cretaceous platform carbonates. The Isernia Sheet is characterized by an upper slope (MaU) and a lower slope-basin (MFU) successions. Slope successions consist of bio-lithoclastic grainstones and rudstones (Calvello Fm., VLO; Campanian-Maastrichtian) resting unconformably on carbonate platform deposits. Moving from east to west, the width of this stratigraphic gap increases to manifest as an angular unconformity between VLO and Triassic platform dolostones (Dolomia superiore Fm.). Moving northwards, the slope-to-basin transition is mostly exposed at Patalecchia Mt. Here, dolomitized calcirudites and calcarenites with chert intercalations (Pesche Fm.; ?Middle Jurassic-Lower Cretaceous) pass upwards to thin-bedded cherty calcarenites, micrites, green shales (Coste Chiavarine and Foresta Fms.; Lower-Upper Cretaceous) and to mass flow and turbidite-rich deposits of VLO. The occurrence of VLO in the Cretaceous slope-basin succession of the Montagnola di Frosolone (Pescatore, 1965; Bertinelli et al., 2005) represents the lithostratigraphic (and paleogeographic) linking element between the upper slope succession of MaU and the lower slope-to-basin succession of MFU. The linkage zone, situated in the Longano area, is strongly deformed by the development of an E-W asymmetric macro-fold structure with a northward vergence. This structure extends along the entire Longano valley for approximately 10 km and is thrusted within its central portion. The new stratigraphic and structural data allow us to well document the tectono-stratigraphic evolution of the Mesozoic carbonate platform margin and its structuration during the Cenozoic. The Isernia Geological Sheet features a legend presenting a dual lithostratigraphic framework for Meso-Cenozoic carbonate platform-to-basin formations: "Campania-Molise" and "Latium-Abruzzi" promoting continuity between adjacent sheets. The boundary between these nomenclatures is the Volturno River valley, filled with Quaternary sediments.

The highest regressive coastal deposits of the Bradanic Trough (Basilicata, Southern Italy): old vs new stratigraphic schemes in the official geological cartography

Cilumbriello A.*[1], Sabato L.[2] & Tropeano M.[2]

[1] Geologo Libero Professionista, Genzano di Lucania PZ.
[2] Dipartimento di Scienze della Terra e Geoambientali, Università di Bari "Aldo Moro".

Corresponding author email: antocilu@tiscali.it

Keywords: regressive deposits, Bradanic Trough, Apennines foredeep.

The study area is located in the central part of the Bradanic Trough, along the chain-foredeep boundary of the Southern Apennines orogenic system and is characterized by the occurrence of lower Quaternary deposits that represent the outcropping part of the topmost in-fill succession of the basin. These deposits form a regressive succession made up of silty clays (Argille subappennine Fm) followed by coarse-grained deposits. The latter in the official geological maps of Italy (1:100.000 scale) are represented by two lithostratigraphic units described and cartografically represented as tabular ones: the Sabbie di Monte Marano Fm below and the Conglomerato di Irsina Fm above. In the New Geological Map of Italy (1:50.000 scale) this scheme was abandoned, and above the Argille subappennine Fm a sandy and conglomeratic unit occurs (regressive coastal deposits by Pieri et al., 1994; 1996). The new scheme is supported by several studies performed along the Bradanic Trough, which also allowed us to obtain the evolutive history of the basin.

In particular, in Genzano di Lucania and Banzi areas the coarse-grained deposits form a lithostratigraphic unit, up to 100 m thick, continental to marine in origin, made up mainly of conglomerates in the WNW sector (Banzi area) and mainly of sands with tongue of conglomeratic layers, in the E-SE sector (Genzano di Lucania area) (Cilumbriello et al., 2008). These successions present an aggradational stacking pattern of conformably lying bodies, induced by the interference between a low-order relative sea-level rise (basin subsidence) and high-frequency sea-level changes during the evolution of a basin margin depositional system. In an adjacent area (Irsina) the same succession (a bit younger in age), known as Monte San Marco formation, shows a progradational and downward-shifting stacking pattern (Sabato et al., 2004). This stratigraphic architecture was induced by the interference between a low-order relative sea-level lowering (regional uplift) and high-frequency sea-level changes.

These stratigraphic features record a geodynamic change in the evolution of the Bradanic Trough during the Early Pleistocene when a still active foreland-basin began to experience an "anomalous" uplift after a long period of "normal" subsidence.

Corresponding author email: angelo.cipriani@isprambiente.it

Keywords: Meso-Cenozoic carbonate platform-basin, Lazio-Abruzzo vs. Campania-Molise successions, lithostratigraphic correlation.

Significant stratigraphic problems may arise when applying lithostratigraphy within the Mesozoic and Cenozoic carbonate platform-basin successions of the south-central Apennines. Inconsistencies in unit definitions and nomenclature among the " Lazio-Abruzzo succession" (LAS) and "Campania-Molise succession" (CMS) could obscure the identification of regional stratigraphic trends. Nevertheless, these successions share major similarities regarding (i) general stratigraphy, (ii) depositional environments, (iii) age, (iv) paleogeographic domain (i.e., the Apennine Carbonate Platform, albeit with local paleotectonic complexities), (v) record of paleoecological events, and biostratigraphic scheme, as well as (vi) tectono-stratigraphic evolution.

The refinancing of the national geological mapping project (CARG Project) at a 1:50,000 scale, which resulted to the ongoing production of several geological sheets in the central (Lazio-Abruzzo) and southern (Campania-Molise) Apennines, has brought to light this long-standing problem, as already highlighted during the previous phase of work on the CARG Geological Sheets in the early 2000s (Di Stefano et al., 2011). Mismatch in lithostratigraphic application thus necessitated coordination led by the Geological Survey of Italy (ISPRA) to prevent discrepancies between adjacent geological sheets.

To enhance clarity and address definitional ambiguities, the geologic, litho-, and biostratigraphic aspects of the Mesozoic-Cenozoic carbonate units described on the already published geological sheets of the CARG Project for the central and southern Apennines were critically examined to produce a super-regional standardization. Differences in nomenclature arise from an historical tradition linked regionally to specific names, reflecting different approaches and criteria rather than lithostratigraphic differences. Revisions to existing frameworks were made and chrono-lithostratigraphic schemes were developed to facilitate correlations across different depositional settings. The aim is to introduce in the ongoing CARG Project, a double legend for Meso-Cenozoic shallow water-to-basin successions, referring deposits of the same age and with comparable litho-biostratigraphic characteristics respectively to the LAS and CMS. The boundary between areas where CMS or LAS nomenclature is applied is primarily morpho-structural and artificial, identified along the Roccamonfina graben to the west and in the upper Volturno River valley to the east and northeast. Four ongoing geological sheets bordering the regions of Lazio, Abruzzo, Molise, and Campania—specifically 392 Castel di Sangro, 404 Isernia, 416 Sessa Aurunca, and 417 Teano—have been identified where the implementation of a double legend is deemed necessary. Such lithostratigraphic approach strategically ensures cartographic consistency between geological sheets exhibiting either Lazio-Abruzzo or Campania-Molise lithostratigraphic affinities.

Recognition of a pre-LGM, km-wide collapsed DGSD in Bregaglia Valley (Italian Central Alps): a case study in the frame of the CARG Project sheet n. 038 "Chiavenna"

Colzada G.*, Arrigoni F., Marinoni A., Pigazzi E., Tantardini D., Apuani T. & Tartarotti P.

Dipartimento di Scienze della Terra "A. Desio", Università di Milano.

Keywords: DGSDs, geomorphological evolution, Central Alps.

Deep-seated Gravitational Slope Deformations (DGSDs) affect large portions of high-relief mountain slopes and the shape of alpine valleys (Crosta et al., 2013), influencing their Neogene and Quaternary evolution. New geological mapping of the lower Bregaglia Valley (Lombardy Region, Italy), in the frame of the CARG Project 1:50.000 scale Geological map of Italy, sheet Nb. 038 "Chiavenna", not only confirms the presence of several DGSDs affecting its southern flank (Tibaldi & Pasquarè, 2008), but also reveals the presence of a landslide body related to DGSD collapse in the area where bedrock has been reported so far. The lower Bregaglia Valley is located between the Tambò Nappe, Chiavenna Unit and Gruf Complex. The southern slope is made of mafic and ultramafic rocks of the Chiavenna Unit, in contact with the Gruf migmatites and paragneisses of the Tambò Nappe. The northern slope is made of Tambò paragneiss. Complex lithological relationships on the south slope have been justified by previous Authors through a combination of folds, faults and tectonic contacts (e.g., Schmutz, 1976). The Marmitte dei Giganti Park (East of Chiavenna, near the confluence of the Liro and Mera rivers) is a ca. 100 m high relief, next to the valley thalweg, well known for its glacial and fluvioglacial forms of excavation. This relief has been mapped so far as a bedrock body (e.g., Schmutz, 1976). South of it, the slope shows widespread gravitative trenches, scarps and counterslopes. The relief is composed of ultramafites and amphibolites that, to the west, do not correlate with the surrounding geology: the nearest amphibolite outcrop is about 1 km south and 500 m higher on the mountain slope. Moreover, evidence from a nearby drill hole SW suggests an inversion of the lithology order, with the Tambò paragneisses being beneath the main body of the park. The relief is crosscut by a network of fractures allowing a constant temperature air circulation, historically exploited for food conservation, that needs large fractured-porous volumes in the rocks to be maintained. This evidence led us to interpret the Marmitte dei Giganti Park relief as a DGDS collapse, namely as a km-wide landslide, made up of hectometer-sized blocks of very resistant rocks originated by sliding of portions of a DGSD-affected slope. The contact between the Gruf Complex and the northern Tambò and Chiavenna units (Gruf Line) acted as a main predisposing factor for large mass-wasting movements on the southern slope of the Bregaglia Valley, which could still have been active after the Last Glacial Maximum (LGM) retreat (Tibaldi & Pasquarè, 2008). However, the DGSD collapse originating the slope surely predates the LGM (Tantardini et al., 2022), being covered by glacial deposits. The volume needed for the emplacement of this collapsed mass leaves room for speculations about the original morphology of the valley and the processes related to its formation.

Keywords: marine geology, seafloor mapping, CARG.

This study is focused on the marine geology of the Taranto area (northern Ionian Sea) which is particularly interesting for several reasons. It includes three different marine basins: a semi-enclosed, shallow basin (Mar Piccolo), a deeper open basin (up to 1500 meters - northern Ionian Sea) and a circular basin with intermediate characters of hydro-dynamism and depth (Mar Grande). It is also a marine area which hosts a large biodiversity, but also deep anthropogenic impacts.

The followed interdisciplinary approach provides a specific study of the seabed in offshore area, highlighting the relationships between physical-geological features, like sediments distribution, bathymetry and degree of light penetration, and bio-ecological ones like distribution of habitats or the degree and type of anthropogenic impact. The main objective of the study is trying to obtain a complete evaluation and mapping of these processes.

In fact, this study fits in a national cartographic project at 1:50.000 scale (CARG). A detailed survey with multi and mono-channel seismic, Sub Bottom Profiler, Side Scan Sonar and Multibeam was performed, as well as some preliminary sampling operations.

The acquired data have been analyzed separately to obtain different information:

Seafloor DTMs from the MBES data processing, in order to recognize the depth and morphology of seabed;

High resolution images of seabed surface from the SSS acquisitions, which have been analyzed to obtain information about the distribution of sediments and rocky substratum outcrops, linked also to the distribution of biotic communities and bioconstructions;

Seismic sections to analyze the geometric and stratigraphic relationship between the deposits, recognized underneath the water-sediments interface.

All data have been implemented in a Geographic Information System to realize complete and updated thematic maps of the seafloor system, showing the lithology of the seabed, the distribution of habitats and the widespread of anthropogenic impacts. These maps give the basis to establish the relationships between physical, biological and anthropic processes. Finally, the dataset allows also to correlate the seismic units with the framework of the Quaternary evolution of the northern sector of the Ionian Sea.

The Mesozoic stratigraphic succession of Mt. Massico ridge in the southern Apennines (northern Campania, Italy): new data from geological mapping (Sheet 429 Mondragone - CARG Project)

Fagioli G.*[1], Artegiani F.[1-2], Pietrosante A.[1], Parente M.[3] & Putignano M.L.[1]

Keywords: geological mapping, stratigraphy, Apennine Carbonate Platform.

The Mt. Massico ridge (812 m a.s.l.) is an isolated relief in northern Campania. The SW to NE morpho-structural orientation of the ridge is the result of Quaternary normal faults that identify the Mt. Massico ridge as a horst block between the Garigliano river plain to the north and the Volturno river plain to the south. A 1:10,000 scale geological mapping was performed in the Mt. Massico area as part of the CARG Project, Sheet 429 Mondragone of the Geological Map of Italy at a 1:50,000 scale. In this area, the Mt. Massico ridge represents the only relief where a well exposed Mesozoic shallow-water carbonate platform succession crops out.

The ridge can be divided into two main sectors. In the southwest, Cenozoic rocks mainly crops out, except for Mt. Petrino, consisting of Cretaceous rocks, which is interpreted as an out-of-sequence thrust (Vitale et al.,2018; Smeraglia et al., 2019). The northeast sector consists of Mesozoic rocks. Although the southwest portion of the ridge has been recently investigated from a tectonic perspective by several authors, the latest stratigraphic studies on Mt. Massico date back to the 1960s (Cestari,1966; Vallario,1966).

The Mesozoic succession of the Mt. Massico ridge, in the portion falling within the Sheet 429 Mondragone, consists of shallow marine carbonates belonging to the Apennine Carbonate Platform, a paleogeographic domain that developed at the southern margin of the Tethys Ocean from the Late Triassic to the Late Cretaceous. Along the slopes of the Mt. Massico ridge, there is an excellent and almost continuous exposure, albeit with some gaps due to tectonic activity, starting from the Lower Jurassic in the northeast sector and ending with the Upper Cretaceous in the southwest sector.

The aim of this work is to provide new data on the Mesozoic succession of the Apennine Carbonate Platform in the Mt. Massico ridge. Lithostratigraphy, biostratigraphy and depositional environments have been defined by integrating field observations with thin section microfacies analysis.

Corresponding author email: alessandro.foti@phd.unict.it

Keywords: Catanzaro Strait, Calabrian Arc, Miocene succession.

The Catanzaro Strait is a sedimentary basin characterized by a thick sedimentary succession (up to 2000 m) ranging in age between the Miocene and the Quaternary. This basin is located in the central part of the Calabrian Peloritan Arc, between the Serre Massif and the Sila Massif, covering an area that goes from the Tyrrhenian offshore, Sant' Eufemia Basin (southern Tyrrhenian Sea), up to the Calabrian onshore, represented from the Catanzaro Basin.

The geological survey has been carried out during the realization of the Geological Sheet 745 "Catanzaro" as part of the CARG Project and it leads to new insight of the arenaceous-pelitic successions found below the Messinian interval of the "Calcare di Base". In the eastern edge of the Catanzaro sheet siliciclastic terrains outcrop with good exposure above basement rocks, we propose that they can be distinguished in different formations that have clear sedimentological and stratigraphic features, although in contrast to what reported in the geological cartography at a scale of 1:25.000 (Cassa del Mezzogiorno). It's noteworthy that these sedimentary bodies are affected by different tectonic activity where terrains characterized exclusively by normal faulting, in accordance with the geological literature of the area, occur with other successions strongly deformed by compressive tectonics. Field observations during the CARG project were useful to better understand some aspect of the geology of the Catanzaro Strait. Together with dating data of different geological formations can provide a new picture of the age of the tectonic deformation in this area of the Calabrian Arc.

Biostratigraphic data in the Pliocene-Pleistocene sediments from the CARG Project surveys in the Central Apennines (Italy): new evidence from the Sheet n. 370 "Guardiagrele"

Keywords: CARG Project, Plio-Pleistocene, biostratigraphy.

The combination of detailed field data and biostratigraphic analyses based on calcareous nannofossils and foraminifers from Plio-Pleistocene successions sampled during the ongoing geological mapping of the Sheet n. 370 "Guardiagrele" is presented. This sheet is part of the CARG Project (Geological map of Italy at 1: 50,000 scale) and, for its realisation, a total of 700 samples have been collected so far. Micropaleontological analyses of about 70 samples have revealed an age ranging from the Pliocene (Zanclean) to the Lower Pleistocene (Calabrian). The post-Miocene (i.e., post-Messinian) deposits are characterised by the Pliocene reflooding with a return to normal marine conditions, due also locally geodynamic contest, as testified by generally well preserved and very diversified foraminiferal assemblages (occurrence of *Globorotalia margaritae* and/or *G. puncticulata*) and calcareous nannofossils species (among others, first occurrence of *Reticulofenestra zancleana*, *R. pseudoumbilicus*, occurrence of *Amaurolithus delicatus*, *Ceratolithus acutus, Discoaster brouweri, D. pentaradiatus* and *Sphenolithus abies;* MNN12-MNN14 Zones, Di Stefano et al., 2023). Therefore, it was possible to identify the Piacenzian stage (Upper Pliocene), with *Globorotalia crassaformis* and *G. bononiensis* among planktonic foraminifers and *D. brouweri,* small *Gephyrocapsa* spp., small *Reticulofenestra* spp*., Helicosphaera carteri* and *H. sellii* among nannofossils (MNN15 Zone). The Pleistocene sediments are also recorded in the area: some of these can be attributed to Gelasian for the presence of *Globorotalia inflata* specimens, *D. brouweri,* medium *Gephyrocapsa* spp. and *Pseudoemiliania lacunosa*, while the Calabrian sediments contains *Globigerinella calida*, *D. brouweri, D. pentaradiatus,* medium *Gephyrocapsa* spp., small and medium *Reticulofenestra* spp. with the absence of *Discoaster*. The Calabrian deposits are the most recent marine sediments recognised in the "Guardiagrele" sheet. The paleoenvironmental reconstruction shows bathymetric changes from the bathyal (Zanclean) to the infralittoral-circalittoral (Calabrian) zones, indicating a clear marine regression. The micropaleontological analyses have also permitted to recognise the presence of deposits referable to Piacenzian-Gelasian (Calabrian?) stages, previously not recognised (Festa et al., 2014; Patacca & Scandone, 2021) inside the orogen into the "Guardiagrele" sheet. These deposits represent a fundamental constraint for the reconstruction of recent tectono-sedimentary evolution of the area between the Maiella Mountain and the Molisane Units.

Keywords: CARG, field mapping, Quaternary faulting.

The Hyblean Plateau (SE Sicily) is deformed by three main faults systems showing locally complex cross-cutting relationships. An NNW-SSE, dip-slip system, coaxial to the Malta Escarpment in the offshore, is observed to occur along the Ionian coastal sector. A NE-SW system affects the north-western and south-eastern sectors of the Plateau and has been interpreted as result of the crustal flexuration under the Sicilian folds and thrusts belt (Billi et al., 2006). Lastly, a NW-SE system, interpreted as a transfer zone between the main NE-SW systems (Cultrera et al., 2015), controlled the deposition of Quaternary series within a basin located west of the city of Siracusa, the so-called 'Floridia Graben'. Instrumental and historical seismicity point to the eastern coastal sector of the Hyblean Plateau as a zone prone to release earthquakes with strike-slip and subordinately normal focal mechanism (Musumeci et al., 2014). New geological fieldworks performed in the frame of the CARG project - sheet 646 "Siracusa" - have allowed to the revision of the geologic-structural setting of the north-eastern sector of the Hyblean Plateau, where most of the outcropping rocks are represented by Miocene reef to slope limestones growth/deposited over Cretaceous volcanic seamounts. The study allowed a better characterization of the above-mentioned faults highlighting the occurrence of a further faults system roughly trending ENE-WSW, which clearly displaced Middle-Upper Pleistocene sediments, whose topographic expression is still limited or absent. Our results provide new insights on the recent activity of Quaternary faults and may help on redefining seismic potential of faults in the area.

Keywords: tectonically controlled slope, paleogeographic reconstruction.

The geological mapping carried out within the activities for the Sheet n.628 "Sciacca" of the Geological Map of Italy (CARG Project) provided relevant information to understand the geological evolution of the south-western sector of Sicily. The data collected on field were of fundamental importance for the reconstruction of the stratigraphic and structural setting of sectors that, framed at a larger scale, help explain the evolution of part of the Sicilian Fold and Thrust Belt (SFTB). The field surveys were carried out at scale of 1:10.000 using digital tools (Field Move software) to obtain georeferenced data that have been represented on the digitized map at scale of 1:50.000.

In the Rocca Nadore area, located in the north-western sector of the Sheet, outcrop the Meso-Cenozoic succession pertaining to the shallow to deep water carbonate facies domain. Here we identified a E-W-trending sharp erosional unconformity between the Hettangian-Pliensbachian weakly dolomitized carbonate platform limestones (Inici Formation) and the Middle-Upper Jurassic reddish nodular-texture calcilutites, rich in ammonites (Buccheri Formation). We interpreted this angular unconformity as an extensional tectonically controlled depositional slope. We conducted a detailed stratigraphic analysis of the deposits lying above the unconformity enabled the identification of the time interval of sedimentation and evidenced various reactivations events. This time span is comprised between the Early Jurassic and the late Oligocene and is recorded in a stratigraphic succession with a maximum thickness of 25 meters. Similar depositional patterns were identified toward north along the Rocca Ficuzza carbonate ridge. In this latter sector, some bodies of carbonates megabreccias consisting of Meso-Cenozoic carbonates fragments in a reddish silty matrix, due to the gravitational collapse from a pre-existing slope, were identified.

This deformation pattern (age, geometry, and orientations) observed in the geological Sheet 628 "Sciacca," allowed to obtain information useful for regional paleogeographic and paleoenvironmental reconstructions. Furthermore, the analyzed sector consists of alternating paleo-structural highs and lows formed by Meso-Cenozoic shallow to deep water carbonate deposits, respectively. Recognition of the stratigraphic patterns and three-dimensional development of carbonate bodies, including boundaries and relationships with surrounding units, can have several spin-offs, including their possible use in support of hydrogeological studies.

New constraints on the southernmost portion of the Ligurian and Sub-Ligurian Domains: insight from the Sheet "363" Civitavecchia

Innamorati G.*[1], Fabbi S.[1], Notaro A.[2], Tentori D.[3], Tancredi S.[1] & Santantonio M.[1]

Keywords: External Ligurian Domain, geological mapping, stratigraphy.

The importance of large-scale geological mapping projects, like the CARG project, lies in the fact that field geologists are not only confronted with topics of local interest, but they must necessarily tackle broader issues. This is the case with the Sheet "363" Civitavecchia where the outcropping Mesozoic-Quaternary sedimentary succession helps deciphering the tectonic-stratigraphic evolution of a wider sector of the Apennine chain, from the earliest phases of compression and chain building, to the extensional phases related to the opening of the Tyrrhenian Sea, *via* the development of wedge top basins.

The Sheet 363 "Civitavecchia" is now about to enter its third year of operations. Parallel to an advancement of knowledge with respect to previous studies, our new findings raise a number of open questions that we believe may impact on the reconstruction of the southern closure of the Ligurian/Sub-Ligurian Domains.

The study area, located in Northern Latium, falls within one of the innermost portions of the Apennine Chain, a troublesome area where different paleogeographic Domains (Internal/External Ligurian, Sub-Ligurian, Tuscan, Epiligurian) meet. In contrast to southern Tuscany, the stratigraphic and tectonic relationships among these elements are buried or poorly exposed and some of the lithostratigraphic units differ from those traditionally associated with both the Ligurian and Sub-Ligurian Domains, making their assigning to either domain problematic.

We propose a reinterpretation of the Mesozoic-Palaeogene stratigraphy, based on our new field survey and a novel dataset mainly covering biostratigraphy (integrated microforaminifera, larger benthic foraminifera and nannofossils analyses) and sedimentology (facies analysis of siliciclastic and calciclastic units; petrographic analyses for provenance studies).

Structural style and compressive structures have been investigated through meso- and micro-structural analyses.

Our results are as follows:

in the study area, the base of the succession is always the Pietraforte, consisting of two diachronous lithofacies (as in the External Ligurian Domain);

With few remarkable exceptions, this unit overthrusts the Flysch della Tolfa, that in our view differs significantly from the "Sillano Fm/Santa Fiora Fm" and from the so called "Helminthoid flysch" (pertaining to the external and internal Ligurian Domains, respectively), as well as from the "Canetolo fm" (Sub-Ligurian domain).

A clastic lower Eocene unit (Cipollari et al., 2024) is unconformably covered by a previously undetected arenaceous/marly Oligocene/Aquitanian unit, similar to equivalent units known in the Sub-Ligurian Domain. These two units are deformed as one coherent body, suggesting a post-Aquitanian age of compression, not comparable to a Ligurian phase.

We are thus dealing with a challenging "hybrid" lithostratigraphic succession sharing features with both the Ligurian and Sub-Ligurian Domains.

Cipollari P. et al. (2024) - "il Casone-Monte delle Fate" olistostrome in the middle Eocene of the Eastern External Ligurian Unit (Monti della Tolfa, northern Latium, Italy): new constraints on the geodynamic evolution of the northern Apennines. Ital. J. Geosci., 143(1), 155-172.

Pre to syn orogenic evolution of the European margin: clues from the Flysch units of the Ligurian Alps (CARG Project - Ormea sheet 244)

Keywords: European Margin, Ligurian Alps, Flysch Units.

Taking advantage of the ongoing new geological fieldwork for the 1:50.000 scale "Ormea Sheet" (n.244, CARG Project), the general aim of our work is to integrate existing data and observations for the reconstruction of the structure and evolution of the European (alpine) margin. The study area is located in the Ligurian Alps (i.e., the SE termination of the W Alps) which represents a key region where the contact between lithological units from two distinct paleogeographic domains, i.e. the Briançonais domain (European passive margin) and the Piedmont-Ligurian sedimentary covers (oceanic domain), is preserved. Here, the arrangement of the nappes pile and the internal structures of the tectonic units (including stacks of thrust sheets, superposed non-cylindrical folds, etc.) are evidence of a complex polyphase tectonic evolution accompanied by a low-grade alpine metamorphic imprint that partially overprint and reworks the original sedimentary structures and pristine features. In this poster we focus on the Flysch Units mapped in the Ormea sheet with particular emphasis on the Colla Domenica-Leverone unit. Previous works have hypothesized that these turbidite systems have been deposited in an abyssal plain, resulted from the Piedmont-Ligurian Oceanic rifting and spreading. These systems include basal complexes characterized by thinly bedded turbidites often containing olistostromes, succeded by sand- or carbonate-rich turbidite systems (Decarlis et al., 2014) that are interpreted as trench environment deposits (Di Giulio, 1992). As the accretionary wedge advanced towards the European foreland, these units underwent a migration and stacking process, resulting in an inverted stratigraphy with the oldest unit in the topmost part. Limited prior research on this unit revealed that a basal erosional boundary overlains two different units (Arnasco-Castelbianco and Borghetto units), contradicting previous assumptions of a tectonic surface. Additionally, geochemical analysis (XRF and ICP-MS) performed on basalt samples collected form the chaotic event within the basal complex of this unit (Colla Domenica Shales) suggest analogies with basalts form Balagne region, northern Corsica (data compared with Saccani et al., 2008). This preliminary evidence assumes that these units, resulting from a basement erosive sedimentary events and different source areas, filled the closing oceanic basin (as suggested by the model of Pandolfi et al., 2016). Petrographic analyses on thin sections of arenaceous samples will be performed to identify the sediment source areas, while geochronological analysis will be conducted withU/Pb analytical techniques on the zircons to compare the results with surrounding crystalline basements providing and additional time constrain limited to the poor biostratigraphic data. Concurrently, enhanced biostratigraphic analyses aim to refine the existing data.

Keywords: geological mapping, digital outcrop models.

We present the main outcomes from the three-year experience of mapping for the CARG 245 – Albenga sheet, which comprises emerged and marine areas. The Albenga sheet (located in western Liguria) displays ca. 450 km2 of emerged area hosting a wide variety of rock type, including: i) Paleozoic to Eocene metaintrusive, metavolcanic and metasedimentary sequences that experienced Pre-alpine and/or alpine orogenic deformation and metamorphism; ii) Oligocene to Pliocene post-orogenic sediments and a large Quaternary mixed marine-alluvial fan. The remaining one third (ca. 150 km2) of the sheet includes the continental shelf and the upper slope both intersected by well carved submarine canyons. The submarine survey is based on the integration of a new set of seismic reflection lines and high-resolution bathymetric data (MBES) with pre-existing available geological and geophysical datasets. On land survey has been performed through the integration of the classic, field-based approach with the analyses of Digital Outcrop Models (DOM) derived from digital photogrammetry and the use of Unnamed Aircraft Vehicles (UAV). We show two applications in orogenic and post-orogenic units/structures: a large Alpine fault zone and earthquake-related soft sediments deformation structures in the Finale Ligure basin. The combination of onshore and offshore observations provides new clues for reconstructing the morpho-structural setting and the (neo)tectonic evolution of the margin of this sector of the western Ligurian Sea. Moreover, our case history provides new insights for the up-to-date discussion about the methodological approaches in geological mapping applications.

CARG geo-tech revolution: digitizing geological maps with innovative tools (practical examples from the CARG project)

Keywords: CARG, Innovative Tools, GIS.

In the current era, data collection and analysis are pivotal for informed decisions-making across all sectors, including geology. The structured management of this data has become integral to our daily operations. While geological information was traditionally stored in paper documents or unstructured digital formats, structured databases now serve as indispensable tools for organizing, managing, analyzing and interpreting such data.

Geological Geographical Information System (GIS) databases are innovative software solutions enabling integrated and standardized storage and organization of geological information, including geological units, mineral and water resources, geotechnical and geophysical characteristics, among others. These tools facilitate easy accessibility to information, reduce interpretative errors, and enhance analysis accuracy. In modern times, geological GIS databases have emerged as essential tools for natural resource management, geological risk assessment, and land planning. However, establishing design standards is crucial to ensure optimal usability and utility that meet the diverse needs.

The CARG Project, spearheaded by ISPRA*, endeavors to create and digitize the 636 geological and geotematic sheets at 1:50,000 scale, covering the entire national territory. Geological data acquired at 1:25,000 scale are stored in a complex database through specific guidelines and dedicated vocabularies.

This contribution seeks to identify and demonstrate various practical solutions to the primary challenges encountered in compiling the database requested in the CARG Project, utilizing practical examples from the Novi-Ligure and Tortona sheets. Special attention will be devoted to phases of work contributing from surveying to the digitization of the geological map. Particularly, leveraging the capabilities of the latest available tools (such as software: QGIS, QField; hardware: Tablet, Desktop office), innovative database compilation tools (dedicated Input/Output modules) will be presented.

Considerable space will be given for discussion on potential improvements and open issues, aimed to collaboratively establish a distinctive and exportable working methodology, applicable not only to other CARG sheets but also beyond.

Multi-scale landscape evolution of Central Alps: another side of the Valchiavenna CARG project

Marinoni A.*, Pezzotta A., Tantardini D., Arrigoni F., Pigazzi E., Colzada G., Apuani T., Zerboni A. & Tartarotti P.

Dipartimento di Scienze della Terra "A. Desio", Università degli Studi di Milano.

Corresponding author email: alessia.marinoni@unimi.it

Keywords: Chiavenna, CARG project, morphometrical analyses.

The CARG project of geological mapping near Chiavenna (sheets 021 "Passo dello Spluga", 022 "Madesimo", 037 "Bodengo", 038 "Chiavenna") investigate an area with a complicated topography, resulting from pre-Quaternary Alpine tectonics and Quaternary evolution. The study area is in the Italian Central Alps and is composed of pre-Alpine basement rocks intruded by Permian and Oligocene granitoids, and of Permo-Mesozoic metasediments of the Penninic and Austroalpine domains characterized by a complex deformation history (Steck et al., 2013). The metasediments include quartzite, calc-schists, marbles, and occasionally ophiolites. To the south, these tectonic units are separated from the Southern Alps by the EW dextral strike-slip Insubric Line; to the north, they are separated from the European foreland by the Penninic Front, a SW-NE oriented thrust. Other important structures are the Forcola Line, a NW-SE normal fault located at the eastern border of the Lepontine dome, and the Engadine Line, a NE-SW sinistral strike-slip fault located between the Engadine Valley and the Bregaglia Valley (Ciancaleoni, 2005). Quaternary glaciations heavily influenced the topographic evolution of the area, while gravitative processes continuously shaped the valley flanks. The aim of this work is to define the controlling factors on landscape evolution through a combination of field survey and morphometric analysis. Field survey permitted to collect lithological, structural, and geomorphological data at various scale and highlighted the interplay between several factors (e.g. lithological and structural properties, gravitational, fluvial glacial, and karst processes). Morphometric analysis helps in quantifying the evolution of topography and channel network development through various indices, calculated from a DEM ALOS with a 30m resolution, such as the χ-mapping (the calculation is based on the comparison of two channels originating at the same position x and terminating at the same base level xb, A(x) is the drainage area upstream of x, while A0 is a reference area and m/n is the concavity; the χ-mapping highlights drainage migration direction) and the knickpoint detection (a geometric approach based on the comparison of the actual flow profile against an ideal one; knickpoint detection allows to identifies breaks in slope; Diercks et al., 2021). The interpretation of such indices suggests that regional scale-drainage divides migrate northward. This could be tuned by several processes, namely the gravitational ones. At the local scale of the Val San Giacomo and Val Bregaglia valleys the development of the rivers' pattern is primarily controlled by changes in lithology and structures, as evidenced by differences in knickpoints. Applying morphometric analysis validates the methods and supports the data collected during fieldwork, enhancing the interpretation of the role of the main controlling factors on landscape evolution in this portion of the Central Alps.

Rock avalanche deposits along normal-fault and thrust-fault-related tectonic slopes: new insights from CARG Project surveys in the Majella-Porrara ridges (central-eastern Apennines, Abruzzo Region)

Morelli F.*[1], Chiarini E.[2], Nirta G.[2], Nocentini M.[2], Piacentini T.[1] & Pizzi A.[1]

Keywords: Quaternary continental deposits, geological-geomorphological mapping, rock avalanches.

The morphostructural evolution of the Abruzzi central Apennines chain resulted primarily from widespread tectonic uplift and the formation of tectonic intermontane basins generated by Quaternary normal faults. The chain features tectonic slopes with high energy relief, largely influenced by intensely jointed carbonate rocks and active Quaternary normal faults, predisposing the area to large mass movements such as rock avalanches, mainly during the Pleistocene.

In previous geological maps of the area, rock avalanches were poorly represented or mapped as different lithofacies deposits due to the lack of detailed multidisciplinary studies. In this work, as part of the ongoing Quaternary deposits geological mapping for the CARG Project (Sheets 379 Capracotta and 370 Guardiagrele), several large rock avalanche landforms and deposits were identified through remote and in-field investigations (detailed field surveys, lithofacies analysis, aerial photograph analysis, 1-meter-resolution LiDAR mapping, and morpholitostratigraphic profiles).

The mapped rock avalanches affected the western slope of Majella Mountain - Cretaceous carbonate platform to slope rock facies and Paleogenic carbonate ramp facies, part of a large-scale NNW-SSE plunging anticline - and the eastern/western slopes of Mt. Porrara – high-angle east-dipping sequences of Cretaceous carbonate platform and Cenozoic carbonate ramp rocks, overthrusted onto Miocene arenaceous-pelitic turbidite successions-.

Along the western side of the Mt. Porrara runs a 9 km long N-S striking west-dipping active normal fault system, the Porrara Fault, whose northern segment ends in a highly faulted/jointed zone crossed by NNW-SSE oriented normal faults that border the western slope of the Majella Mountain (i.e., the Caramanico Fault) and NW-SE oriented thrusts (eastern Mt. Porrara thrust zone). Evidence of deep-seated gravitational slope deformations is widespread along the ridges and slopes, often acting as predisposing factors for large-scale mass movements.

The source areas of the rock avalanches often correspond to amphitheatre-shaped scarps that face the slopes. The landslide deposits show different arrangements: from asymmetrical to elongated shape, with surface area up to >6 km2, thickness up to 75-80 m and runout distance from 1 km to >4 km.

This study presents a geological-geomorphological map of the detachment, sliding, and accumulation zones of the rock avalanches, serving as a starting point for a more accurate study and chronological attributions.

Geological mapping of submerged areas withing the CARG project. The example of "Asinara" sheet (n. 425)

Orefice S.*, Pensa A. & Fiorentino A.

Dipartimento per il Servizio Geologico d'Italia, ISPRA, Roma.

Keywords: geological mapping, CARG, submerged areas.

The Geological Survey of Italy-ISPRA, thanks to the new funding received in the past few years, has resumed the realization of the geological mapping CARG Project, coordinating the Project at national scale. The survey of more than eighty geological sheets at the 1:50,000 scale was started; among them more than twenty maps include submerged areas, two of them (Bracciano and Varese) with lake areas.

The Geological Survey of Italy realizes directly, in collaboration with colleagues of other research institutes and universities, the geological sheets "Torretta Granitola - Pantelleria" and "Isola Asinara", for both the emerged and submerged areas.

According to the 1:50,000 scale CARG guidelines, criteria adopted to characterize units in submerged areas are as much as possible the same used on land. Data in submerged areas are acquired at the 1:25,000 scale, mainly by indirect surveys carried out by geophysical methods, which however have to be groundtruthed by samplings, video inspections or scuba diving.

Geological information to be represented on the maps refer to the surface distribution of the deposits cropping out on the seafloor. Unconsolidated sediments are characterized by age, environmental/depositional systems, grainsize, biogenic and mineralogical content. Rocky outcrops are correlated to their on land counterparts whenever possible; alternatively, they are identified as undetermined rocky substrates according to their seismic characteristics. Additional features represented in the maps are: tectonic elements, morphological features (such as shelfbreak, sandwaves, canyons, gullies) and the main biocenoses (such as phanerogam meadows and bioconstructions) that are relevant from a sedimentological point of view. The thickness of the late-Quaternary depositional sequence is also identified, subdivided where possible into systems tracts (high stand, transgressive, falling stage and low stand).

The study area, comprised in sheet 425 "Isola Asinara", is located in the north-western part of Sardinia. Bathymetric data were obtained by the Hydrographic Institute of the Navy (IIMM) complemented by multibeam surveys performed by the National Institute of Oceanography and Experimental Geophysics (OGS) and the Institute of Marine Sciences of the National Research Council (ISMAR-CNR).

Backscatter data, acquired by the Sassari University, ISMAR-CNR and OGS, were used to identify the distribution of acoustic facies which were successively interpreted on the base of the analysis of several grab samples collected to characterize sediments grainsize. Moreover, seismic-stratigraphic surveys were addressed at investigating the buried substrate; high resolution but low penetrative seismic lines were acquired by a sub bottom profiler, whereas, for the investigation of deeper structures, a sparker source was adopted for the seismic surveys.

Tectonic imprints on Quaternary landscapes: insights from morphometric analysis and new luminescence dating in Southwestern Sicily

Parrino N.*[1], Srivastava E.[1], Caldareri F.[1], Burrato P.[2], Gasparo Morticelli M.[1], Di Maggio C.[1], Agate M.[1], Bonfardeci A.[1] & Sulli A.[1]

[1] Dipartimento di Scienze della Terra e del Mare, Università di Palermo. [2] INGV, Roma.

Keywords: landscape evolution, optically stimulated luminescence, crustal deformation.

Despite being shaped by uniform, although variable trough time, climatic forcing, the late Pleistocene coastal landscape of southwestern Sicily between Capo S. Marco and Capo Bianco exhibits significantly different landforms across its various sectors. The western sector features a portion of the Grande Terrazzo Superiore (GTS), a gently sloping Quaternary polycyclic surface extending approximately for a 100 km long stretch of the area. This landform terminates abruptly east of Sciacca, where deeply incised, V-shaped valleys dissect the remnants of a 20 km long flight of late Pleistocene paleoshorelines.

The southwestern coastal sector of Sicily is characterised by a complex segment of the Sicilian Fold and Thrust Belt, located at the collisional boundary between the African and European plates, in the central Mediterranean. This area, characterized by an active Plio-Quaternary frontal fold and thrust system, has been extensively surveyed through the ongoing 1/50k geological mapping of the Foglio n. 628 (CARG Project). This mapping has revealed two distinct orientations of the main thrusts: the roughly N-S trending and W verging blind thrust of the Gela Thrust Front (GTF) and the NNE-SSW and ESE verging thrust outcropping in front of the carbonate ridges San Calogero mountains.

Our study aims to discriminate and differentiate the morphometric signatures of these main thrust systems to understand better their differences and determine which set of structures has most significantly driven the landscape evolution in the area and has been more active in recent history. To achieve this result, we interpret how marine and fluvial geomorphic markers have recorded regional and local tectonic activity across the GTF and the ESE verging thrust systems.

This research utilizes new optically stimulated luminescence ages of the fluvial and marine sediments sampled in the area, which help define the ages of the geomorphological markers extracted using the methodology described by (Parrino et al., 2023). The findings have been integrated into the general seismotectonic setting of the study area. The results of this research are expected to provide new insights into the structural and seismotectonic framework of the area, thereby enhancing our understanding of its complex geodynamic context.

Parrino N. et al. (2023) - Plio-Quaternary Coastal Landscape Evolution of North-Western Sicily (Italy). Journal of Maps, https://doi.org/10.1080/17445647.2022.2159889.

Digital structural analysis from outcrops and VOMs: case studies from Umbria turbiditic successions

Pasqualone L.*[1-2] & Urbani M.[1-2]

Keywords: digital field mapping, virtual outcrop models, geological map.

The advent of modern technologies in the geosciences has enhanced the development of new advanced methodologies for geological survey. Digital devices equipped with GPS systems allowed to increase the precision of data sampling and cartography of geological elements.

Moreover, photogrammetric techniques from drones and terrestrial laser scanner allowed the construction of Virtual Outcrop Models (VOMs) to integrate fieldwork-based analysis and to provide access to remote outcropping rocks. VOMs are becoming widely used in geological sciences and are the result of recostructions of a 3D object through the analysis of multiple, partly overlapping images of the same outcrop taken from different points of view.

The studied area is located in a part of the Umbria region (Italy), between the NW sector of the Mt.Subasio and the main calcareous ridge of the Umbria Apennines. This area is characterized by wide outcropping turbiditic successions of the Miocenic foredeep (Marnoso-Arenacea Fm.) and by foreland-ramp hemipelagic deposits (Schlier Fm.).

A structural geological survey has been conducted in both physical accessible and inaccessible well exposed outcrops. Fieldwork has been performed by using mostly digital methods, in order to have detailed observations of the studied area.

In accessible outcrops, geological survey has been carried out on FieldMove Pro (from Petroleum Experts Limited) and Strabospot2 (from Kansas University). These two app works on portable devices (tablet and smartphones) equipped with digital clino-compass, that allows to measure georeferenced planar and linear elements.

For inaccessible outcrops, more than 200 partly overlapping photos obtained from drone have been imported into licensed Agisoft Metashape Professional, in order to create the VOMs.

The generated models have been then exported to open-source software Cloudcompare to extract structural data such as bedding and fractures orientation.

Both datasets (from fieldwork and drone) have been analyzed in order to compare the two acquisition methods. Structural data have been obtained by using Steronet 11.

Preliminary results shows that both acquisition methods give similar results. The studied turbiditic sequences, from outcrops and VOMs, shows structures related to the compressional tectonics, that are comparable with the regional field stress that developed the Apennines chain.

We present a section of the geological map with the relative structural and microstructural study that allowed to define the tectonic setting and the deformations of the area of interest.

Fracture network analysis in a polyphasic tectonic framework: the importance to integrate field-based structural data in the era of digital geology (CARG Project 245-Albenga)

The Ligurian Briançonnais represents a key point to unravel the Alpine evolution. Indeed, the Ligurian Alps structure is the result of the staking of paleogeographic domains belonging to a passive margin. The Ligurian Briançonnais represents the innermost portions of the Paleo-European margin. Its intricate framework is interpreted as the result of inherited pre-collisional structures influence and a polyphase deformation (Vanossi et al., 1984; Bonini et al., 2010). The simpler example is the inversion of pre-Alpine normal faults that could be preferentially reactivated as thrust during the collisional stacking (Butler et al., 2006). The polyphasic deformation is characterised by the main thrust and folds development during SW-vergent phase (D1), a subsequent NE-vergent back-thrusting phase (D2) and following faulting phases (D3-D5) (Maino et al., 2013). Moreover, to reconstruct the kinematic evolution of this domain, each structure should be analysed considering the summation of the contribution of overlapping multiple deformation phases, both fragile and ductile, as well as the continuous feedback between pre-existing conditions and changing stress domains. However, how the early fault and fracture network influences the following evolution of brittle structures is poorly quantified. Close to Finale Ligure (Mt. Caparazoppa), a tectonic element part of the Castelvecchio-Cerisola unit, displays a km-sized recumbent fold characterised by a curvilinear fold axis resulting in a sheath-like fold morphology. These structure records fold imputable to the D2 phase too and it is unconformably covered by post-collisional deposits of Pietra di Finale formation. This peculiar fold is an ideal place where to study the influence of the early deformation features (folds and faults/fractures) on the development of the following stages.

The aim of the research is to understand if (and how) the early fracture sets, associated with the first folding phases (D1), control the development of the successive fracture orientation. A classic field-based structural investigation has been coupled with the analysis of an Unmanned Aerial Vehicle (UAV)-based Digital Outcrop Model (DOM). The dataset is large and provides a statistically sounding definition of fracture sets, the variation in orientation of which correlates with the different structural locations throughout the fold 3D geometry. We highlight the importance to integrate the digital workflow with a fully comprehensive field-based characterization of the local litho-stratigraphic and structural setting to prevent misusing of the opportunity to treat large amounts of data with partially automated procedures.

The medium- to high-grade metamorphic basements of NW Sardinia: the example of the Sheet n. 425 "Isola Asinara"

Pieruccioni D.* & Simonetti M.

Dipartimento per il Servizio Geologico d'Italia, ISPRA, Roma.

Corresponding author email: diego.pieruccioni@isprambiente.it

Keywords: geological map, Variscan basement, CARG Project.

The Asinara Island (NW Sardinia) represents an area where it is possible to investigate the medium- to high-grade metamorphic basement which formed the inner part of the Variscan orogen and a km-scale transpressive shear zone, *i.e.* the Posada-Asinara shear zone, that drove the exhumation of the metamorphic core of the belt (Carosi & Oggiano, 2002). Even though Asinara island offers good exposure of the main tectonic units building up the Sardinian Variscan belt, because of the former limitation of access that lasted for many years, only recently structural-geological map of the island was made (Carosi et al., 2024).

The island falls in the area covered by the geological sheet "424 - Isola Asinara" of the CARG Project. The sheet, currently under production, is based on existing data integrated with a new detailed survey. It offers the opportunity to test the modern approach and standards to map crystalline basements suggested by the new project normative (Simonetti et al., 2022) provided by the Italian Geological Survey. This basement is characterized by two tectono-metamorphic units, *i.e.* the Medium- and High-Grade Metamorphic Complex (Carosi et al., 2004), and three intrusive units, *i.e.* the Castellaccio and Punta Sabina intrusive unit and sheeted dykes complex.

The Medium-Grade Metamorphic Complex consists of i) albite/oligoclase bearing micaschist; ii) garnet and staurolite bearing micaschist; iii) quartzite; iv) amphibolite; v) Cala Reale orthogneiss; vi) sillimanite bearing micaschist.

The High-Grade Metamorphic Complex consists in i) mylonitic sillimanite bearing micaschist; ii) Cala d'Oliva ortogneiss; iii) amphibolite, and iv) migmatite.

The two complexes are separated by the Posada-Asinara Shear Zone that, in agreement with the new normative of the CARG project, was mapped taking into account the occurrence of both high-grade metamorphism (appearance of sillimanite) and evidence of non-coaxial deformation.

The Castellaccio Intrusive Unit consists of inequigranular granodiorite-monzogranite characterised by large laths of K-feldspar, which often define a magmatic foliation. The Punta Sabina Intrusive Unit consists of peraluminous granitoid with stromatic enclaves, and finally, the sheeted dykes complex consists of peraluminous micro-leucogranite and pegmatite from decimetric to plurimetric thickness. From a structural point of view, four ductile deformation phases are recognized (Carosi et al., 2004): i) D1 is locally preserved and the S1 is visible in D2 hinges; ii) D2 is the most pervasive deformation phase and S2 is the main foliation that progressively becomes a mylonitic foliation approaching the Posada-Asinara shear zone (Carosi et al., 2004); iii) D3 is weak and produces upright folds, mainly developed in the central and northern parts of the island; iv) D4 is associated with a sub-horizontal crenulation cleavage.

Keywords: Southern Apennines, foreland basin systems, CARG project.

Foreland basin systems can be characterized by a rather intricate paleogeography especially those developing oblique to the main orogenic front. The morphologic complexity of such a "broken" foreland system is due to the reactivation of pre-existing tectonic structures, leading to a mosaic of topographic and bathymetric highs and lows. Such a configuration causes the compartmentalization of sedimentary pathways and depositional areas within the foredeep on short to very short distances. We here document how the Cenozoic reworking of Late Cretaceous normal faults fragmented the subsidence of the Southern Apennines foreland system in the Alburni Mountains, leading to strong local sedimentary facies variations and erosional features. The whole Alburni area was mapped as part of the CARG project (Sheet 487 "Roccadaspide"). In this carbonate platform carbonate massif, the synorogenic drowning succession does not conform to the typical one characterizing the associated Alburni-Cervati-Pollino tectonic unit, elsewhere in the region. Calcareous breccia unconformably crops out atop the Late Cretaceous platform, likely representing epi-breccia deposits while the Eocene platform carbonates of the Trentinara Formation are barely present, often replaced by outer margin and ramp calcarenites. The Early Miocene Roccadaspide and Bifurto formations are lacking whilst coeval deeper basinal marls and cherty calcilutites, fill small scattered depocenters few hundreds to kilometers apart. These laterally and vertically discontinuous sequences are blanketed by a matrix-supported polymictic conglomerate with a yellowish calcareous matrix and successively covered by Middle/Late Miocene deposits containing large crystalline rounded blocks, possibly deposited in an alluvial to coastal environment. This complex deposition environment discontinuously developed since the Cretaceous-Paleogene boundary as suggested by the first calcareous monomictic breccia only containing Late Cretaceous clasts. The unconformable contact between the Late Cretaceous platform and the epi-breccia is sharp as well as the boundary with the overlying Miocene basin-fill succession which is also marked by the occurrence of a diagenetic overprint of cherty nodules and oxidized crusts right onto the paleo-escarpment surface. These paleo-escarpments developed as the outcome of extensional tectonics since the Early Paleogene and were revitalized when the migrating foreland-related subsidence reached the area in the Early Miocene leading to further deepening of the succession

Rosso Ammonitico Veronese (Bajocian - Tithonian, Jurassic) from the Trento Platform to the Belluno Basin: can we really map it?

Corresponding author email: alberto.riva@unife.it

Keywords: Jurassic, Southern Alps, Rosso Ammonitico.

The Venetian Prealps were marginally involved in the rifting stage of the Piedmont-Ligurian ocean during the Early Jurassic, and then were part of a passive margin during the Middle-Late Jurassic. The near 100 km wide region between Lake Garda and the western Grappa Massif was part of a structural high and shallow water carbonate platform known as "Trento Platform", while from the eastern Grappa Massif to the Cansiglio Plateau, a ca. 50 km wide deep water basin existed (Belluno Basin: e.g., Winterer & Bosellini, 1981).

The Jurassic Trento Platform drowned near the end of the Early Jurassic; above, the renowned <50 m thick Rosso Ammonitico Veronese formation, ARV, covers a time span from the Bajocian to the Tithonian, with several long hiatuses in between (Martire et al., 2006). Meanwhile, in the Belluno Basin, a >= 600 m thick succession deposited, made of oolitic calciturbidites (Vajont Oolitic Limestone, **OOV**) and micritic limestones with chert and minor clay (Fonzaso Formation, FOZ).

This lithostratigraphic framework is the result of centuries of studies, and hence, it should result in a stable and undisputed nomenclature. With the geological sheet 063 Belluno (1992), it was found however that above the Fonzaso Formation, the Rosso Ammonitico is atypical, being gray rather than red, having nodules of chert and yielding little or no ammonites. It was noted that east of the mapped area, the two units could not be separated, and may belong to a unified unit called Soccher Formation. The transition between Fonzaso and Rosso Ammonitico Veronese formations on the west, and Soccher Formation on the East, was left unresolved. The name "Soccher" (SOC) has been recently reinstated in the CARG sheet 046 Longarone but with a different meaning respect the original definition, standing for a variegated unit above ARV and encompassing a Tithonian p.p. - Santonian interval.

We present a ca. 50 km long transect of Bajocian - Tithonian carbonate units cropping out from the top of the Grappa Massif to the deepest part of the Belluno Basin, highlighting how the nomenclatural confusion between Fonzaso Formation and Rosso Ammonitico Veronese is still not resolved enough for mapping according to CARG standards. We propose a new lithostratigraphic framework that makes sense of Jurassic nomenclature in this critical portion of the Alps. Less studied intervals may hide even more convoluted problems, which might take most of the lifecycle of a geological sheet production to be disentangled. We advocate an action to frame - if not resolve - lithostratigraphic and nomenclatural issues before - and not during - the mapping of geological sheets, otherwise the consistency of adjacent maps is unlikely to be maintained.

Martire L. et al. (2006) - The Rosso Ammonitico Veronese (middle-upper Jurassic of the Trento Plateau): a proposal of lithostratigraphic ordering and formalization. Rivista Italiana di Paleontologia e Stratigrafia, 112, 227-250.

Corresponding author email: giuseppefrancesco.rizzo@unipa.it

Keywords: 3D geological model, Sheet 628 Sciacca, CARG project.

The CARG project allowed to collect new useful multidisciplinary data for the reconstruction of subsurface geological model. For the Sciacca area (Sheet 628) data from geological survey (collected through advanced digital tools and processed through FieldMOVE) were used to reconstruct the geological map at 1:50,000 scale from which the geological sections of the onshore sector were reconstructed. The obtained data were integrated with those derived from seismo-stratigraphic and structural interpretation of 2D seismic reflection profiles, collected from both from public and non-databases of submarine regions, calibrated with stratigraphic well-logs provided by ISPRA. By working in a combined 2D/3D environment, data as surfaces and lines (from 2D seismic interpretation) were cross-checked with dedicated software to ensure that all interpretations were consistent. Depth conversion have been performed using velocities derived from sonic well-logs and literature data to identify the correct geometries and thicknesses of the layers in depth (m) interpreted in time domain (TWT).

The integration of multidisciplinary data was challenging to obtain a continuous interpretation from onshore to offshore sector. The major stratigraphic levels and the tectonic surfaces affecting them were represented in a 3D view with the aim of determining the large-scale structural framework, joining the onshore and offshore sectors interpretation. The combined onshore/offshore geological reconstruction was also used to depicts the isolines of the main stratigraphic/structural layers derived from 3D surfaces.

Field data restitution and 3D map visualizations are essential for understanding the development of the geometries of fundamental structures in depth. Such data are a key tool for proper geological information restitution that ensures both development and environmental sustainability at the same time. A well-defined subsurface geological model, guided by geological reasoning, provides the key tools to identify, characterize and manage georisks and georesources.

Field preliminary data to reconstruct the tectono-stratigraphic evolution of the Mt. di Muccia-Mt. Val di Fibbia area (Northern Apennines, Italy)

Romagnoli G.* & Muraro C.

Keywords: geological surveys, structural analysis, resedimented shallow water deposits.

We carried out a critical review of the previous geological maps, new detailed geological surveys, sedimentological and biostratigraphic studies, combined structural analysis of the main tectonic lineament in the Mt. di Muccia-Mt. Val di Fibbia area. It extends for about 150 km2 in the SW sector of the sheet 313 "Camerino" (still in progress) within the National Geological Map of Italy Project, at 1:50.000 scale (CARG Project; https://www.isprambiente.gov.it/Media/carg/index.html). The area is located in the Umbria-Marche Apennines, the external sector of the Northern Apennines, which is a thrust and folds NE verging belt, resulting from Neogene deformation related to the convergence of the African-Adria and European continental margins.

The outcropping Late Jurassic-Late Miocene lithostratigraphic units are part of the thick calcareous-marly siliceous pelagic succession of the Umbria-Marche Basin, and are characterized by resedimented shallow-water deposits derived from the Latium-Abruzzo Carbonate Platform.

In the mapped Cretaceous-Neogene lithostratigraphic units, we observed great variations in thickness, even over short distances, and variations in the presence, abundance, and composition of resedimented shallow water deposits. which are not closely related to each other. This suggests an articulation of the palaeotopography of the basin, probably related to tectonic events.

Our studies provide preliminary constrains to reconstruct the tectono-stratigraphic evolution of this sector of the chain.

Jurassic evolution and paleogeography of the Fiastrone gorge (Marche, Italy): new data from detailed geological mapping

Rossi G.*[1], Cipriani A.[2] & Fabbi S.[1-2]

Keywords: Jurassic, Sibillini Mts., Apennines.

A new geological mapping project at 1:10,000 scale allowed to re-interpretate the geological evolution of the Fiastrone gorge. The study area is located in the Marchean ridge, one of the most external structural elements of the Northern Apennines, where the Meso-Cenozoic rocks of the Umbria-Marche sedimentary succession crop out. Sedimentation of this succession was strongly influenced by the complex paleogeography derived from the Early Jurassic rifting of Western Tethys. At the eastern end of the Fiastrone gorge, a portion of the Sibillini Mts. Thrust spectacularly crops out. Here, the Calcare Massiccio overthrusts the Scaglia Cinerea with the interposition of Maiolica and Scaglia Rossa duplexes. Over the years, most authors have interpreted the study area as a Jurassic structural high covered by a condensed pelagic succession represented by the Bugarone Group, in tectonic contact with younger Jurassic units. New field data revealed that the contact between the Calcare Massiccio and the overlying Jurassic units coincides with a complex unconformity, and no horst block-top condensed units occur in the area. Exceptions are represented by rare, scattered patches of condensed epi-escarpment deposits. The unconformity surface is marked by pervasive silicification of the Calcare Massiccio, due to silica-rich fluids circulation provided by the siliceous basinal pelagic units, and by the centrifugal attitude of the pelagic beds abutting the onlap surface as a result of differential compaction. The youngest Jurassic unit onlapping and burying the Calcare Massiccio is the Bajocian-Kimmeridgian Calcari Diasprigni, which means that this structural high was less elevated than the main highs in the UMS domain (commonly buried by the Lower Cretaceous Maiolica). The Fiastrone Jurassic high describes a cusp-shaped geometry rather than a flat-topped pelagic carbonate platform. Pre-orogenic, post-Jurassic (since they also cut the Maiolica and Scaglia Rossa), faults with limited throw (cumulatively about 100 m), have lowered some portions of this high towards the west, and are cut by the Sibillini Mts. Thrust. At present, the Fiastrone High is in hanging wall ramp with respect to the Miocene thrust and the paleotectonic reconstruction of this Jurassic horst-block, coupled with the analysis of geometrical relationships between Tethyan inheritances and compressive deformations, permitted to infer that the Sibillini Mts. Thrust may have reactivated a paleostructure, potentially a Jurassic domino fault bounding a wider Jurassic high to the east in present-day coordinates (now at the footwall of the thrust).

A previously unknown loess deposit in the Quaternary Gubbio basin (Umbria, central Italy): a stratigraphical record of the paleoenvironment of the area

Silvani F.*[1], Mirabella F.[1], Pazzaglia F.J.[2] & Barchi M.R.[1]

Keywords: Gubbio basin, Loess, Quaternary deposits.

Recent mapping and description of the basin-fill of the Gubbio intermontane basin (Umbria, central Italy) has identified a weathered, decimeter-thick, fine-grained, ochre-colored deposit that mantles ridges in the southern and northern, incised portion of the basin that we interpret as a late Pleistocene loess. These deposits lie directly on the middle Pleistocene (?) clay unit of the basin infill, which is particularly enriched in Fe-Mn concretions near the topographic surface. Grain size analyses returned a predominant percentage in silt (> 65%) and the total absence of gravels. Analyses with a scanning electron microscope (SEM) and energy-dispersive X-ray spectroscopy (EDS) were conducted to determine the textural and chemical characteristics of the samples, showing the presence of poorly rounded granules and silica as the predominant element (quartz granules). These results, in conjunction with the extensive areal distribution observed in the Gubbio basin, suggest that these deposits may be associated with aeolian processes, as a wind-transported deposits that might does not undergo abrasive processes (Liu et al., 2006). The sources of these deposits can be multiple, including glaciofluvial deposits, fluvial deposits (dry riverbeds), local silty sediments from bare slopes in hilly lands, and Saharan dust (Costantini et al., 2018). In central Italy, loess deposition is documented during the glacial and stadial periods of the late Pleistocene, which occurred between approximately 70 and 35 kyr BP (Cremaschi et al., 2014). The distribution of this loess, with pending luminescence ages, is emerging as a key stratigraphic interval that helps us construct a regional age model for the deposits that constrains both the tectonic subsidence history of the basin and drainage integration through this part of the northern Apennines.

Keywords: luminescence dating, fluvial-marine terraces, eustatic variations.

We present a comprehensive chronological framework of a flight of marine and river terraces, derived from integrated luminescence dating and geomorphological, sedimentological, and stratigraphical analyses in the Foglio n. 628 “Sciacca”, surveyed during the ongoing 1/50k geological mapping CARG Project (southern Italy, central Mediterranean Sea). The optical luminescence dating of the river terraces, belonging to the Carboj R. drainage network, revealed a correlation between late Pleistocene eustatic sea-level fluctuations and fluvial aggradation and incision phases (Erturaç et al., 2019). Our results indicate that the fluvial incision of the Marine Isotope Stage (MIS) 7 marine terrace, which began during MIS 6, resulted in the subsequent formation of a series of fluvial terraces in the Carboj River channel network between 146-134 ka. This process extended to the lower reaches of the trunk stream until about 120 ka. The terraces formed during this time interval exhibit varying stream power levels, as evidenced by an alternation of nested sedimentary deposits. These range from high-energy, matrix-supported gravels to low-energy fine and coarse sands, showing at least two transitions between marine and continental environments (Antoine et al., 2000; Blum & Törnqvist, 2000). The presented data highlight, for the first time in Western Sicily, the presence of sea inlets within today’s river valleys and that the sediment flux and terrace development were primarily driven by episodic small-amplitude eustatic sea-level oscillations, and by a tectonic controlled regional lowering of the base level that significantly forced the Late Quaternary landscape evolution of this Sicilian coastal sector.

Keywords: Sheet 628 SCIACCA, subsurface, offshore.

The Sheet 628 "Sciacca" is located in an onshore-offshore sector of SW Sicily where the external segment of the Sicilian Fold andthrust belt- develops. This Sheet is composed by 1:50.000 geological and subsurface maps and a 3D geological model, obtained by field survey in the onshore sector and seismoacoustic investigation in the offshore sector.

The data collected during the marine and field survey, integrated with the subsurface data coming from the interpretation of wells and multi-channel seismic profiles made available by ENI S.p.a, have made it possible to reconstruct the 3D geological model up to the depth of 4 km by correlating the emerged with the submerged sector, as well as the kinematics and chronology of the main deformation events that affected this region.

The Lower Jurassic-Pleistocene successions were studied with stratigraphic, sedimentological and palaeontological methods: the latter allowed for an accurate dating of the lithostratigraphic units, which for the late Quaternary deposits was integrated by absolute dating with OSL methodology.

In the western outcropping-sector and south-western offshore areas, a Meso-Cenozoic shallow to deep water carbonate succession (locally named Saccense) crops-out and it is covered by Neogene-Quaternary syntectonic deposits.In the north-easternsector, a Meso-Cenozoic deep water carbonate succession (known as Sicanian) crops-out.In the eastern and south-eastern sectors deformed Neogene syntectonic deposits (Gela Thrust Wedge) are covered by Upper Pliocene - Lower Pleistocene syntectonic terrigenous deposits.

The tectono-sedimentary analysis highlighted a multi-stage tectonic evolution, characterized by: a):- a Meso-Cenozoic extensional tectonics responsible for the formation of thick slope deposits, cropping-out along the southern slope of the main carbonate reliefs; b)- a Messinian compressional event during which the Eocene-Oligocene portion of the Saccense succession was shortened and detached from its Mesozoic carbonate substrate; c)

- a Late Pliocene-Early Pleistocene compressional event, during which low- and high-angle thrusts were responsible for the exhumation of the main carbonate reliefs and for the building of the Gela Thrust Wedge; d)

- a post-Early Pleistocene compressional-transpressional event, responsible for the activation of the two most important tectonic lineaments recognized in the Sheet: (i) the NNE-SSW-oriented, left-lateral transpressive fault that develops across the Sheet, displaying a southward continuity in the offshore; (ii) the northern dipping thrust, bounding the carbonate reliefs in the northern sector of the Sheet.

Both tectonic structures allowed for the overthrust of the Meso-cenozoic carbonate tectonic units (Sicanian and Saccense) on the Gela Thrust Wedge.

The small-scale problem: loss of significant geological features in small scale geological maps. The case of the northern sector of the Murgia Materana, South Italy

Venezia V.*, Festa V. & Tropeano M.

Dipartimento di Scienze della Terra e Geoambientali, Università degli Studi di Bari "Aldo Moro".

Corresponding author email: vitantonio.venezia@uniba.it

Keywords: geological maps, Murgia Materana, CARG project.

In this work we compared 1:5.000 scale geological map of the northern sector of the Murgia Materana with three geological maps of the same area at a much smaller scale: the 1:25.000 scale geological maps presented by Radina (1973) and the sheets 187 "Altamura" (Servizio Geologico d'Italia, 1968) and 201 "Matera" (Servizio Geologico d'Italia, 1971) of the Geological Map of Italy at a 1:100,000 scale.

The comparison clearly shows the need of several simplifications, such as:

The grouping of different informal units, recognised by Festa et al. (2018) within the Calcare di Altamura Fm (Senonian), in only one informal member, named "Matera Member" by the same authors. This leads to the loss of the different facies and environmental significance of each single unit within the member;

The mapping of only main structural features, which leads to the loss of information about the relations between smaller, but not less important, tectonic structures outcropping in the area;

The tracing of the boulders between the Calcarenite di Gravina Fm (Late Pliocene – Early Pleistocene) and the Calcare di Altamura Fm can-not be very detailed, leading to the loss of information in small boundaries zone of specific significance.

The problem of the scale of "small" units, structures and contacts in the Matera area deserves special attention, especially in view of mapping of the Sheet 472 "Matera" of the Geological Map of Italy at 1:50.000 scale (CARG Project). In fact, the adoption of the above simplifications prevents the mapping of all the features that can lead to fundamental interpretations on the geological evolution and environment development of the area (e.g. the intraplatform basin in the Calcare di Altamura Fm and the relations between his evolution and the tectonic contest). This means that the adoption of a large scale implies a loss of relevant features that are fundamental to reconstruct the geological evolution of the area.

Sheet 158 "Casale Monferrato"of the Geological Map of Italy at 1:50.000 scale (CARG Project): preliminary results

Zanellato N.*[1], Dela Pierre F.[1] & Festa A.[1-2]

[1] Dipartimento di Scienze della Terra, Università di Torino. [2] Istituto di Geoscienze e Georisorse, CNR, Torino.

Corresponding author email: nicolo.zanellato@unito.it

Keywords: CARG, geological mapping, sedimentary geology.

Field work for the realization of Sheet 158, "Casale Monferrato," of the Geological Map of Italy (CARG Project), started in winter 2024. The sheet is located in the eastern part of Monferrato, one of the tectono-sedimentary domains that compose the Tertiary Piedmont Basin. This domain is made up of an upper Eocene to Pliocene succession that unconformably overlies a lower-middle Eocene calcareous flysch known as the Casale Monferrato Formation of the External Ligurian Units. The succession has been divided into 4 unconformity-bounded stratigraphic units (UBSU), which are delimited at the bottom and top by regional-scale unconformity surfaces. The criteria used to identify these surfaces in the field include the erosional truncation of underlying strata and the vertical superposition of sedimentary facies, in contrast to Walther's rule.

The first UBSU consists of the hemipelagic marls of the Monte Piano Formation (Upper Eocene). Locally, thick beds of bioclastic turbidites, which record the dismantling of a shallow water carbonate platform, were observed. The Monte Piano Formation is sharply overlain by fan delta conglomerates and shelfal sandstones and mudstones of the Cardona Formation (Rupelian). These are, in turn, overlain by slope marls of the Antognola Formation (Chattian-Aquitanian). These sediments make up the second UBSU, which is strongly deformed by approximately west-northwest-striking transpressive faults. These faults are overlain by a prominent angular unconformity that marks the base of the third UBSU. The third UBSU consists of Burdigalian to Serravallian carbonate ramp deposits and hemipelagic marls, namely the Pietra da Cantoni and Mincengo Formations. These sediments are gently deformed at a regional scale by east-west-directed open folds. The lateral and vertical stacking pattern of these formations suggests a westward deepening of the ramp and a transgressive trend leading to the drowning of inner ramp sediments, which are composed of rodhalgal carbonates.

The fourth UBSU is delimited at the base by another angular unconformity, overlain by Tortonian-Lower Messinian hemipelagic fine-grained sediments of the Sant'Agata Fossili Marls. This unit is followed by sulfate evaporites of the

Vena del Gesso Formation, which record the onset and development of the Messinian salinity crisis. These evaporites consist of primary bottom-grown gypsum beds interbedded with shales, as observed in the nearby Moncalvo gypsum quarry. The end of the Messinian salinity crisis is finally recorded by Zanclean marine marls of the Argille Azzurre Formation, which grade upwards to inner shelf sandstone of the Sabbie di Asti Formation.

Future work will focus on more detailed stratigraphic, sedimentological, and structural analyses aimed at reconstructing the tectono-sedimentary evolution of this sector of the Tertiary Piedmont Basin.

Geomorphological evolution and activity of some large earthflows in southern Italy

Annibali Corona M.*, Guerriero L. & Calcaterra D.

Dipartimento di Scienze della Terra, dell'Ambiente e delle Risorse, Università di Napoli "Federico II".

Corresponding author email: mariagiulia.annibalicorona@unina.it

Keywords: earthflows, gullies, state of activity.

This study presents an analysis of the state of activity of fourteen earthflows in the Southern Apennines of Italy, located in Campania, Basilicata, Calabria, Molise, and Abruzzo regions, with the aim of elucidating how earthflows respond to change in rainfall regimes and sediment availability (i.e. distance from watershed). These events, generally occurring within silt- and clay-rich structurally complex formations (examples are the Varicoloured clay, San Bartolomeo flysch, or Faeto flysch formations), have been selected because of their significant size, typical hourglass-shaped form with an amphitheater-like source zone, an elongate narrow transport zone, and a lobate depositional area and the availability of previous data about evolution and activity (in a number of cases). Employing a combination of high-resolution satellite imagery from Google Earth Pro and aerial photographs from Terraitaly, a comprehensive analysis of the geomorphological evolution of each earthflow was conducted for the last 20 years. Such analysis was based on the visual interpretation of historical imagery to discern morphological elements indicating earthflow boundaries and terrain features indicating their state of activity (ordinary active, extraordinary active, suspended, and dormant). Starting from the reference earthflow evolution model of Mackey & Roering (2011), elements such as crowns, scar zones, scarps, pressure ridges, flank ridges, shear surfaces, backtilted surfaces, ponds, gullies, lobate compressional deposits and watershed were considered for the analysis. Distribution of such elements were used for identifing earthflow areas and their state of activity, as well as duration of activity phases, including the identification of the occurrence and eventually the number of paroxysmal/surging reactivations (extraordinary activity). In this sense, the temporal persistence of the axial gully was used as a proxy of the duration of the suspended/dormant phases, often interspersed between the extraordinary and ordinary activity phases. Understanding the interconnectedness of gullies and earthflows is crucial for assessing landscape stability, erosion processes, and earthflow evolution. To supplement the analysis, rainfall data from stations nearest to the selected earthflows has been acquired and analysed to identify potential correlations between the activation of earthflows and hydrologic forcing. The occurrence of surges in relation to sediment availability in the form of distance between earthflow crown and main watershed was also analysed. The results of this study provide a comprehensive overview of the activity of earthflows in the Southern Apennines, contributing to the understanding of underlying geomorphological processes and the assessment of associated hazard. The analysis highlighted a diversification in the kinematic behaviour of the events, some of them characterized by a long period of quiescence (with the well-recognizable development of axial gullies) and others characterized by alternation of active and inactive phases (thus characterized by the formation and obliteration of axial gullies). Additionally, some earthflows have remained mostly active with a total absence of axial gullies. The conducted analyses allowed verifying how a significant portion of landslides exhibited a decrease in activity (highlighted by the persistence of axial gullies) in the last decade and emphasized the importance of rainfall in this context.

Mackey B.H. & Roering J.J. (2011) - Sediment yield, spatial characteristics, and the long-term evolution of active earthflows determined from airborne LiDAR and historical aerial photographs, Eel River, California. Bulletin, 123(7/8), 1560-1576, https://doi.org/10.1130/B30306.1.

The Derna dam collapse erased a century of urban sprawl

Azzoni R.S.*, Forti L., Pezzotta A. & Zerboni A.

Dipartimento di Scienze della Terra "A. Desio", Università di Milano.

Corresponding author email: robertosergio.azzoni@unimi.it

Keywords: urban geomorphology, hazard, remote-sensing.

Between September the 10th and 11th 2023, the heavy rainfall brought over North Africa by the storm Daniel triggered the failure of two dams in northeastern Libya, resulting in the accelerated discharge of 30 million m3 of water and debris. The flood destroyed a large part of the city of Derna and caused more than 10000 fatalities and the displacement of thousands of people from their homes. Here, we present the geomorphological interpretation of the effects of such calamitous event whose effects were increased by the Derna urban sprawl occurred in the last century. Our geomorphological assessment is based on the analyses of old cartographic sources, allowing the reconstruction of the evolution of the settlement of Derna, and high-resolution remote-sensing data. The latter permitted to assess the general settings of the local drainage system and the geomorphological effects of the event, also quantifying the volume of transported sediments through DEM of Difference analysis. Our analysis suggests that the effect of the flood was strictly connected to the urban sprawl and the destruction mainly affected the more recent areas of urban expansion.

Distinguishing between Medicanes and common seasonal storms using microseism

Corresponding author email: alfio.borzi@phd.unict.it

Keywords: microseism, Medicane, climate change.

Microseisms, the most continuous and ubiquitous seismic signal on the Earth resulting from interactions among the hydrosphere, atmosphere, and solid Earth, can be used as an indicator for understanding climate change. Numerous studies have explored the connection between microseisms and sea conditions, as well as cyclonic activities, focusing particularly on tropical cyclones, hurricanes, typhoons, and the more recent Medicanes (small-scale tropical cyclones in the Mediterranean Sea). In this work, we explored various meteorological events occurring in the Mediterranean Sea between November 2011 and February 2023 from a seismic point of view. Specifically, we investigate nine Medicanes and four more common seasonal storms. Despite their distinct characteristics, all these events led to intense rainfall, powerful wind gusts, severe storm surges with significant wave heights typically exceeding 3 meters, and damage along the exposed coastal areas. Some of these events also resulted in fatalities and injuries.

We analyzed the seismic data acquired from 104 stations installed along the coasts of Italy, Malta, Greece, and France, as well as 15 stations in the Etna area, primarily used for array analysis. Our analysis focuses on the correlations between the meteorological events and microseism features in terms of spectral characteristics, spatiotemporal amplitude variations, and source locations identified using two methods: a grid search based on seismic amplitude decay and array techniques. Comparing the microseism source locations from our study with storm surge areas from hindcast data, we found an agreement for 10 out of 12 events analyzed (two Medicanes show low meteorological features, and the microseism amplitude remained relatively stable).

Furthermore, we conducted two analyses to obtain the seismic signatures of these events using a method that exploits continuous seismic noise coherence and a measure termed Microseism Reduced Amplitude to assess their seismic intensity. By combining insights from these approaches, we can distinguish between Medicanes and more common seasonal storms based on seismic data. This highlights the potential for developing a novel monitoring system for Mediterranean meteorological events by integrating microseism data with other commonly used techniques like wave buoys and HF radar. Additionally, given that seismometers were among the earliest geophysical instruments deployed, digitizing old seismograms and analyzing historical data could offer new perspectives on extreme weather events within the context of climate change.

Geoheritage along the high rocky coast of Eastern Liguria: an emblematic case of interaction between natural hazard and human impact

Brandolini P.*[1], Faccini F., Ferrando A.[1], Bollati I.[2], Pelfini M.[2] & Azzoni R.S.[2]

[1] Dipartimento di Scienze della Terra, dell'Ambiente e della Vita, Università di Genova.
[2] Dipartimento di Scienze della Terra "A. Desio", Università degli Studi di Milano.

Keywords: geomorphological risk, anthropogenic impact, coastal areas.

As part of research on the geoheritage of the Ligurian coast and the assessment of the impact/risk resulting from settlements and infrastructure, the main aspects related to the dynamics of the rocky coast between Marina di Bardi in the municipality of Zoagli and the Tigullio Rock locality in the municipality of Chiavari, in the eastern sector of the Metropolitan City of Genoa, are presented.

In light of its great environmental and natural value, the area is included in the Natura 2000 network and includes, in the terrestrial part, the Sites of Community Interest (SIC) "Pineta Lecceta di Chiavari" and "Rio Tuja Montallegro"; in the seaward sector, it includes the SIC "Fondali Golfo di Rapallo," split into further subsites corresponding to remnants of a vast Posidonia Oceanica meadow. For its cultural and landscape value this stretch of coast also is included in the preliminary perimeter of the Portofino National Park, which has in its geological and geomorphological heritage one of its strengths.

This stretch of rocky coast, developed for about 3 km in the central-western sector of the Gulf of Tigullio, represents a significant example of geomorphological evolution of a coastal slope shaped in the limestone-marly flysch and affected by natural hazard due to marine, slope and running water processes and a high vulnerability related to buildings and infrastructure, from which significant geomorphological risk scenarios are derived (Brandolini et al., 2009).

Natural hazards seem to show an increase in frequency in recent decades partly due to climate change evidenced by an increase in mean annual air temperature, a change in rainfall patterns (Faccini et al., 2017), and an intensification of sea storm surges.

In this territorial context, the relationship between geomorphological hazards, related to cliff retreat phenomena and slope gravitational processes (De Vita et al., 2012), and tourist and residential settlements, road infrastructure (railways, roads and footpaths) and bathing areas, which have had significant expansion in high hazard areas over the past decades, have been analyzed and investigated in depth.

Evaluating the effectiveness of "River Morphodynamic Corridors" for flood hazard mapping: insights from an application in the Cordevole River catchment (Italy)

Brenna A.*, Poletto G. & Surian N.

Dipartimento di Geoscienze, Università degli Studi di Padova.

Corresponding author email: andrea.brenna@unipd.it

Keywords: channel dynamics, alluvial plain, Vaia Storm.

In dynamic rivers the assessment of flood hazard related to geomorphological dynamics assumes crucial importance. Recently, some geomorphological approaches have been developed to assess channel dynamics in response to floods. In this study we explore the River Morphodynamic Corridors, which can be defined as planform domains that include the current active channel and portions of the adjacent alluvial plain that have been or may be affected in the future by its lateral dynamics (Rinaldi et al., 2015). The procedure for the delineation of the morphodynamic corridors includes: (i) reconstruction of historical planform positions of the active channels; (ii) definition of potential future erosion on the basis of the mean rate of bank retreat; (iii) delineation of the alluvial plain by identification of natural elements of confinement; (iv) identification of structures preventing lateral channel mobility. These procedures involve the use of remote sensing imagery, historical maps, digital terrain models and field surveys.

In order to assess the effectiveness of such corridors for mapping flood hazard, we delineated the morphodynamic corridors along a river network of 74 km in the Cordevole River catchment (Italy) and compared the corridors with the channel changes that were triggered by a high-magnitude event (Vaia Storm) that hit the study area in October 2018. We observed that the morphodynamic corridors are capable to define areas where localized channel dynamics are most likely to occur and have proven satisfactorily effective in predicting abrupt channel widenings triggered by a severe flood. The results show that it is crucial to adopt different procedures for corridor delineation based on channel width, i.e., for small streams (width < 30 m) a more precautionary approach should be adopted that considers the entire alluvial plain as an area potentially affected by channel dynamics. The study also highlighted an inherent limitation of the approach, since erosion that can affect valley slopes or fluvial terraces (i.e., widening of the alluvial plain) is not taken into account.

This application represents the first extensive validation of the River Morphodynamic Corridors approach by comparison with geomorphic effects produced by a large flood event. Through this analysis, it can be inferred that, notwithstanding its relatively simple procedure, the approach allows a robust mapping and delineation of flood hazard due to river channel dynamics. The River Morphodynamic Corridors, when applied jointly with traditional hydraulic model for assessing inundation processes, allow an overall assessment of flood hazard, particularly in dynamic river contexts. Given the effectiveness of such geomorphological tools, their use should be widely adopted by competent agencies for an effective territorial planning and management.

How the interplay among geological and geomorphological factors, land use, and changing climate can bias very short-term landscape evolution: an example from Basilicata, southern Italy

Contillo L.*, Dimola G., Giannandrea P. & Schiattarella M.

Dipartimento delle Culture Europee e del Mediterraneo, Università degli Studi della Basilicata, Matera.

Keywords: climate change, landscape evolution, anthropic impact.

Erosion is a complex phenomenon influenced by relevant factors such as climate, morphology, hydrology, vegetation, and excessive human intervention in shaping landscape.

In recent years it has been observed an increase in extreme events related to climate change whose effects are directly proportional to the vulnerability of the territory. Climate change, variations in land use, and anthropogenic pressure have caused land degradation and incipient desertification phenomena rather significant in the Mediterranean areas which are becoming drier and even more vulnerable to drought. Basilicata region, in southern Italy, represents one of the most exposed to geomorphological risk and desertification processes Mediterranean areas.

The increasing number of weather extreme events represents the trigger and driving factor, as well as agricultural practice, of fluvial erosion (Scorpio et al., 2015; de Musso et al., 2020, among others) and mass-wasting processes, in terms of efficiency and rates, and contributes to the alteration of slope stability. During times of global change, it is of interest to properly analyse different stages of gully erosion processes, which constitute the most severe form of soil erosion (Stark et al., 2020). The importance of extreme events in controlling erosion and sediment transport in semi-arid areas has long been appreciated but their effects on specific landforms are not widely recognized.

The analysis of some categories of markers, such as the geomorphological and sedimentary ones, in key areas where climate changes combined with wrong land management may cause environmental hazard seems a best practice for the territory safeguard. The application of semi-quantitative methodologies for the estimation of erosion processes constitutes a valuable tool for the application of sustainable land management policies and for the definition of interventions for risk mitigation. This work proposes an example from Basilicata (in the surroundings of Matera town) of how land cover and climate can influence accelerated erosion and landscape evolution. Preliminary analyses of rainfall and temperature multi-temporal series and aerial photos ranged from 2001 to present day have been combined with GIS-based techniques for the estimation of such erosional processes.

Ancient slate quarries as geosites: degradation risk and enhancement issues

Ferrando A.*[1], Facciolo M.[2], Mandarino A.[1], Faccini F.[1] & Brandolini P.[1]

Keywords: geoheritage, geosites, degradation risk.

Among geosites of anthropogenic origin, ancient abandoned quarries have multiple interests. In some cases the quarry faces expose particular rock formations or stratigraphical sequences that are not well visible in natural outcrops. On the other hand, they are also important from the point of view of cultural geology: they reflect the techniques and the expertise of quarrymen who worked on them, and the stone material extracted from the quarry can be used as building stones or ornamental stones, contributing to the cultural identity of a region (Pijet-Migon & Migon, 2022).

Around the Tigullio Gulf, in the central-eastern part of the Liguria region (NW Italy), slate is one of the most common and used stone resources in architecture and construction. Slate extraction in this area probably began as early as the pre-roman times, but the first solid information on the presence of quarries dates back to the late Middle Ages. Quarrying activity was particularly flourishing between the 19th century and the first half of the 20th century, concentrated mainly in two poles: the Mt. Capenardo massif and the Fontanabuona Valley. From the second half of the 20th century, the activity steadily declined.

In recent times, a number of initiatives have arisen to enhance some of the old abandoned slate quarries for tourism purposes (Brandolini et al., 2007). In the area there are two geosites concerning ancient slate quarries, recognised at the regional and national level: the Tribogna 'theatre-quarry' and the Mt. San Giacomo quarries.

The aim of this work, in addition to a summary of the main geoheritage values of these two geosites, was to perform an analysis of their risk of degradation. The main issues concerning the possible tourist use of the two sites were then analysed, taking into consideration the objective risks for visitors and the state of the routes to get there. In the case of the quarries of Mt. San Giacomo, a detailed analysis was carried out on the practicability of the network of ancient paths used by quarrymen and slate porters.

The results of this work may be useful for planning a correct management and enhancement of the two geosites concerning ancient slate quarries, as well as for the mantainance of the existing trail network and for identifying new proposals for themed trails in the surrounding area.

Keywords: coastal geomorphology, Umm al Quwain, Anthropocene.

Coastal lagoon systems are highly sensitive environments currently experiencing the impact of climate change and human pressure. Lagoons are quickly reacting to such factors through changes in biodiversity and alterations of their geomorphic dynamics. Climate- or tectonic-induced changes in sea level – even the small ones – and/or shifts in the base level and/or flow rate of rivers connected to inlets heavily affect the balance of lagoon ecosystems, triggering ecological changes and/or alterations in landforms. For instance, the coastal region of the Arabian Peninsula, stretching from the Red Sea to the Persian/Arabian Gulf, are dotted by coastal lagoons that are undergoing deep transformations. Across the Holocene, Arabian lagoons underwent subsequent phases of modification triggered by sea level changes, modifications of ocean circulation, and post-post-Last Glacial Maximum shifts in the discharge of main rivers (e.g., Tigris and Euphrates rivers). These factors reshaped the geomorphology of such contexts, promoting the evolution of fresh ecosystems along the shorelines of the United Arab Emirates (UAE) and influencing the growth of extensive mangrove forests. In recent years, human agency has disrupted the pristine dynamics and ecosystems of coastal-lagoon systems between Abu Dhabi and Ras al-Khaimah. In fact, local lagoons have undergone significant changes due to urban expansion involving land reclamation initiatives along the coast to expand coastal areas, including the construction of artificial islands and the consequent changes in circulation and reduction of mangrove forests. The lagoon of the Emirate of Umm al-Quwain (UAQ), thanks to the slower rate of urban sprawl and limited land reclamation operations, still preserves an extensive mangrove ecosystem, pristine landforms, and almost unspoilt tidal dynamics. For that reason, it constitutes the ideal context for a geomorphological assessment based on a combined multi-temporal remote sensing (from 1968 to 2023) and field validation approach, aimed at achieving a deep understanding of the formation and dynamics of tidal-lagoon and coastal systems and landforms. Furthermore, a detailed geomorphological reconstruction of specific sectors of the UAQ lagoon traced its evolutionary history, informing interpretations of past human communities' adaptation strategies and resource exploitation patterns.

Relationships between fluvio-lacustrine landscape, human occupation and historical earthquakes: a multidisciplinary study of the Santa Gada archaeological site (Pollino Geopark, southern Italy)

Keywords: geoarchaeology, archaeological excavation campaigns, Pollino geopark.

Recently, a multidisciplinary working group started an archaeological survey campaign in a wide sector of the Mercure-Lao River valley, southern Italy, which discovered an important archaeological site (i.e. the Santa Gada site) with evidences of a large settlement dated between the 6th and the 3rd centuries B.C. Apart from the extraordinary richness of the archaeological remains, the Santa Gada site is of particular interest from a geological and geomorphological viewpoint. It is located within the Pollino UNESCO Geopark and its setting shows a strong relationship with peculiar landscape elements. The study area is located in a Middle Pleistocene tectonic basin of the axial zone of the southern Apennines, Italy, filled by a thick fluvio-lacustrine succession. The landscape is featured by different orders of SSO-dipping low-angle surfaces that are separated by rectilinear scarp of variable height. Preliminary archaeological data highlight a close connection between these landforms and settlement patterns and a possible influence of destructive earthquakes on the sudden abandonment of the site. To solve this issue, geological and geomorphological investigations were mainly focused on the definition of the possible tectonic origin of the scarps. Indeed, although the border of the Mercure basin and, more in general, the Pollino area are featured by the presence of impressive Quaternary faults with clear geomorphic and structural evidences of a long-lasting tectonic activity, no significant seismic events are reported in the historical records. Strict relationships among fluvial landforms, active faulting, and settlement evolution have been investigated by the integration of geological, geomorphological, and geophysical data. Archaeological data revealed the sudden abandonment at the end of the 3rd century BC of a vast residential complex. The morpho-genesis of landform elements, the role of major faults as seismogenic sources, and the relationships between landscape and settlement location were discussed in the context of the long-term landscape evolution of the study area. The settlement was built up on the top of a fluvial terrace and is bounded to the north by a morphological scarp. Our investigations suggest a fluvial origin of the morphological scarp of the study area and a possible role of important seismogenic sources of the Pollino area for the sudden abandonment of the site.

Coastal erosion in urban areas and socio-environmental challenges: the case of São João da Barra, Rio de Janeiro, Brazil

Keywords: rivers, costal erosion.

Coastal erosion affects several beaches worldwide in association with natural and human pressures, especially in urban areas. In recent decades, the coastland of São João da Barra city – near the Paraíba do Sul River delta - has been recognized as one of the main areas that suffer from this geomorphological process. Furthermore, the scientific literature, even if scarce, has pointed out that these dynamics are causing negative socio-environmental responses and making the area less resilient. In the last few decades, urban structures have become debris due to erosion caused by sea ingression, triggered by the coupling of environmental processes and dynamics occurring at different spatial and temporal scales. Therefore, the present research aims to analyze how the recent geomorphological changes on the coast of São Jão da Barra have become a socio-environmental challenge on the spatial planning, arising from the problem of coastal erosion. For this, anthropogenic pressures in fluvial-marine dynamics and multi-scalar (space and time) environmental factors are addressed to analyze this problem and propose possible mitigation solutions.

Urban geomorphology and geostructural aspects of Pozzuoli, southern Italy

Keywords: urban geomorphology, coastaland, Phlegraean Fields.

The geomorphology and geostructure of Pozzuoli, in the active Phlegraean Fields volcanic area, are related to anthropogenic changes that occurred since 2200 years BCE. Late Quaternary pyroclastics from ~50 volcanoes, among which those of the last eruption of Monte Nuovo (1538 CE), modified the coastland through emplacements of deposits dislocated by volcano-tectonics and bradyseismic phenomena, forming the marine terrace of La Starza, 30-80 m a.s.l., on which the city partially founds. Despite the uplift of ~1.2 m since 2005 with daily earthquakes up to magnitude 4, in the long period, the lowering of the bay submerged the Roman age ruins of *Baie* down to ~6 m of depth.

The recent crisis modified physiography and littoral dynamics, controlled by marine waves and currents, triggering the seabed emersion and beach progradation. As a consequence, since the uplift acceleration of 2015, several buildings were damaged, slope gradient and runoff altered and the risk of flash floods increased, depth diminished and port accessibility reduced, new sandy beaches developed and others enlarged, and many underwater gas emissions transformed the mobile marine substrate into a softer and more erodible seabed. Mitigating these effects seems hard work, while urban structure adaption is a possible alternative.

Hiking trails for discovering the geomorphological heritage: fruition and related hazard, risk and impact scenarios

Keywords: geomorphology, hazard, geoheritage.

Valorization of the local geoheritage is even more realized through thematic trails and paths (such as geotrails, glaciological trails, etc.) (Brandolini & Pelfini, 2010) supported by in situ or virtual informative materials (Perotti et al., 2020). These cultural routes in different kind of environments (natural, urban) often follow existing marked trails, or paths, with observation points. accessible in different ways and addressed to diverse audiences, ranging from the general public to students. Originally designed for hikers, these trails are now being adapted for e-bikers and e-mountain bikers as well (Senese et al., 2023). Geocultural trails may be located in diverse morphoclimatic environments, some of which exhibit high geomorphic dynamics that could pose hazards and risks to visitors and the geo-cultural sites themselves (Bollati et al., 2019) Additionally, tourism pressure may impact on geosites and related trails, accelerating their degradation and erosion. This study presents findings from prior research and new data regarding the interplay between geoheritage promotion and hazard-risk-impact scenarios, along with strategies aimed at mitigating tourism vulnerability. Specifically, it presents: i) results related to hazard census affecting trail networks in select mountain and coastal areas; ii) analyses of the path characteristics that are influenced by active geomorphological processes, affecting usability and user vulnerability; iii) analyses of the tourism-induced erosion on trails and, iv) a discussion on the importance of dissemination, including simplified thematic maps to highlight path features and geomorphological elements along the trail. Keywords: geoheritage, anthropic geomorphology, geoscience.

Human activities affected geomorphic processes in all climatic contexts for millennia, resulting in several landforms directly and/or indirectly related to anthropogenic processes (Brandolini et al., 2020). Vice versa geomorphic processes and consequent natural hazards have wide impacts on the humankind, on infrastructures and human economy (Alcantara-Ayala, 2002), also affecting cultural and geological heritage (Pelfini & Bollati, 2014). Some environments are more sensitive than others to human action, requiring risk mitigation strategies and geoconservation initiatives when the vulnerable element is represented by geological and geomorphic heritage sites (geosites and geomorphosites). Since geodiversity bears witness to the evolutionary history of our planet, it is essential to safeguard geosites as elements of a territory's cultural heritage. For example, high mountain and coastal areas are particularly sensitive environments to geomorphic dynamics and climate change, and in both cases human interventions lead to erosive geomorphic processes. The GEOTRes project intends to propose a new holistic approach by investigating the close correlation between human activities and natural geomorphic processes in various morphogenetic and morpho-climatic contexts, on a selection of Alpine (Valtellina, Valle Anzasca, Val di Cogne, Val d'Ossola) and coastal areas in Northern Italy (Monte Portofino Promontory). Planned activities include the analysis of geomorphologically sensitive areas, the assessment of risk scenarios and the formulation of strategies for geoheritage conservation. This will be achieved through a multidisciplinary approach combining traditional survey methods, analysis of historical archives and innovative remote sensing techniques. The results, presented through thematic maps, will be available for territorial management and valorization, especially of nature reserves and geoparks, for which valorization can represent an economic resource, and to assist public administrations in the management and valorisation of geo-cultural heritage, helping to mitigate the vulnerability of tourists and hikers through training courses and environmental information on the territory.

Keywords: historical analysis, geomorphological evolution, river management.

Climate change in recent decades is resulting in the increase of extreme events that often represent a risk for the population. In alluvial plains, among the most densely populated areas on the planet, frequent floods are increasing the instability of the riverbanks and promoting episodic or progressive changes in river morphology. The most significant risk in these areas is represented by the river system dynamics and their inadequate management.

This work aims to investigate the historical geomorphological evolution and the present evolutionary trends of the valley portion of the Serio River (Lombardia, Italy) - ~ 80 km long - in order to propose a sustainable management of its river corridor. We investigate the active channel dynamic since the mid-1800, and the possible future river evolution. We focus on (i) channel width changes, (ii) variation of channel morphological configuration, (iii) bank erosion rates, and (iv) bed level changes. Analyses were based on multi-temporal mapping of the active channel from historical maps (since 1889) and orthophoto (from 1954 to 2021) in GIS environment (with higher temporal resolution over the last 25 years); multitemporal DTMs and topographic cross sections comparison and field surveys.

Results show that multi-channel reaches are the most dynamic, they narrowed from a maximum of about 350 m in 1954 to a minimum of about 130 m in 1988, with decrease in braiding index. By the 1990s alternated phases of widening and narrowing (between about 10 and 40 m). Single-channel reaches - where the morphology configuration did not change over time - narrowed from a maximum of about 80 m in 1954 to a minimum of about 35 m in 1975. Starting from 1988 single-channel reaches did not exhibit significant variations over time, with maximum widening and narrowing of about 15 m. Correspondence between the widening and the occurrence of flood events was observed. The high river dynamic process results in bank erosion, that locally affects more than 40% of the banks (up to 95%). Bank erosion rates, calculated over the last 15 years at the reach scale, range from a minimum of 0.3 m/y to a maximum of 2.7 m/y. Analyses of bed level changes reveal widespread incision along the river, up to about 3 m.

The final outcome was the delineation of (i) the corridor of historical channel shifting, starting from the multi-temporal active channel mapping, and (ii) the future potential erosion areas, estimated by calculating the bank retreat rates. The combination of these two areas allows to define the erodible corridor area, the area where future channel dynamic is expected.

Future work, which includes the definition of a sustainable river management plan that mitigates geomorphic risks and improves the morphological state of the river, aims at the recovery of the Serio River channel within the erodible corridor area.

The contribution of toponyms to geomorphological hazard: hillslope processes and landslides highlighted by the Italian Military Geographycal Institute maps at 1:25.000 scale

Keywords: geomorphological hazard, toponyms, historical maps.

Toponymy is a linguistic discipline, which has already been used as a tool for geographical studies not only in Italy, but also in international contexts.

Geographical studies have already classified the toponyms in main categories (Arca, 2004): physical geography, human geography and socio-economic geography. By selecting the place names connected to physical geography, we study those suggesting the presence of landslides or hillslope processes (Guimbatan-Fadgyas, 2021).

We focused on the Italian Military Geographic Institute maps at 1:25.000 scale, edited between 1936-1939 and related to a pilot-area in the Basilicata, Campania, Emilia-Romagna, Liguria, Piemonte and Valle d'Aosta region.

The place names tied to landslides or hillslope processes have been compared with the IFFI project (Italian Landslide Inventory), carried out by ISPRA and the Regions and Autonomous Provinces, which supplies a detailed picture of the distribution of landslide phenomena within Italy.

Terms attributed to the forms of soil erosion that trigger geomorphological hazard have been identified. If the frequency of terms such as "sasso" and "pietra" (to which "creta" with its derivatives should be added) spread throughout the country shows pathologically favorable situations for erosive action by exogenous agents, emblematic of the calamity represented throughout Italy by landslides are the terms "lama" with all its derivatives: lavina, lavanga, calanca, diroìta, rovina, ravina, motta e smotta, sciolle.

Frequent slope gravitational processes are identified by the terms: macereti, ghiaioni, brecciai, boe, mare, lama, calanchi, forra. In many parts of the territory, localities with place names related to the terms "campo" or "piano" are highlighted, clearly aimed at associating a form of the flat landscape on slopes ascribable to ancient and relict landslide deposits. Other terms linked to landslide are "moggia", "liggia" or "crosi" and similar, which respectively mean swampy deposits, landslides or gullies.

The comparison with the IFFI project gave satisfying results: we found a good correspondence between names and natural hazard.

The use of toponyms allowed a geographycal interpretation of the slope dynamics and it suggests a possible use of toponymys in land planning activities (Planas-Batlle et al., 2023).

Keywords: Portofino Promontory, historical toponyms, hydrogeomorphological features

The analysis of toponymy provides keys to understanding the nature of the territory, revealing information on environmental and anthropic aspects and their evolution over time. This research identifies, classifies and discusses toponyms related to the geomorphological nature of Monte di Portofino, which extends over about 20 km2 in the eastern sector of Genoa. In particular, toponyms related to land morphology, orography, springs and surface dynamics were identified: coastal erosion, landslides and floods. Cartographic research was based on the 1:25.000 scale maps of the Italian Military Geographical Institute (1878-1939) and the Region of Liguria (1994), and the 1:10.000 scale Regional Technical Map (1984-2010). Historical maps from the end of the 18th and beginning of the 19th century (Matteo Vinzoni's Atlas and Minute di Campagna degli Stati Sardi di Terraferma) and the 1:2.000 cadastral map of 1966 were also analysed. Toponyms associated with the physical-geographical nature of the territory account for about 50% of the total, with an average density of 2 toponyms/km2. Toponyms associated with land morphology (e.g. Punta Chiappa, Pietre Strette, Poggio), land use (e.g. Fogliasso, Costasecca, Prato), and hydrography (e.g. M. Pollone, Cala dell'oro, Fosso dell'Acqua Viva) have been identified.

Other toponyms are indirectly linked to physical-geographical features and concern meteo-hydrological elements and vegetation and settlement patterns.Some toponyms are linked to the geo-hydrological hazard of the territory, both from landslides (e.g. Scogli Grossi) and from flooding (e.g. Fosso dell'Alluvione) and have proved useful within the Horizon 2020 Reconect project (Regenerating ECOsystems with Nature-based solutions for hydro-meteorological risk rEduCTion). In fact, the comparison with basin master plan provided encouraging indications, making it possible to verify a correspondence between toponyms and hydrogeomorphological conditions, confirming the usefulness of the use of toponymy in the field of land and city planning.

Analysis tools for supporting the exploitation of MTInSAR products in monitoring landscape evolution

Argentiero I.*[1], Bovenga F.[1], Borrelli R.[2], Massimi V.[2], Nutricato R.[3] & Nitti D.O.[3]

[1] Istituto per il rilevamento elettromagnetico dell'ambiente, CNR, Bari. [2] Planetek Italia s.r.l.
[3] GAP s.r.l. Bari.

Keywords: MTInSAR, tool, instability phenomena.

Multi-temporal SAR interferometry (MTInSAR), by providing both mean displacement maps and displacement time series over coherent objects on the Earth's surface, allows analyzing wide areas, identifying ground displacements, and studying the phenomenon evolution at a long-time scale. The analysis of MTInSAR-based displacement time series can provide useful information for long-term monitoring, management, and risk assessment at the regional level, when combined with planning tools, and support decision-makers at a local level in risk management. This analysis can be complicated due to the amount of data and, for this reason, it is essential to identify tools to accelerate the investigation of MTInSAR products.

This work presents the results obtained by using analysis tools of MTInSAR data in Rheticus® Safeland, developed by Planetek Italia, which provides prevention and mitigation services of land instability hazards. We tested two tools (density and distribution tool) aimed at assessing the reliability of the information provided by MTInSAR products and two automated procedures (Fuzzy Entropy indicator, FE, Nonlinear Trend Analysis, NLTA), recently developed (Bovenga et al., 2022; Bovenga et al., 2021; Refice et al., 2022), for the identification of a smaller set of coherent targets (CTs) showing nonlinear displacement trends related to instability phenomena.

The density tool concerns the percentage of surface of the study area covered by CTs. The tool combines the satellite geometry defined according to parameters coming from the MTInSAR processing (i.e. LOS direction and orbital state vectors), and the ground geometry obtained by exploiting geomorphic information (i.e. the average slope, the prevailing exposure, and the surface area). The distribution tool evaluates the spatial distribution of CTs: the velocity values derived from a dense spatial distribution of CTs covering uniformly the whole study area are more reliable than those derived from a few sparse targets.

The FE index is able to recognize displacement time series characterized by strong non linearities and jumps related to phase unwrapping errors, which should be corrected before further analysis. The NLTA, based on the Fisher statistics, allows classifying targets according to the degree of a polynomial function, which optimally describe the displacement trend.

Density and distribution tools were successfully exploited for assessing the reliability of the data provided by MTInSAR products, and, based on this, for identifying areas where the actual displacement is properly represented by MTInSAR data. FE and NLTA were very effective in supporting the analysis of ground displacements provided by MTInSAR, since they allow focusing on a smaller set of CTs corresponding to unstable areas or structures on the ground. Consequently, the integration of these tools within Rheticus® Safeland increases the level of information for users, who may respond more effectively to their needs.

The isoradiometric shoreline extraction method as a proxy for Medicane impact quantification: a case study of Bals event along the Sciacca coast (southern Sicily)

Keywords: remote sensing, medicane, shoreline dynamics.

The increase in the frequency of extreme weather events due to climate change is well known. Within the Mediterranean basin, a primary climate hotspot according to Giorgi (2006) and Trincardi et al. (2023), a rise is recorded due to the occurrence of Medicane, cyclones with characteristics comparable to those of tropical ones. These have a significant repercussion on the coastline evolution and pose a challenging task for coastal management. In this frame, remote sensing techniques could play a key role in shoreline dynamics analysis, enhancing earth observations through time series.

Here we propose the application of an Isoradiometric shoreline extraction Method (IM) (Maltese et al., 2023; Maltese et al., 2024) performed in the frame of the activities related to the development of Foglio n. 628 Sciacca, surveyed through the ongoing 1/50k geological mapping (CARG Project). In particular, we extracted the coastline of the Sciacca coast before and after the Medicane Bals that hit western and southern Sicily in November 2021. The research aims to compare the retrievals of two different near-infrared spectral bands, acquired by two optical sensors onboard Planetscope and Sentinel-2 satellites, with a spatial resolution of 3 and 10 m respectively. This method, with an accuracy of approximately one-third of the spatial resolution of the satellite products, allows us to distinguish the areas from which sediment has been removed from areas where it has instead been deposited, also allowing us to estimate the amount of material mobilized. This methodology has been applied along the coast of Sciacca (southern Sicily) in a sector about 40 km long with an alternation of wide beaches and rocky coast.

The results obtained demonstrate that IM has good performance for coastline extraction and coastline variability analysis so, by using this method, it is possible to estimate the impact of these extreme events. Moreover, this approach could be useful in preparing recovery plans that anticipate the interventions in Medicane occurrence.

Systematic monitoring of river landform evolution across scales: from localized change detection to catchment connectivity

Keywords: sentinel 2, network scale, river geomorphology.

Satellite imageries are starting to become for geomorphologists a new tool to monitor medium-large river dynamics at a high revisit time (i.e., from weekly to daily). The Sentinel 2 mission, in particular, provides a multi-spectral image of the Earth surface at 10 meters resolution every 5 days (cloud cover permitting). Machine learning algorithms can then classify automatically these images, discriminating those river macro-geomorphic features, i.e., water, sediment and vegetation classes, that describe how a river responds to different hydrological and sediment supply impulses, under specific boundary conditions. As part of the IRIDE project (ESA-founded), we used state-of-the-art algorithms to automatically detect and delineate rivers geomorphic active channel (i.e., a combination of water, exposed sediment and newly grown vegetation on sediment bars) across the Po River Catchment, in the Northern Italy. The active channel is divided into 500 m long sectors and the information about water, sediment and vegetation areas detected each month within each sector is systematically stored. This discretization of the river network allows analyses across scales, aggregating the information for single geomorphic units, such as sediment bars, up to catchment scales. This data can then be used, for example, to monitor changes of secondary channels or sediment bars around the removal of localized river infrastructures (such as river groynes), or to quantify the dynamics of different river types (e.g., braided vs sinuous river reaches) in response to seasonality or external drivers such as floods or droughts. Such systematic, uniform information across a whole hydrographic network and the associated monitoring of its geomorphological dynamics from upstream to downstream can eventually provide insights on the river sediment (dis)connectivity and identify hotspots of incoming long-term river morphological changes; an information that is key for a more informed river management.

A newly developed Shoreline Extraction tool from satellite imagery: case studies in Sicily (Central Mediterranean region)

Keywords: shoreline extraction tool, FAIR principles, geosciences.

The recent development of the remotely sensed shoreline extraction technique improved investigations about Shoreline Change Analysis. These techniques, allow to quantify the recent coastal landscape evolution and facilitate inferences about its main driving forces, climate changes, tectonics, and anthropic processes improving and providing critical information for forecasting future coastal landscape scenarios for better coastal management and mitigating the natural hazard linked to erosion processes.

Here, we propose the use of a newly developed Isoradiometric shoreline extraction Method (IM) which allows delimiting the shoreline with subpixel accuracy using optical satellite imagery, and the production of time series (Maltese et al., 2024; Maltese et al., 2023).

Such a tool, was designed, tested and validated through a GNSS-delimited shoreline from field surveys on three sandy beaches in Sicily (Central Mediterranean), and was then applied on over than 60 km of Sicilian coastline using up to 40 years of freely available satellite products.

The tool is designed to be released in the frame of the Geosciences IR - National Recovery and Resilience Plan (PNRR) and will respect the FAIR (Findable, Accessible, Interoperable, and Reusable) data principles of the Research Data Infrastructures (RDIs).

The proposed shoreline extraction tool could represent a valuable task for coastal management and coastal erosion risk detection and mitigation and could also support researchers in data management and collaborative analysis.

External forcing on drainage divide evolution in rifted margins: case of Madagascar

Clementucci R.*, Uchusov E., Willett S. & Wang Y.

Department of Earth Sciences, ETH Zurich, Switzerland.

Corresponding author email: romano.clementucci@uniroma3.it

Keywords: landscape evolution, quantitative geomorphology, numerical modelling.

The landscape of Madagascar is characterized by tilted western plateau and two main topographic scarps on the western and eastern margins of the island. Generally, the western side, the topography is characterized by relict relief and a highly sinuous plateau edge. Conversely, the landscape on the eastern side is dominated by the great escarpment with a linear plateau edge. His simple morphology is locally perturbed by the formation of the active Alaotra-Ankay rift and emplacement volcanic complexes during the Cenozoic. These active processes control the rates of topographic changes and drainage divide location and may indirectly, promote the evolution and diversification of endemic species (*e.g.*, Liu et al., 2024).

Here, we explore the long-term relief and drainage divide evolution of the different morpho-structural domains of Madagascar. Although western and eastern margins display distinct topographic patterns and a general long-term westward divide motion driven by the the retreat of the eastern great escarpment, we observed a discrepancy between Gilbert-metrics and χ-metric in diagnosing the mobility of drainage divides in Central and Northern Madagascar. This discrepancy arises when tectonic processes and volcanic activity influence the topography and control the position of the drainage divide.

To test the hypothesis that late Cenozoic activity controls divide mobility, we conducted numerical modeling simulating a double escarpment retreat, focusing on the evolution of a divide-type and knickzone-type margin. We provide insight into the processes that lead to transient landscape and relief evolution of rifted margins and rejuvenated plateau landscape.

Keywords: Ofanto, connectivity, index.

This thesis work applies a geomorphometric analysis aimed to the monitoring of surface processes within a hydrographic basin. Specifically, the area of interest is the catchment of the Ofanto River, the most important river of the Puglia region.

The analysis is based on the computation of the sediment connectivity index, which describes sediment pathways from the upstream to downstream, estimating sediment erosion and transport on the surface, and the sediment supply to the hydrographic network (Zingaro et al., 2020). In particular, the Sediment Flow Connectivity Index (SfCI, Zingaro et al., 2019) has been calculated using a quantitative approach applied through Geographic Information Systems (GIS). The aim of this method is twofold: (1) to provide a detailed description of surface processes influencing the conformation of the hydrographic basin and (2) to analyze the interaction between these processes in order to understand the evolution of the catchment.

This approach is particularly relevant in the context of river monitoring in the Ofanto basin, as it improves the understanding and the management of hydrological and geomorphological risks, by allowing the application of SfCI in the analysis of other surface phenomena such as mass movements and the displacement of archaeological evidences useful in landscape archaeology investigation (Zingaro et al., 2023).

Keywords: multiscale geological datasets, WebGIS, Interactive visualization.

Recently, the necessity to show data and charts referring to different scales and representations, thematic maps to link laboratory data, 3D or AR digital twins in conjunction with spatial analysis have become increasingly common. In all of these cases, it is necessary to contend with different paradigms of representation and well-differentiated information technologies in order for users to visualize and interrogate data on the web.

The aim of this contribution is to identify a methodology for publishing multiscale data on a website without using external providers. With a serverless approach, it is possible to generate easy-to-publish webGIS from geological surveys, 3D models, UAV surveys, and microstructural image analyses. The proposed methodology is developed with popular JavaScript libraries such as: Bootstrap and JQuery for layout, OpenLayers and LeafLet for geodata, THREE.Js for 3D models and Chart.JS for advanced features of microscale data. Through some purpose-built algorithms in Python, which can also be used on Qgis and ArcGIS, pre-configured HTML5 files can be generated for a quick publication on a blog or website.

The case study of the Palmi Shear Zone (PSZ) has been considered a good test site since it is amply supplied with ready-to-use multiscale data. The PSZ is characterized by the occurrence of mostly sub-vertical lying meso-Alpine mylonitic rocks well exposed due to continuous coastal erosion. The outcrops are scattered over a 400 m wide, 1500 m long area. The Ulivarella stacks, consisting of an alternation of mylonitic rocks formed at the expense of metasomatic metacarbonates, paragneiss and tonalitic granitoid rocks intruded by pegmatites, are the most iconic outcrops of the PSZ. Despite the good exposure, the kinematics of this shear-zone still remains controversial (Ortolano et al., 2020), also due to the formation of a complex sheath-folding system.

The main goal achieved with this methodology was to establish a standardized practice for the increasingly independent use of external services for multiscale data publication, from UAV surveys up to the digitized microfabric analysis of suitably oriented thin sections (Visalli et al. 2021).

As a result of this methodology, the role of the geoscientist and digital cartographer remains strategic throughout the data publication process to ensure an effective dissemination of results.

Corresponding author email: alok.kushababa@iusspavia.it

Keywords: sediment connectivity, NDVI, land use changes.

Land cover is a key factor in controlling surface sediment dynamics. Geomorphological processes such as sediment erosion, transportation and deposition are strongly conditioned by land cover type, which controls sediment production and mobility on the earth's surface. To analyze sediment connectivity through different indices and models, land use and land cover data are the significant variables. However, it should be considered that land cover changes can impact these processes, especially if they occur over a short period. In the present study, we analyzed the land cover changes in three different hydrographic river basins, such as Severn in the United Kingdom, Vernazza in northwestern Italy and Lama Camaggi in southern Italy, concerning their sediment connectivity patterns, as described by the Sediment flow Connectivity Index (SfCI) in previous works (Zingaro et al., 2019; Zingaro et al., 2020; Zingaro et al., 2023). The main focus of the study is to evaluate the land cover changes in sediment connectivity analysis by using a multispectral index. In particular, we have computed the normalized difference vegetation index (NDVI) in each study site through sentinel-2 multispectral datasets, considering the time frame from a reference year and the last year (2023). The results revealed the variations in NDVI values, highlighting land cover changes over a short period in many parts of the basins. Also, the integration of NDVI in SfCI on sediment mobility can affect sediment connectivity patterns. The use of NDVI can improve the analysis of sediment connectivity by providing more dynamism in the description of sediment pathways on both spatial and temporal scales. The present experimentation gives new insights into considering surface cover changes in SfCI contributing to updating the algorithm and investigating the possibility of its enhancement.

Keywords: sediment connectivity, geomorphology, landscape archaeology.

Geology and Geomorphology are essential for landscape archaeology to understand the relationship between the environment and human activities. Integrating geomorphological analysis in archaeological investigations could increase the capacity to identify the archaeological sites and to improve the reconstrucion of the historical landscape (Cremaschi et al., 2018; Herz & Garrison, 1998). The experimental application of sediment flow connectivity index (SfCI) in landscape archaeological researches is proven to be useful to recognize, monitor, and interpret the historical evidence in the evaluation of surface processes that condition landscape evolution (Zingaro et al., 2019; Zingaro et al., 2023).

This work describes the investigation applied in the basins of Lama Misciano and Lama Balice (area of interest, AOI) in the Apulia region (southern Italy), characterized by the presence of archaeological evidences found on the surface during inter-site field survey in 2023-2024 years. In particular, the research is aimed to evaluate the influence of the geomorphological processes (erosion, transport and supply of sediment) in surface displacement (and visibility) of archaeological record. Assuming that archaeological material, brought to the surface, can move as the sediment following runoff processes and then be deposited (on the surface or in alluvial or colluvial layers) or continue to move following the dynamics described by the sediment connectivity index, the SfCI was computed in AOI and the corresponding maps were compared with the archaeological evidence documented on the surface. The results show (1) the correlation between areas of medium-high sediment connectivity and areas with archaeological occurrence (i.e. surface findings and the archaeological site of Misciano that is characterized by the presence of a church with cemetery dated to 6-10th century); (2) the location of archaeological record on sediment paths defined by SfCI. This analysis demonstrates the contribution of SfCI in landscape archaeological investigations for the capacity of the index to identify surface processes that may potentially affect the readability of the archaeological records supporting data interpretation. These results confirm the advantage of applying an interdisciplinary approach in archaeology and opens innovative research scenarios

Keywords: provenance, source-to-sink analysis, long-lived knickpoints.

An increasing number of source-to sink studies exploit the sedimentary archive to constrain landscape evolution and its response to tectonic and climatic forcing. Within this framework, sediment yield variations and quantitative analysis of fluvial topography are often independently used to detect major river capture events and episodes of drainage re-organization. The source-to-sink system of the Golo River, the largest catchment of Corsica, provides a well-established test-case for this kind of studies, where some authors have focused their attention on the onshore part of the system during the late Quaternary, and others have focused their attention on the offshore sink and highlighted major variations in sediment yield during the late Pleistocene and the last glacial cycle. In this study, we expand the analysis of the river network of Corsica back to the Miocene, and we provide evidence of major river capture events affecting the former Paleo-Ostriconi River in the late Neogene (Malusà et al., 2024). We document the impact of river piracy on offshore sedimentation and use a dataset of *in situ* ^{10}Be cosmogenic analysis on river sands to analyze the influence of disequilibrium inherited from river capture on pattern and rates of Holocene erosion.

Our results illustrate how the landscape of Corsica has reacted and is still adapting to the disequilibrium caused in the late Miocene by the uplift of Alpine Corsica. Tectonic uplift pushed the drainage divide, originally located on Variscan Corsica, eastward and generated a linear, fault-controlled valley that hosted the north-flowing Paleo-Ostriconi River. The landscape responded to the uplift via multi-stage river capture, and the divide eventually migrated back to the west to again become largely fixed on the resistant Variscan spine. In this framework, ~1300 km² of basin area originally draining towards the Ligurian Sea were abruptly connected, since the Pliocene, to the base level of the capturing Tavignano and Golo rivers. This led to the formation of a large Pliocene-Quaternary submarine fan offshore the Tyrrhenian coast, associated to an increased sediment yield that was three times greater than the average sediment yield in the same source-to-sink system during the Holocene. Concentrated erosion persists today around long-lived knickpoints that are still moving through the drainage system after millions of years. Our results demonstrate that a full consideration of landscape response times to onshore disturbances is a prerequisite for any reliable interpretation of the offshore sedimentary archive.

Malusà M.G. et al. (2024) - Impact of river capture on erosion rates and offshore sedimentation revealed by geological and *in situ* ^{10}Be cosmogenic data (Corsica, western Mediterranean). Earth Planet. Sci. Lett. (in press).

How long does the signature of tectonic events last in the landscape? Topographical analysis of Jebel Akhdar dome and surrounding Semail Ophiolite in the Al-Hajar Mountains (northern Sultanate of Oman)

Earth's surface undergoes significant modifications due to tectonic events, which occur at different spatial and temporal scales with various deformation magnitudes and rates. Surface processes respond to these topographic modifications, striving to achieve a state of equilibrium. Active tectonic processes leave intense signals on the landscape, and, after their cessation, the responses become more litho-structurally and climatic controlled. Thus, understanding the overprint of tectonics on the topography and the preservation of this record is crucial to comprehend and describe how surface processes shape landscapes.

Morphometric analysis and field survey were employed to investigate the Jebel Akhdar dome (JAK) and surrounding ophiolites in the Al-Hajar Mountains (Sultanate of Oman). This orogenic belt, located in the NE-Arabian plate, is renowned for hosting the Semail Ophiolite, one of the most complete obducted ophiolite sequences globally (Searle, 2007). The obduction occurred during the Late Cretaceous, resulting in the emplacement of ophiolites over JAK autochthonous units, composed by pre-Permian sedimentary and volcanic sequence and Permian-Late Cretaceous carbonate platforms. The Late Cretaceous and subsequent Cenozoic tectonics have resulted in the doming of JAK and the deformation of its rock sequences by predominantly transtensional structures (Searle, 2007). Field survey shows that river networks, structural elements, and karst systems heavily influenced the topographic evolution. This has been confirmed by morphometric indices, such as terrain ruggedness index (TRI), topographic position index (TPI), hypsometric integral (HI), and swath profiles. At regional scale, TRI, HI, and swath profiles show higher values for JAK and lower ones for Semail Ophiolite, emphasizing tectonic windows in JAK with intermediate-lower values. At a more detailed scale, escarpments, faults, and canyons are underlain by differences in values of TPI and TRI. In this way, morphometric results permit to quantify the topographic evolution, suggesting the influence of multiple factors at the local scale, including litho-structural setting, karst, (neo)tectonic activity and base-level variations. The combination of field observations and geomorphometry permits to understand the evolution of the topography, controlled by litho-structural setting, that played an important role in the drainage and karstic network development, leading to the formation of narrow and incised canyons in JAK, and larger and dendritic valleys in the Semail Ophiolite. Furthermore, the results indicate that the regional landscape evolution may be influenced by ongoing geological processes, such as uplift related to rebound processes of the Arabian crust, overlapping the offshooting effects of JAK doming and orogenic collapse that have not yet reached a topographic equilibrium, while the Semail Ophiolite may have reached equilibrium because not involved in the doming processes.

Sedimentary successions record the evolution of palaeogeographic domains and orogenic systems, which can be described referring to a sequence of Geologic Events (GeoEvents). The GeoEvents are preserved in the stratigraphic record in different ways, such as, unconformities, distinctive lithofacies, chronostratigraphic gaps, condensed successions, hardgrounds, paleoescarpments etc. The recognition of the GeoEvents gives a chance to correlate tectonic and paleoenvironmental processes at large regional scale across sedimentary basins and coeval orogenic belts (Piana et al., 2017; Mantovani et al., 2020). The GeoEvent concept is one of the main cornerstones of the Geologic Feature classification in the IUGS GeoSciML and INSPIRE (Data Specification on Geology) standard for geology, so it should drive the organization of the Map Legend and the design of the DataBase structure of the modern digital geological maps. The GeoEvent class has a specified geologic age and may have specified environments and processes. Even though the GeoEvent age can represent an instant in time and/or an interval of time, the GeoEvent approach can allow correlation between rock units of different geological domains, even if they were subjected to different, post-depositional, tectono-metamorphic conditions. Some examples of geologic correlation across the successions of syn-orogenic sedimentary basins and those scattered in coeval, adjacent orogenic belts are given, and a discussion on the scientific consistency of this approach is proposed.

In the study of ground instability phenomena, geo-spatial methods are widely used through per-pixel analysis of post-event images and cluster analysis of pre- and post-event images by applying a variety of machine and deep learning techniques to assess hazard connected to gravitative processes.

In particular, the deep learning approach with the U-net architecture (Ronneberger et al., 2015) has been widely used for landslide mapping, proving to be a fast, powerful and accurate tool for segmentation of landslide bodies even in complex detection conditions and in poor data scenarios (Nava et al., 2022). This model has been trained on large landslide dataset consisting of 3799 files, from the Iburi-Tobu Area of Hokkaido in 2018, Kodagu District in Karnataka in 2018, Rasuwa District in Bagmati in 2015, and Western Taitung County in 2009 (Ghorbanzadeh et al., 2022). Each file containing 15 data matrices 128x128 pixels, where first 12 matrices are for Sentinel-2 satellite spectral bands, matrices 13 and 14 represent the slope and the elevation derived from Digital Elevation Model (DEM) of ALOS PALSAR satellite mission. The matrix 15 is a landslide presence/absence map (i.e. a binary map in which a "0" value indicates the cell where a landslide is not present while the "1" value identifies the cell where a landslide is present). In this work, we present a test of first semi-automatic segmentation system to identify active landslide bodies. The main aim is to evaluate the performance of the algorithm in areas of Italy, by applying automation techniques and artificial intelligence and image processing technologies. The methodology is based on two main steps:

1. The code implementation of the algorithm by using python programming language;
2. The application of CNN U-Net model to satellite data from multi-spectral Sentinel-2 images (as RGB images and normalized difference vegetation index maps) and morpho-topographic data (as slope and elevation) extracted from the Italian DEM TinItaly 1.1 (Tarquini et al., 2023).

The model was tested in sites particularly exposed to hydrogeological instability in order to explore the capacity of the system to recognize active landslides triggered by extreme rainfall events. In particular, two areas were selected:

1. the island of Ischia (central Italy), located in the Tyrrhenian Sea;
2. part of Emilia-Romagna region (north central Italy), located in Po River Valley.

The predictions obtained showed a good performance of the U-Net model which proves to be suitable in the identification and segmentation of landslides in test areas, despite a lower accuracy (reaching 52%) than in the training phase (exceeding 82%) probably due to the lack of available data on geological setting that affect the optimization of the pre-trained model. The present research provides a useful contribution for future advances in the development of alert systems in landslide risk management.

Keywords: Geomorphological mapping, GIS, Geomorphological risk analysis.

The drafting of geothematic cartographies is part of the Integrated Territorial Information System, which provides knowledge of the territory from a lithological, structural and morphological point of view representing a useful tool for land use planning.

Over the years, various mapping projects have enabled to uniform cartographic representation using a nationally interpretable language (the CARG project is an example) .

Nowadays, a new approach to geomorphological mapping with "full geographic coverage" becomes part of the tools for geomorphological risk assessment, management, and mitigation for proper land-use planning. Compared with the "traditional" cartographic approach, it does not involve the use of symbols and colors for the representation of morphogenetic data, but rather polygonal and point vectors. This new approach allows no point or areal to be missed during the interpretation process and each element to be discretized, providing a complete and dimensionally correct representation of the complexity of the physical landscape (landforms, deposits and processes) at different scales.

In order to support the visual inspection activities for digitize the morphogenetic features, data were collected and information layers were processed using GIS software. Starting from IGMI (Italian Military Geographic Institute) topographic base, the methodology involved the integration of various layers including orthophotos, hydro-geomorphological data, digital terrain models (DTM) (available at Integrated Territorial Information System - SITPuglia, see http://www.sit.puglia.it/portal/sit_portal) and LiDAR data. By exploiting the information contained in the terrain elevation, it is possible to derive, through GIS processing tools, maps of geomorphological indices to support the interpretation and mapping of landforms. Examples are the layers: (1) "hillshade", a raster that represents the surface using light and shadow, simulating a 3-D effect, and (2) "geomorphon", a raster that uses different classes (colors) to visualize the most common shapes of the landscape such as slope areas, flat plateaus, depressions, valleys, but also high points such as ridges and crests (Amatulli et al., 2018). Therefore, these layers play a pivotal role in delineating geomorphic-topographic units, contributing to the recognition of morphologies and enhancing comprehension of the morphogenetic mechanism that drive landscape dynamics.

In conclusion, these supporting elements are considered a key aspect of full-coverage geomorphological mapping, enabling the accurate discretization of landscape forms and processes by improving the assessment of geomorphological hazard and/or risk.

Fluvial record interpretation for the extraction of climatic and tectonic signals in the Adriatic Piedmont Zone of the Apennines (central Italy, Marche region)

Ruscitto V.*[1], Delchiaro M.[1], Della Seta M.[1], Gribenski N.[2], Richard M.[3], Iacobucci G.[1], Piacentini D.[1], Zocchi M.[1] & Troiani F.[1]

Keywords: low-rate tectonics, climate change.

Fluvial terraces serve as an important continental record, functional to understand the influence of tectonics, varying climate, and base level change on landscapes (Merritts et al., 1994). A well-preserved staircase of fill terraces is present in the Adriatic piedmont of the Apennines (central Italy), generated by the cyclical alternation of fluvial aggradation and incision over the Middle and Late Pleistocene, in response to the combination of low-rate tectonic uplift and climate changes. Compared to strath terraces the use of fill terraces for incision rate derivation is complex, due to their cyclical nature, but they remain a thorough record of incision and deposition that allows to derive interpretations about both tectonics and climate (Pederson et al., 2006). While the staircase has been already described at length with examples from numerous valleys of the Adriatic Piedmont (see Delchiaro et al., 2024), there is a necessity to expand its geochronological constraints, especially for the older terrace levels, to enable the acquisition of reliable climatic and tectonic signals from terrace deposits.

This study presents the analysis of sedimentological and granulometric characteristics of fill terraces within the Tesino, Aso and Tenna River basins in the Marche piedmont zone of the Apennines, and includes the differentiation and correlation of terraces, with systematic tracing of morpho-stratigraphic sections. This was made possible by integrating semi-automatically extracted data on the altimetric and along-valley terrace distributions, with geomorphological field surveys for the identification of the geomorphic markers. The semi-automatic extraction of the treads of the terraces allowed a preliminary level classification as a function of the terrace height above the modern channel thalweg, isolated with the support of Relative Elevation Models (REMs) converted from 1 m/pixel Digital Elevation Models (DEMs) collected from a 1x1 LiDAR dataset. Additionally, Infrared Stimulated Luminescence (IRSL) data on terrace chronology have been incorporated, providing geochronological constraints for the regional-scale paradigm of cyclical formation and development of Quaternary fill terrace staircases within the slowly uplifting Adriatic piedmont of the Apennines. The main phases of fluvial aggradation appear to coincide with colder periods, followed by river incision and floodplain-channel abandonment during inter-glacial periods. This validates previous results from the last fluvial aggradation-incision cycle (Late Pleistocene) and, furthermore, the results demonstrate the persistence of this same formation mechanism in the older (Middle Pleistocene) terraces. The use of a dated fill terrace staircase allowed the estimation of a Middle Pleistocene long-term bedrock incision rate ranging from 0.3 to 0.5 mm yr^{-1}, that agrees with earlier studies in the central-northern sector of the Adriatic Apennines (Sembroni et al., 2020).

Keywords: satellite imagery, multispectral analysis, GIS-based toolbox.

Multispectral satellite imagery is a powerful tool to drastically reduce geological survey time over large areas or to provide data from inaccessible localities. The images interpretation requires a preliminary accurate classification of reflectance of different rock-types. This can be obtained distinguishing on images the fresh rock outcrops from areas covered by vegetation, anthropic and soil. We here propose a GIS-based semi-automatic procedure for a rock-classification, including a first step to clean the images by the noise that mask the rock footprint and a second step to upgrade the resolution of the output.

We tested the method on satellite images of eastern Sicily, where large spectrum of lithologies, including sedimentary, volcanic and metamorphic rocks, are exposed.

The study was based on the free access Sentinel-2 imagery, covering the entire study region, with revisit times of 2-3 days. Sentinel-2 has 12 sensors, covering the entire light spectrum from ultraviolet to SWIR (Short-Wave Infra-Red), including four visible and near-infrared bands at 10 m resolution, six red-edge/SWIR bands at 20 m resolution and, finally, two atmospheric correction bands, at 60 m of resolution. The adopted source images, therefore, provide an opportunity to calculate the variability of reflectance values on the Earth's surface over a wide range of wavelengths, which is useful for discriminating the different footprint of rock outcrops.

To classify the rock types, we imported the images into ArcGIS Pro, where we used a new toolbox, developed by ModelBuilder, to clean up all the "noise" from the images, resulting in a residual that pertains only to rock outcrops. The method is based on comparation between the satellite images with a categorized ortophoto. To handle lightened output files, we performed the analysis on distinct adjacent 10 km2 wide areas. Within each of the selected areas of interest we create a point Shapefile which will be populated with 4 classes: Vegetation, Anthropic, Soil and Outcrops. This Shapefile will be used like a ROI (Region Of Interest) for a supervised automatic classification of the orthophotos of the area.

Once the pixels of the classified orthophotos have been sorted in the 4 classes of the ROI, we can exclude the 3 classes that are "noise" and obtain the residual pixel to refer as rock outcrop to relate to the reflectance values of the satellite images. The method requires that the cleaned orthophotos might be resampled at the same resolution of the twin satellite imagery, in order to minimize the errors, due to data missing or doubling. The pixels of our interest in the classified orthophotos were converted to point Shapefile that are populated with the reflectance value of the respective pixel taken from the multispectral imagery. With this methodology it is possible to select the actual values from rock outcrops, helping avoid errors in semi-automatic/automatic processes.

Unified Global Landslide Catalog - A single global-scale standardized landslide dataset

Sblano A.*[1], Mancino S.[1], Lovergine F.P.[2], Massimi V.[3], Capolongo D.[1] & Amatulli D.[4-5]

[1] Dipartimento di Scienze della Terra e Geoambientali, Università di Bari "Aldo Moro". [2] Istituto per il rilevamento elettromagnetico dell'ambiente, CNR. [3] Technical Manager, Planetek Italia. [4] School of the Environment, Yale University. [5] Spatial Ecology, 35A, Buckinghamshire, UK.

Corresponding author email: anna.sblano@uniba.it

Keywords: landslides, catalog, global.

Landslides are a serious threat to all communities due to their potential for property damage and loss of life. Triggered by different natural, climate and anthropic activities, their identification, monitoring and management is therefore very complex (Kirschbaum et al., 2010).

Mitigating landslide risk entails assessing the likelihood and consequences of landslides on communities through measures like land-use planning and early warning systems.

These proactive steps are essential for minimizing risk and protecting both lives and property from the impact of landslides (Gómez et al., 2023).

This study presents a single global scale standardized/harmonized landslide dataset, the Unified Global Landslide Catalog (UGLC), which can be a fundamental reference for land risk assessment and management (Virro et al., 2021).

The UGLC integrates multiple open-source landslide catalogs, and reports spatio-temporal data with landslides triggering factors. It is compiled from various sources including government agencies, universities, and researchers. Landslide occurrence data are collected from extensive field surveys, GPS data, GIS techniques, satellite imagery, and historical records.

The UGLC contains more than 1 million landslide events as point and polygonal data collected from circa 1700 to 2023, standardized according to 18 field attributes grouped into 7 categories, which are:

- UGLC Reference: uniquely identifies the event record within the new catalog;
- Source Reference: uniquely identifies the original event record from the source catalog, allowing record back-tracing;
- Spatial Accuracy: describes the spatial accuracy and geographic location of the event record;
- Temporal Accuracy: describes the temporal accuracy of the event;
- Geological Information: describes the geological characteristics of the area involved in the event and trigger information;
- Reliability: describes the inherent reliability of the record. The authors also intend to explore a validation method using radar data;
- Notes and information: additional information about the event, source links, authors, scientific publication, and other information.

The UGLC is intended as a robust dataset of standardized worldwide information on landslides. It will contain various types of data useful for global analyses and compensate for the shortcomings of small scale heterogeneous datasets. The objective is to provide a powerful, accurate, and user-friendly source for a global characterization of landslide occurrence. It will facilitate a deeper understanding of landslide phenomena in relation to the surrounding landscape, climate and impact on human populations and built environment (Kirschbaum et al., 2015).

Geomorphic signature of the eastward marching of Quaternary extensional tectonics in the Northern Apennines (central Italy): the Colfiorito intermontane basins key area

Silvani F.*[1], Melelli L.[1], Mirabella F.[1], Cardinali M.[3], Bucci F.[3], Santangelo M.[3], Pazzaglia F.J.[2] & Barchi M.R.[1]

[1] Dipartimento di Fisica e Geologia, Università degli Studi di di Perugia. [2] Department of Earth and Environmental Sciences, Lehigh University, Pennsylvania, USA. [3] Istituto di Ricerca per la Protezione Idrogeologica, CNR, Perugia.

Keywords: Colfiorito basins, drainage divide evolution, drainage anomalies.

The Colfiorito basins that defines the drainage divide in the Umbria-Marche region are a well-known example of syn-orogenic uplift, shortening, and extension of the Apennines. Detailed mapping and construction of a synthetic stratigraphic age model, along with a synthesis of related topographic and erosional features including drainage patterns, wind gaps, alluvial fans, and paleo-surfaces are used to model the processes and timing of drainage transformation and disarticulation from a transverse, east-flowing river system to an internal, subsiding, hanging-wall basins by an active, segmented, normal fault system. The Colfiorito basins are bounded to the east by the SW-dipping Mt. Le Scalette normal fault, which separates them from the Adriatic drainage headwaters of the Chienti river. The progressive eastward migration of the Apennine watershed (Alvarez, 1999; Della Seta et al., 2017) has resulted in the dislocation of part of the headwater area of a paleo-Chienti river catchment into a series of tectonic basins. Some of these basins are connected by wind gaps, paleo-river valleys in which the incising river is absent. Anomalies such as streams piracy, elbow deviations, fluvial inversions, and headward erosions occur along the westernmost basins, which have already been subject to fluvial capture by Tyrrhenian-draining rivers. Beheaded valleys are characteristic of the Adriatic-draining rivers paleo-channels at the intersection with major normal fault lines. The study employed quantitative analysis of the areal extent of alluvial fans and respective drainage basins, plotting the values on bi-logarithmic graphs. These fans, which are directly fed by mountain fronts, represent excellent geomorphic markers in karstic environments. Pleistocene alluvial fans, which are no longer related to current morphogenetic and morphodynamic conditions, exhibited significant catchment area deficits in comparison to the areal extent of the deposits and when compared with the trend of Holocene alluvial fans values. The presence of fluvial saddles in their headwater areas provided evidence of drainage inversions, which allowed for the reconstruction of a possible catchment delineation of a paleo-river with eastern drainage. WSW-ENE oriented swath profiles also support this reconstruction, highlighting remnants of faulted paleo-surfaces slightly inclined towards the E-NE, in agreement with the paleo-drainage trend.

Catchment-averaged denudation rates in the Northern Apennines and Ligurian Alps and implications for landscape dynamics

Vance G.*, Clementucci R., Picotti V. & Willett S.D.

Department of Earth Sciences, ETH Zurich.

Corresponding author email: gabrielle.vance@erdw.ethz.ch

Keywords: terrestrial cosmogenic nuclides, drainage reorganization, Northern Apennines.

In tectonically active areas, faulting and uplift lead to drainage reorganization. The Northern Apennines are an active orogenic wedge, where horizontal shortening and topographic advection lead to river capture and drainage divide migration. In contrast, the adjacent Ligurian Alps are a remnant of the Alpine orogen with little modern deformation. In this study, we combine geomorphic and stream profile analyses with 10Be-derived denudation rates from river sediments to quantify landscape dynamics in both orogens. Geomorphic metrics are asymmetric across the main drainage divide and associated divide asymmetry indices suggest main drainage divide migration from the Ligurian coast to the Adriatic Po Plain, accompanied by river captures. In the Northern Apennines, this suggested drainage divide migration direction is towards the NE, opposite that of the horizontal tectonic advection of topography. Geomorphic metrics show greater contrast across the main drainage divide in the Northern Apennines than in the Ligurian Alps. Our results allow us to quantify horizontal tectonic advection of topography and drainage divide migration. These quantitative constraints on landscape evolution help us assess how drainage divides evolve and provide insights into tectonically driven drainage reorganization, which may have important biodiversity implications, e.g., influencing the intraspecific genetic diversity of endemic riverine fish.

Deep learning to automatically map braided palaeochannels from optical traces in the Venetian - Friulian Plain (NE Italy)

Vanzani F.*[1], Carbonneau P.[2] & Fontana A.[1]

[1] Department di Geoscienze, Università di Padova. [2] Department of Geography, University of Durham, UK.

Corresponding author email: federica.vanzani@phd.unipd.it

Keywords: geomorphology, deep learning, alluvial plains.

In the past 10 years, the rapid rise of deep learning algorithms such as Convolutional Neural Networks (CNNs) has dramatically transformed the field of remote sensing studies. Deep learning algorithms have been successfully adapted with the aim of classifying, mapping, and quantifying various geomorphological processes. At the same time, the increasing number of available remote-sensed data has encouraged significant advancements, particularly in alluvial plains geomorphology. Alluvial plains are mainly the product of fluvial systems but in many regions, as in Europe, the anthropogenic activities have significantly altered the original setting since ancient time. Generally, one of the key operations for reconstructing the evolution of these plains involves the recognition of optical and/or topographic traces related to abandoned paleochannels. An example is evident in the Friulian Plain (NE Italy) showcasing an abundance of braided palaeohydrographic traces related to LGM (Last Glacial Maximum, 29-19,000 years BP) rivers which drained glaciers in the Alps. Despite being widespread, the overlapping urbanization and complex cropland patterns, hinder any efforts to manually map them. In this work, we took advantage of available high-resolution (1 m) aerial photos to build an Attention U-Net deep learning algorithm, training it to detect and segment palaeohydrographic traces. The model, consisting of more than 500,000 trainable parameters, required 24,800 images to train. On the test dataset we obtained a F1-score, which measures the performance in terms of both precision and recall, of 0.79, and the overall accuracy of the model was 92%. Afterwards, the trained model was used to automatically map more than 250 km2 of braided palaeochannels traces in the apical portion of the alluvial plain. This map represents the first step in classifying different geomorphological units, quantifying past fluvial processes, as well as characterizing LGM landscapes. Moreover, to assess the generalization capability of our model, we selected satellite data from two other areas in North Italy and one area in Montenegro which showcase similar braided paleohydrographic pattern. In each new case study, the braided pattern was successfully detected and mapped by the algorithm, despite local differences and diverse source datasets. This work highlights the breakthrough potential of these kind of state-of-the-art algorithms to rapidly detect and map complex geomorphological traces in intensely urbanized plains. At the same time, it also addresses the many challenges and limitations of applying AI methods in these environments. As one of the first implementations in the scope of palaeohydrography detection and mapping, we also aim to encourage scientists working on late Quaternary alluvial plains to take advantage of similar deep learning algorithms in their research.

Incision rates into Quaternary lava flows of the Middle Atlas and Western Mesta (Morocco): implications for landscape evolution

Keywords: incision rates, lava flows, Middle Atlas, Massif Central, morphotectonic evolution.

Understanding the rate of erosion plays a crucial role in characterizing landscape evolution and unravelling the relationships among tectonic activity, climate dynamics, and surface processes within active orogenic regions. Valley-filling volcanic rocks are valuable geomorphic markers for measuring fluvial incision rate and gain insight on the forcing mechanisms.

This study combines fluvial incision rates observed on dated lava flows within the valleys of the Moroccan Massif Central and Middle Atlas with geomorphic analysis using digital elevation models (DEMs). The findings reveal varying rates of incision, approximately 0.01 to 0.1 mm/yr for the Middle Atlas and the Massif Central, respectively. This spatial disparity aligns with geomorphic metrics, showing lower rates in areas of low relief and higher rates along more dissected margins.

Our analysis suggest that lithology and climate may not be the main determinants of spatial variation in incision rates between the Middle Atlas and Massif Central. Instead, surface uplift, possibly linked to flexural uplift of the Rif foreland and/or dynamic mantle-related processes, likely contribute to higher incision rates in the Massif Central.

Soil erosion assessment using the Revised Universal Soil Loss Equation (RUSLE) in Google Earth Engine in Bradano Basin

Keywords: soil erosion, Rusle Model, Google Earth Engine.

Because of the potentially disastrous effects that global warming may have on the environment, society, and the economy, the issue of soil erosion has drawn attention from all around the world. Erosion poses a major threat to the integrity of soil stability, and fertility. Ultimately, it will reduce land productivity, threaten food security, and result in socioeconomic issues.

Traditional field measurements of soil erosion are expensive and time-consuming, even if they are precise and dependable. Consequently, a lot of scientists are currently employing predictive models that use satellite data to estimate soil erosion.

In order to assess the issue of soil erosion, the RUSLE model can be employed. It requires input data from geophysical and meteorological sources, such as slope, topography, rainfall patterns, soil erodibility, vegetation cover, and land use, even at different scales, such as regional, national, continental, and global, in order to forecast the long-term average rate of erosion (Hateffard et al., 2021; Luvai et al. 2022).

The RUSLE model is widely recognized as the most appropriate for estimating surface erosion. In the present work, the model was applied to assess potential soil erosion in the Bradano basin, located in southern Italy, using data provided by the Google Earth engine. Recent decade (2013- 2024) data from the RUSLE model, evaluated with the Google Earth engine, indicate that soil erosion has posed a severe threat to 94.4 percent of the basin, 4.4% of which has very high potential, and less than 1 percent of which has moderate to modest potential of soil erosion.

Keywords: sea level rise, vertical land movements, Italy.

The coastal zone of the Italian region is highly exposed to multiple natural and anthropic hazards due to the ongoing sea-level rise triggered by global warming and land subsidence. Here we focus on the current and future relative sea level (SL) trends up to 2150 for this area which is affected by spatially variable rates of natural and anthropogenic Vertical Land Movements (VLM) (Anzidei et al., 2014). To estimate the current VLM rates we used geodetic data from about 27 years of continuous GNSS observations at a set of stations belonging to Euro-Mediterranean networks located within 5 km from the coast (Serpelloni et al., 2022), InSAR data from the Copernicus European Ground Motion Service (https://egms.land.copernicus.eu/) and additional InSAR data sets. Revised SL projections up to the year 2150 are provided for the entire coast and at the location of some tide gauges belonging to the PSMSL (https://psmsl.org) and ISPRA (https://www.mareografico.it/) networks, by including the estimated VLM in the SL projections released by the IPCC in the AR6 Report (www.ipcc.ch). Our results show that the current IPCC projections are often underestimated and not representative of the expected future sea levels since they neglect the effects of tectonics and local factors.

Here we show that revised multi-temporal sea level projections at 2030-2050-2100 and 2150 show significant differences with respect to those of the IPCC for different Shared Socio-economic Pathways and global warming levels (Vecchio et al., 2024). Finally, we present the first high resolution map of the expected flooding scenarios for 39 main coastal plains of the Italian region, based on the spatial analysis of LiDAR data available from the Ministero dell'Ambiente e della Tutela del Territorio. The geoprocessing analysis of territorial data highlighted that about 10.000 km2 are yet exposed to flooding risk, with enhanced impacts on the environment, human activities and coastal infrastructures. In this regard, land planners and decision makers should take into account these scenarios for cognizant coastal management and to support vulnerable populations to adapt to the expected relative sea level rise by 2150 and beyond.

Spheres vs. disks: real-time movement of pebbles in the swash-zone of coarse-clastic beaches

Bertoni D.*[1], Diana E.[1], Luppichini M.[1], Trembanis A.[2] & Sarti G.[1]

[1] Dipartimento di Scienze della Terra, Università di Pisa. [2] School of Marine Science & Policy, University of Delaware.

Keywords: gravel beach, sediment transport, pebble shape.

In the past few years several scientific studies have been carried out to increase the knowledge about coarse-clastic beaches (e.g., Soloy et al., 2022). The focus on such a peculiar environment was driven by the need to get more details about the processes working, as gravel and pebble beaches have been frequently used as a form of coastal protection. The Radio Frequency Identification (RFID) proved to be the most reliable technique to analyze transport patterns of tracers both in the long- (e.g., Allan et al., 2006) and in the short-term (e.g., Bertoni et al., 2024). The results from these studies identified many interesting transport trends, in particular if sorted by the shape of the pebbles. Indeed, the shape controls the movement of the tracers in short timespans (hours): spheres tend to roll down the beachface, disks move longshore. Questions arising: What process is responsible for this separation? Is that attained immediately after the injection of the tracers or after a while?

A series of very short tracking experiments have been realized to respond to these questions. Fifty pebbles were sorted based on their shape: half were spheres, half were disks. The pebbles (ca. 4-7 cm intermediate diameter) were collected directly on the beach to avoid differences with the native sediment. As the aim of the study was highlighting the early response of the tracers to swash-zone processes, we decided to use a drone in stationary flight (at an elevation of ca. 10 m) continuously filming the movement of the tracers in the swash-zone of a coarse-clastic beach at Marina di Pisa (Italy). This methodology allows to provide information about the movement of the pebbles from the injection position to the recovery position. The pebbles were painted with bright colors to improve their identification: red are the spheres, yellow are the disks. Each video is 15 minutes long and clearly documents the early stages of movement immediately after the tracer injection.

Data acquisition was carried out under different wave conditions, but never during high-energy events due to visibility limitations. The videos were post-processed to reduce vertical tilts, horizontal shifts, and camera rotations through software such as HandBrake, DaVinci Resolve, and Tracker. This way every movement of the tracers could be tracked and easily measured in accordance with the wave state at the time of the filming. The preliminary results show that the first uprush flows already are capable to move the spheres, which roll down the beachface; gravity facilitates this process too. Disks are less prone to early movement. When the waves are very low, the tracers do not move significantly: burying processes prevail as some pebbles disappear after just a few minutes. This study fosters the use of autonomous vehicles not just for topographic surveying activities.

Keywords: coastal erosion, coastal land use, DSAS.

Coastal zones are the most densely populated areas in the world and most of the human activities are developed here (i.e. transportation, manufacturing, energy production). As such, during the last decades, the rapid increase of population migration to the coasts has induced significant changes in coastal landscape and settings. For these reasons, understanding mid- and long-term past coastal changes and investigating coastal dynamics can support the increase of coastal community resilience and long-perspective coastal zone management and planning. The availability of free or low-expensive remote sensing data pushed forward the research on this field allowing the scientific community to seek a deeper comprehension of coastal geomorphological variations on a large or global scale (Paprotny et al., 2021). Even though global scale studies on coastal change posed the basis for identifying the main evolution trends worldwide, site-specific analyses, which also take into account local coastal behaviour, provide data and information for developing site-tailored strategies and actions for sustainablecoastal zone management. Indeed, coastal retreats are a long-term concern for coastal populations representing not only a risk for human life but also for compromising the environmental and socio-economic resources worldwide. Here, we present a combined methodology approach which couples shoreline change analysis with a detailed land cover/land use change pattern analysis along with the characterization of climate conditions. The Southern coast of Sicily (Italy) was chosen as the study case, due to the rapid population and urbanization growth which highly increased the pressures on rural and natural habitats leading to a significant change in the coastal landscape pattern. Moreover, this coastal area setting still maintains in some parts a natural geomorphological profile with a wide coastal wetlands system back to the dunes ridge and beaches thus providing a starting point for putting in place innovative coastal restoration strategies to increase the resilience of the coastal environment. The shoreline change analysis covered the period 1955-2022, the land cover/land use change analysis was performed by applying the Corine Land Cover of Coastal Zone (CLC-CZ, ref) nomenclature and codes to a 1966 map and by comparing these data to the 2018 CLC-CZ map. The analyses showed that significant coastal erosion occurred from 1955 to 2022 with negative rates up to -1.26 m/yr recorded at the beach of the touristic village of Granelli, which also underwent a significant land cover/land use change pattern passing from natural and semi-natural land cover/land use classes to artificial classes. Indeed, coastal behaviour is not uniform and the highest shoreline landward migration was registered in the correspondence of the most densely populated and urbanized areas, likely due to the reduction of inland sediment supply as well as to the decrease of the width and surface of dunes and beaches which act as buffers in responding more efficiently to landward shoreline migration.

Keywords: sea level rise, drone, coastal areas.

Global mean sea level (GMSL) is rising about 3.7 mm/year and by 2100 SL could be 1.1 m higher than the current level due to global warming (Fox-Kemper et al., 2021). Therefore, there is the need to understand the expected SLR scenarios for the next decades to mitigate the effects of coastal flooding, especially along the low-lying coastal zones which are the most exposed to SLR. In addition, increased frequency and intensity of extreme meteorological events that trigger high water levels, coupled with coastal erosion and saltwater intrusion into freshwater aquifers, are among the most critical environmental consequences of SLR (Cazenave & Le Cozannet, 2014).

Beyond the global SLR, local-scale assessment must include the contribution of vertical land movements (uplift and subsidence) due to natural and anthropogenic factors, that can produce significant local variations in relative sea levels. Therefore, the rates of VLM need to be included in SLR projections for accurate evaluation of the vulnerability of specific coastal areas exposed to flooding (Vecchio et al., 2023). To assess the impacts of sea-level rise triggered by ongoing global warming, we have conducted a thorough evaluation of the expected coastal flooding up to the year 2150 for the different sea-level rise projections released by the IPCC www.ipcc.ch in the AR6 Report. To this end, we included the current rate of local land subsidence (VLM), estimated via GNSS data collected by the available GNSS station located in the studied area. The assessment included high- and very high-resolution digital terrain and marine models extracted from topographic LiDAR data, photogrammetry surveys via UAV and high-resolution multibeam bathymetry. Through these efforts, we developed detailed multitemporal maps of expected inland extension of SLR for 2030, 2050, 2100, and 2150 of the three most exposed coastal zones of the Cinque Terre coast. The expected potential inundation scenarios, as well as in storm surge conditions, for return times of 1 and 100 years, were also modeled. In this work, we integrate ultra-high resolution digital terrestrial and marine elevation models obtained from state-of-the-art optical and acoustic sensing techniques framed within the National Reference System (RDN2008 and Italgeo 2005) on which we model relative sea-level rise scenarios according to the revised IPCC projections for VLM under ordinary and storm surge conditions. With these scenarios, there is an urgent need for adaptation strategies to address the social and economic losses due to the expected RSLR for this area.

A new isoradiometric remotely-sensed shoreline extraction method: a time series case study in southern Sicily (Central Mediterranean region)

Caldareri F.*[1], Balsamo L.[1], Parrino N.[1], Maltese A.[2] & Sulli A.[1]

[1] Dipartimento di Scienze della Terra e del Mare, Università di Palermo.
[2] Dipartimento di Ingeneria, Università di Palermo.

Corresponding author email: francesco.caldareri@unipa.it

Keywords: landscape evolution, remote sensing, isoradiometric method.

The recent development of remotely sensed shoreline extraction techniques significantly improved the understanding of the coastal Landscape Evolution (LE) supporting the management of the natural (e.g. climate change, tectonics) and anthropic processes shaping these areas. Improving our understanding of the past evolution could provide critical information for forecasting future coastal landscape scenarios for better coastal management and mitigating the natural hazard linked to coastal erosion processes.

Here, we propose a newly developed Isoradiometric shoreline extraction Method (IM) to accurately locate the shoreline using optical satellite imagery and for time series production (Maltese et al., 2023, 2024). We designed and tested our methodology along 10 km of sandy coastline in Sicily (central Mediterranean) and, subsequently, we applied it along 40 km of Southern-Sicily coastline. We extracted the shoreline using over than 40 years of publicly available satellite imagery, by also relating with rainfall and marine weather data. The IM application, characterized by a geometric accuracy of approximately one-third of the satellite product's resolution, allowed us to discriminate and quantify the coastal sectors affected by erosion and deposition processes.

Our results highlight that the IM by performing accurately for coastline positioning and coastal LE, could represent a valuable tool for coastal management and for the erosion risk detection and mitigation. Furthermore, relate the time series shoreline analysis to rainfall and marine weather data, could also represent a proxy for the quantification of the impact of extreme weather events which are increasingly affecting the Mediterranean region.

Keywords: rocky coast, cliff collapse, Camogli (Italia).

On 22 February 2021, a portion of the rocky cliff in the north-eastern sector of the municipality of Camogli collapsed. The landslide phenomenon involved part of the cemetery structures that stand on the edge of the cliff, causing international media attention.

Camogli is a renowned Ligurian seaside village of touristic importance, located about 20 km east of Genoa; its territorial layout reflects the main features of the high, rocky Ligurian and Mediterranean coastline.

The cliff is made up of rock masses belonging to the Mt. Antola formation: marly limestones and marls with siltstones and shales interlayers. It is an active coastal landform, i.e. currently shaped by the sea.

The layout of the coastline in a north-west/south-east direction is a predisposing factor in terms of slope instability, as it exposes the rocky scarp to the SW wave action ("Libeccio" auct.), which in extreme conditions can have heights of more than 5 m.

The structure outlined leads to a dynamic of the rocky cliff in substantial retreat: collapse phenomena, from the escarpment to the sea, occur annually; in January 2014, a phenomenon similar to the one under examination occurred between Genoa and Bogliasco.

The widespread urbanization that has taken place since the second half of the 19th century, first slowly, by infrastructure building, and then rapidly, through the construction of buildings with different purposes, has made this stretch of coastal strip at high geo-hydrological risk.

This research presents information on the historical, recent and current morphological dynamics of the Camogli cliff obtained through a multi-temporal analysis based on cartographic comparisons, topographic surveys and remote sensing activities.

Particularly meaningful was the survey carried out in 1915 along the coastal strip during the planning of the railway extension: a comparison of the position of the cliff edge in 1915 and in 2014, from another survey, revealed a retreat of up to 5 m.

Finally, a detailed, change detection analysis, carried out on imagery from the last 50 years testifies cliff evolution.

Analysis of coastal retreat and slope movements on rocky coastal cliff between Sori and Pieve Ligure (Eastern Liguria, Italy)

Faccini F.*[1-2], Ferrando A.[1], Picchio F.[3] & Scannapieco A.[4]

Keywords: cliff retreat, natural hazard, coastal monitoring.

About 80% of Mediterranean coasts are represented by the high rocky type, which is characterized by erosion phenomena; the cliff retreat rate is generally not constant due to the rock masses properties.

Ongoing climate change results in intensified hydro-meteorological hazards, including storm surges: the effect on high rocky coasts leads to significant energy impacts. This is evidenced in the Mediterranean area by the events that have occurred in recent decades, with often destructive effects on the coast, as in the case of Cyclone Vaia in 2018 and other storms that have affected the Mediterranean Sea in the third millennium (Borzì et al., 2024).

Also nationally, the coastal morphotype is about 2/3 high and rocky, for large stretches characterized by active geomorphological dynamics. In this area, in addition to the recognized hazard level, often related to different natural processes, high risk conditions are materialized too: in fact, the interaction of natural hazards with the presence and vulnerability of both strategic infrastructure, such as roadways and railway lines, and with anthropogenic activities and structures, such as buildings with different purposes, occurs.

This research shows the results of geomorphological evolution and monitoring activities of the high rocky coast between Sori and Pieve Ligure, less than 10 km from the city of Genoa.

The coastal sector under study consists almost entirely of cliffs, with small beaches at the mouths of streams (Provincia di Genova, 2004). The cliffs are shaped in the Mt. Antola Flysch, consisting of marly limestones, marls with sandstones and shales interlayers.

The cliffs are between 10 and 30 m high, in some areas more than 50 m; they are always active and have very steep gradients, sometimes they are vertical (Lucchetti et al., 2014).

Recent and current coastal dynamics were assessed both through original cartographic and photographic comparisons, and experimental surveys conducted by employing photogrammetric restitution techniques from aerial images taken by UAVs with the support of high-precision topographic measurements of known points on the ground and 3D surveys made by terrestrial laser scanners.

Keywords: storm surge, climate change, coastal vulnerability.

Climate and sea-level changes are some of the main topics mankind will have to face in the coming decades. This research focuses on an integrated approach based on using innovative modeling tools and technologies to estimate the effects of sea storms, whose frequency and magnitude are increasing due to climate changes, and sea level rise expected for 2150 on low-lying coastal areas. It is oriented to past storm surges, sea-level, and shoreline reconstructions to model future coastal changes driven by climatic forcing, taking into account anthropic impact and coastal subsidence.

Volturno coastal plain is one of the most populated coastal areas along the mid-Tyrrhenian Sea; it spans both sides of the namesake river and is the second widest river plain in Southern Italy. We will be monitoring this area as it is part of the PRIN project "GAIA", concerning the flood risk assessment of the most important plains and beaches along Italy's coastline.

The area is mostly exposed to meteo-marine forcings in the sector between 200 and 280 N°, therefore major storm surges registered by a near wave buoy were analyzed for this sector, to evaluate the coastal effect of the main flooding that occurred in the last 35 years. Peak Over Threshold (POT) methodology was used for this evaluation by considering events with a minimum significant wave height greater than the 90° percentile of total records and a duration of at least 12 hours. So obtained storms were divided into 5 categories, based on their energy index, and a frequency histogram was calculated for the obtained events to retrieve the return period referring to each category. A crucial step of this work was the calculation of shoreline movement trends, carried out in a GIS environment, for 3 zones: the northern sector, from Mondragone to Pescopagano, has remained stable over the last 20 years; the Volturno river mouth sector was strongly eroding before the year 2000, but this trend has inverted over the last 20 years thanks to the construction of two submerged breakwaters and substantial beach nourishment; the southern sector, from south of Pineta Grande to Lago patria, is substantially stable, slightly eroding with a rate of about 1,5 - 2 meters per year where the coastline is not protected by any breakwater.

Local basin authority reports classify this coastal area into four flood risk categories as a result of the combination of hazard level, erosion rates, and exposed value; flooded areas were evaluated as a function of wave runup and wave setup calculation for a storm surge with a return period of 100 years.

A similar approach was proposed to estimate how sea level variations will affect extreme events frequency and their impact: numerical modeling allowed the estimation of flooded areas, also taking into account sea level rise prediction reported by the IPCC in their last work. These refer to three different scenarios and provide, for each of them, the expected sea level rise, until the 2150.

Beach-dune systems in a transgressive domain along the Sardinian coasts

Fontolan G.[1], Bertoni D.*[2], Bezzi A.[1], Casagrande G.[1], Conforti A.[3], De Falco G.[3], Deiana G.[4], Orrù P.E.[4] & Simeone S.[3]

[1] Dipartimento di Matematica, Informatica e Geoscienze, Università di Trieste. [2] Dipartimento di Scienze della Terra, Università di Pisa. [3] IAS-CNR Oristano. [4] Dipartimento di Scienze Chimiche e Geologiche, Università di Cagliari.

Corresponding author email: duccio.bertoni@unipi.it

Keywords: coastal dunes, sedimentologic analysis, geomorphological survey.

Coastal transgressive dune fields represent an unusual state of the beach-dune system in current temperate zones. Knowledge of the factors responsible for the transgressive activation is a tool for inferring similar conditions in the past and evaluating the potential of sand drift re-activation in the context of climatic change. The sole examples of active transgressive dune fields in Italy are on Sardinia's west coast, due to conditions of strong unimodal wind from the north-west. In the context of a project funded by the Italian Ministry of University and Research (MUR-PRIN 2022), we present a series of preliminary results regarding the land-sea continuum of the coast of Piscinas (Sardinia, Italy), where an active dune field develops, covering 132 ha. The main aim is to investigate the role of transgressive aeolian episodes as potential environmental indicators as part of a larger understanding of their significance on a local and global scale.

The first results, regarding the Piscinas site, are based on a detailed geomorphological description obtained by UAV and GPR surveys, as well as a stratigraphic survey of the Pleistocene aeolianites outcropping along the coasts. On the continental shelf facing the study area, geophysical data have been acquired in the last 15 years, including high-resolution morpho-bathymetric surveys, acoustic backscatter maps, and high-resolution seismic profiles. The main parabolic dune, aligned with the prevailing Mistral wind (from the northwest), extends from the coast for about 2 km inland to a maximum altitude of 113 m. Topographic sections and GPR profiles show the presence of a geological control due to the gradually sloping Paleozoic rocky basement over which the dune accommodated while climbing. Buried post-LGM (Late Glacial Maximum) aeolian deposits of partially consolidated sands were also recognized. These sands represent the sediment layer of the established transgressive dune field and serve as the sediment source of the current active dune lobes, migrating downwind. Extensive outcrops of Middle and Upper Pleistocene aeolianites throughout the coasts attested to extensive aeolian activity in the context of sea level rise variation and tectonic stability in the past. A preliminary examination of the marine landforms on the inner shelf reveals the presence of parabolic bodies at a depth range of 31-40 m. These relict coastal landforms attest to an aeolian pulse affecting the exposed continental shelf during the LGM, as a continuum to connect with the analogous signature on land.

The integrated analysis using direct and indirect stratigraphic information collected in the coastal area will allow reconstruction of the depositional palimpsest and order of accommodation of several aeolian transgressive bodies during the transgression, highlighting possible differences or analogies between the current transgressive domain and the climatic phases that drove aeolian activity during the late Quaternary.

Analyzing coastal cliff stability and recession rates along the Safi Atlantic Coast, Morocco

Imam C.*[1], Chaibi M.[2], Ayt Ougougdal M.[3] & Charif A. [2]

[1] Department of Geography/GEGEL, Faculty of Letters and Humanities, Cadi Ayyad University, Marrakech, Morocco.

Keywords: coastal cliffs, recession rates, DSAS method, Atlantic coast.

Coastal cliffs play a crucial role in the stability and sustainability of coastal regions, having an impact on infrastructure, settlements and economic activities. Understanding cliff recession rates and the underlying factors that influence them is essential for effective risk management. This study examines the evolution of coastal cliffs along a 48 km stretch of the African Atlantic coast in Morocco, from Cap Beddouza to Jorf Lihoudi.

The instability of these cliffs presents significant geological risks, as evidenced by the various types of landslides along the coastal cliffs. These landslides cause the cliff tops to retreat, while the collapsed blocks at the base of the cliffs offer some protection. Using aerial imagery, in particular aerial photography from 1954 and orthophotography from 2020, and GIS techniques, we calculated the rate of change of cliff tops since 1954. Spatial assessments using statistical methods such as LMS (Least Median of Squares), LRR (Linear Recession Rate), and EPR (End Point Rate) were used to estimate rates of coastline change.

Our results show that most of the coastal area of the Safi region has experienced cliff recession, with rates varying between 0.07 and 0.04 m/year. The central part of the study area showed the highest rate of recession, exceeding 0.10 m/year. This spatial variability in recession rates is influenced by geological and morphological factors such as the composition of low-strength clay rock formations, which favour large-scale gravitational movements.

The results of the study offer new perspectives on coastal hazards in this densely populated region of Morocco. Cliff recession has a significant impact on economic, social and environmental risks in the region. In addition, this research represents one of the first applications of the Digital Shoreline Analysis System (DSAS) on an African coastline and provides new information on cliff recession rates in Africa.

Mediterranean Sea surface response during the cyclone events: mpacts on physical and biogeochemical parameters

Kushabaha A.*[1-2], Scardino G.[2-3], Sabato G.[2] & Scicchitano G.[2-3]

[1] Scuola universitaria Superiore IUSS, Pavia. [2] Dipartimento di Scienze della Terra e Geoambientali, Università di Bari "Aldo Moro". [3] Centro Interdipartimentale di Ricerca sulla Dinamica Costiera, Università di Bari "Aldo Moro".

Keywords: Mediterranean sea, cyclones, sea surface response.

The Mediterranean Sea is becoming a hotspot for intense tropical-like cyclones, called "Medicanes" (Scardino et al., 2024). The distinctive characteristics of the Mediterranean basin make it an important area of study for monitoring global environmental changes. Italy, Greece, and Malta perceive the most frequent cyclone landfalls among coastal regions and bear significant destructive impacts (Pytharoulis et al., 2018). However, the hazards associated with these events are escalating due to rapid urbanization, extensive socio-economic development, and global warming. Despite their advanced development, these regions remain susceptible to such disasters. The impact of cyclones, characterized by strong winds, heavy precipitation, and storm surges, leads to severe economic losses and casualties (Bakkensen, 2017). Consequently, this study aims to unveil the Mediterranean sea surface response during cyclone events, focusing on key variables such as sea surface temperature, significant wave height, surface currents, and the transport of dissolved nutrients influenced by upwelling processes triggered by these cyclones (Menna et al., 2023). Understanding these variables is essential for comprehending cyclones' complex dynamics and potential impacts on coastal geomorphology.

Ongoing vs. Holocene morphodynamic effects of sea-level changes: a new perspective for the assessment of coastal resilience to climate changes

Mattei G.* & Aucelli P.P.C.

Dipartimento di Scienze e Tecnologie, Università di Napoli "Parthenope".

Corresponding author email: gaia.mattei@uniparthenope.it

Keywords: climate change, resilience to coastal flooding, relative sea-level rise.

In the context of ongoing climate changes, low-lying coastal areas certainly are the most vulnerable to accelerated sea-level rise and increase in magnitude and frequency of storm events (Zhongming et al., 2022).

This study reconstructs the Late Holocene morpho-evolution and relative sea level (RSL) changes to predict future morpho-dynamic trends taking into account IPCC predictions and recent coastal subsidence in a mid-Tyrrehnian sector along the Mediterranean shores. A RSL geodatabase was compiled according to international standards from direct geoarchaeological measurements, stratigraphic and palaeoecological interpretations of new borehole data, and reinterpreting bibliographic information.

Based on the collected data, a first stage of accelerated sea level rise between 8.0 and 6.5 ka BP, was evaluated with a mean rate of 25 mm/yr, during which the plains in the study area were progressively flooded. During the second stage with sea-level rise rates less than 5 mm/yr, the coastal progradation prevailed. In particular, geoarchaeological data demonstrated that RSL rise in the last 2000 years was no higher than 0.55 ± 0.29 m MSL (Caporizzo et al., submitted). Presently, the RSL rise is accelerated by coastal subsidence between -0.58 ± 0.94 mm/y and -1.23 ± 1.53 mm/y (https://egms.land.copernicus.eu/) inducing a progressive reduction of the progradation trend toward a coastline equilibrium (annual variations of less than one metre).

A statistical approach was applied to this dataset to evaluate the coastal response of these low-lying sectors to past and future climate changes. Specifically, a three-step procedure was applied to data analysis. Firstly, we computed the curve of RSL change rates using the model "Errors in Variables Integrated Gaussian Process" (EIV IGP, Cahill et al., 2015) that performs Bayesian inference on the sea-level change dataset. Secondly, we dated the morpho-dynamic inversion from submersion to progradation that occurred in the mid-Holocene when the rate in sea-level rise globally decreased due to glacio-hydro-isostatic effects. Finally, we compared the local curve of RSL change rates with the RSL rise rates expected up to 2100 according to the three most probable IPCC scenarios (i.e., SSP2-4.5, SSP3-7, SSP5-8.5), by correcting them with recent local coastal subsidence. The probability of flooding reaches 100% for the worst SSP5-8.5 scenario for all the low-lying sectors. Instead, in the case of SSP2-4.5 and SSP3-7.0 minor likelihood of resilience was measured.

In conclusion, the potential resilience to the climate-driven effects of expected sea-level changes was assessed along the mid-Tyrrhenian coasts through the comparison between past behaviours, future RSL rise and present morphodynamics in terms of shoreline movements.

Keywords: Artificial Intelligence, marine conservation, litter detection.

This work presents cutting-edge research based on the application of artificial intelligence (AI), image processing, and computational intelligence methods to address the critical issue of marine and coastal ecosystem conservation, focusing on emerging and submerged environments.

Specifically for underwater debris detection, research is conducted using the ARGO drone equipped with onboard cameras and minimal computational resources for real-time data processing (Mattei et al., 2024). Central to the advancements is the ArgonautAI platform, which uses a distributed processing system on single-board computers, orchestrated via Kubernetes, to facilitate efficient marine debris detection. This setup enables real-time, accurate object recognition with minimal environmental impact, making it suitable for use in protected marine areas. Furthermore, the study incorporates image processing methods such as SeaThru for color reconstruction and SCOUTER (Li et al., 2021), a slot-attention-based classification, to improve the accuracy and explainability of underwater litter detection. In addition, a novel methodology that integrates Graph Convolutional Networks (GCN) with Explainable Artificial Intelligence (XAI) aims to significantly improve marine debris classification and provide transparency in the decision-making process of AI models.

Our research is dedicated to addressing the critical issue of beach debris management by applying state-of-the-art methods for detecting, classifying, and tracking debris. By integrating advanced technologies such as the SegmentAnything (SAM) (Kirillov et al., 2023) and the Vision Transformer (ViT) (Dosovitskiy et al., 2020), we aim to redefine the landscape of marine debris monitoring and conservation. These state-of-the-art algorithms enable us to achieve unprecedented levels of accuracy and efficiency in identifying debris in aerial drone imagery, facilitating targeted cleanup efforts and conservation initiatives. In addition to our focus on surface litter, we recognize the importance of exploring the underwater domain to gain a holistic understanding of litter distribution and dynamics. Through the use of optical flow techniques, we seek to meticulously track the movement of marine debris below the surface to shed light on its behavior and transport patterns. We are also actively involved in the development of advanced multi-object tracking algorithms tailored to the unique challenges of detecting and tracking moving debris in aquatic environments. These sophisticated algorithms allow us to monitor the movement of debris in real time, facilitating timely intervention to prevent further environmental degradation and protect fragile marine ecosystems.

The presented work aims to integrate these innovative methodologies to allow a synergy of work and research from the perspective of acquisition tools, data processing, and algorithms aimed at marine litter research, both emergent and submerged, and on beaches.

Keywords: coastal moprhodinamics, machine learning, remote sensing.

The coastline is a dynamic environment that is subject to continuous changes induced by natural and anthropogenic factors. Understanding these changes is critical for sustainable management of coastal resources. In this study, we propose a methodology for assessing coastal dynamics in the Mediterranean Sea by combining Sentinel-2 satellite images and storm surge data. Sentinel-2 images were used to extract coastlines using the open-source CoastSat library (Vos et al., 2019). Storm surge data from Copernicus Marine "Med-WAW: Mediterranean Sea Waves Reanalysis" was used to assess the influence of storm surges on coastal morphology. To access the remote sensing dataset, it is possible to take advantage of the free endpoint service offered by Google Earth Engine to automatically download a set of multispectral images from Copernicus Sentinel-2. Individual scenes were classified by a neural network using the Python library scikit-learn; for each pixel of each multispectral scene, four classes were defined: sand, water, white water, and others. In addition, the 3 × 3 variance of each pixel and spectral index made it possible to improve the classification (e.g., to distinguish sand from some types of roofs or terraces). A pretrained neural network was freely available by the CoastSat project (Vos et al., 2019). In a subsequent step, the boundary between sand and water was determined by applying an index called MNDWI (Xu, 2006), after using a super-resolution border segmentation (Cipolletti, 2012) algorithm is possible to obtain *iso-values* and coastline for each scene. Knowing the slope of the beach, it is possible to correct the derived position using astronomical tidal data. In cases where the retreats or advancement of the shoreline due to tides are largely less than the geometric accuracy of the data extracted from Sentinel-2 images, these corrections can be omitted. Several sections orthogonal to the coastline, called transects, are defined, for each of which a time series of the coastline's position along its development can be derived by intersecting the previously obtained data. The Copernicus Marine dataset "Med-WAW: Mediterranean Sea Waves Reanalysis" (EU Copernicus Marine Service Information, 2024) offers the possibility of hindcasting analysis of weather and sea conditions. Through correlation analyses with shoreline movement, it is possible to assess the presence of physiological response phenomena to storm surges using the coastal dune system. We then proceeded to extract the extreme marine events that characterized the investigated area in the chosen period using a threshold for the significant wave height VHM0 parameter. Thus, the temporal "list" of extreme events was obtained. For each of these storm surges, it is possible to investigate the morphodynamics of the coastline due to extreme events through comparison with the transect time series.

Keywords: deep learning, storm surge, coastal monitoring.

In recent years, the development of artificial intelligence and machine and deep learning techniques have attracted the attention of various research fields. Among them, the field of land and environmental study has seen some development in applications of this type by placing some interest in remote data acquisition, measurement of marine parameters and their automated analysis (Scardino et al., 2022; Sabato et al., 2023). This work focuses on the implementation of a deep learnig model based on Inception V3 capable of automatically measuring, after appropriate training, the height of tides and storm surge at a given site using fixed camera images. This solution is useful at sites where tide gauges are far from the measurement point and especially for calculating storm surge at the site of interest. The study was carried out on two different Italian locations, the first in southeastern Sicily, in the center of the Mediterranean and called Santa Lucia, and the second in the north of the country called Lignano Sabbiadoro. For convenience and better performance, the development environment was created on Google Colab. To train the deep learning model, a dataset of images was created for each site, and each frame was axed with the corresponding value measured by an in situ instrument. The dataset partitioning was done according to the literature, which as the best partitioning has 70% of the images used for Convolutional Neural Network (CNN) training and the remaining 30% for validation (Götz et al., 2022). Once the model was trained, prediction was performed on images of the site. The algorithm performed well with accuracy above 90% and Categorical Cross Entropy Loss less than 1. Confusion matrices also show good results and the calculated F1 score is above 0.9 (Huang et al., 2015). Finally, from the comparison of the actual values and those processed by CNN, it was possible to see that the values are very similar to each other and the corresponding time-sheets could be processed. In conclusion, the incorporation of systems such as the one presented in this paper could bring many advantages, such as having almost instantaneous feedback on the consequences from intense weather events and eliminating the need for in-person inspection by the operator. These findings underscore its potential to fill the data collection gap in challenging coastal environments, offering valuable insights for coastal management and hazard assessment. This study makes an important contribution to the rapidly growing field of remote sensing and machine learning applications in environmental monitoring, facilitating greater comprehension and decision-making in coastal areas.

On the resilience to climate change of sites of community importance (SCI): the case of Cala del Cefalo (Southern Italy)

Sorrentino A.*, Fasciglione G., Mattei G., Pappone G. & Aucelli P.P.C.

Dipartimento di Scienze e Tecnologie, Università di Napoli "Parthenope".

Corresponding author email: alessia.sorrentino001@studenti.uniparthenope.it

Keywords: climate change, coastal resilience, dune system evolution.

On sandy shorelines, coastal dunes represent a reservoir of sand for waves during storm surges. Storm-cut erosion and recovery is a normal coastal process, but, in the last centuries, human activities have altered this natural balance, making coastal evolution studies crucial for sustainable management of the coast, particularly in areas with a relevant role in naturalistic conservation.

The aim of this research is the evaluation of coastal changes that occurred since 1954 along the sandy stretch belonging to the site of community importance (SCI) "Spiaggia del Mingardo e Scoglio di Cala del Cefalo" in the Campania Region (Southern Italy). The area is part of the PRIN project "GAIA", concerning the flood risk assessment of the most important plains and beaches in Italy.

Through an integrated GIS/Google Engine analysis of topographic maps, aerial and satellite photos, and new high-resolution photogrammetric data, a retreating trend of both the shoreline and the dune system has been observed. Shoreline trends show that the coast has retreated about 82 meters since 1954. Still, it is important to underline that the erosion trend has significantly slowed down since the institution of the SCI.

Dune shows a similar retreat trend, quantified over the whole period, with a maximum of 78,5 m in the northern sector; the highest degradation has been detected between 1998-2006 and 2011-2016, witnessing the great erosive effects of the two storm surges occurred in 1999 and 2014. The great influence of storm surges on the state of conservation of the coast is testified by wash-over fans and strongly degraded vegetation cover.

The Normalized Difference Vegetation Index (NDVI) clearly shows an intense alteration of dune toe vegetation, deeply stressed out by the increasing frequency of significant storm surges. Numerical modelling testified that even storm surges with significant heights of less than 5 m and long peak wave periods can strongly impact dune toe stability and flood the backshore area. Another result is the estimation of flooded areas and the calculation of the run-up for high-magnitude storm surges, which goes from 3 m to 7,5 m.

The inversion of the dunal succession has been observed thanks to a floristic transect carried out along the main Natura 2000 pathway, with the secondary vegetation present up to the hind dunes and the salinization of an entire swath of vegetation. The progressive retreat of the dune can be also observed thanks to the presence of pines along the secondary vegetation line.

This work provides evidence of the high impact of storm surges on beach and dune environments, showing the importance of an integrated approach for the analysis of coastal dynamics in a fast-evolving world, where human presence could strongly interfere with natural processes. The potential erosion risk is crucial for correct coastal management which considers the expected increase in storm surge frequency and magnitude strictly related to climate change.

Coastal flooding risk scenario for the city of Grado, northern Adriatic Sea

Spadotto S.*[1], Fracaros S.[1], Bezzi A.[1], Casagrande G.[1], Popesso C.[1] & Fontolan G.[1-2]

[1] Dipartimento di Matematica, Informatica e Geoscienze, Università di Trieste.

Keywords: coastal flooding, storm surge, sea level rise.

Sea level rise, along with fast urbanization, has significantly raised flood hazards in coastal areas due to both increased population and the frequent urgent situations encountered in the urban context (Neumann, 2015). Rigid defensive systems along shorelines, backshore, and perimeter embankments at the lagoon border must therefore undergo structural verification and accurate elevation control, adapted to the expected sea level rise over which extreme events emerge.

In this regard, a thorough investigation was conducted on the city of Grado, located in the North Adriatic Sea and representing one of the most important coastline and heritage sites in Friuli Venezia Giulia. The city is located on a barrier island and is prone to flooding from both the sea and from the back lagoon.

The examination of the historical dataset of mean sea level and maximum levels recorded between 1991 and 2022 allowed us to first obtain local elevation estimates while also including subsidence. The study then looked at the duration of annual exceedance of the minimal threshold level of 110 cm, which marks Grado's first significant marine ingression. Annual extremes were then processed using the Gumbel-type distribution law (Gumbel, 1958; Coles, 2001), which modulated the level thresholds with their respective return times for the location. Finally, the reconnaissance includes a downscaling examination of the impacts on the urban fabric, which is divided into regions of different vulnerability. Inundated areas were compared from high-resolution DEMs using a GIS-based technique and a modeling approach utilizing MIKE software, analyzing both the magnitude and exposure of the urban setting to flood risk estimated for 2050 and 2100. As of today, approximately 56% of Grado's inhabited area is inundated with a sea level threshold value of 151 cm, which occurs during surge episodes with a 30-year return period. By 2100, with an optimistic forecast (SSP1-2.6) of local sea level rise of around +50 cm, the same threshold will be met with events with a 30 times shorter return time. As a result, by 2100, 56% of the land area will be submerged at least once a year due to 101 cm surges. Extreme levels linked with more catastrophic events with secular recurrence times will be achieved on a multi-year basis, flooding more than 70% of the urbanized area. This makes it more important than ever to develop proper adaptation measures from the outset. The simulations developed are thus essential for medium to long-term urban planning, with the goal of securing the city, which, like Venice, is indicative of the processes that may affect other coastal realities and historical cities of great national worth.

Keywords: sea level rise, DTM, Panarea.

The volcanic complex of the island of Panarea and the islets of of Bottaro, Lisca Bianca, Lisca Nera, Panarelli and Dattilo located in the Aeolian Archipelago (southern Tyrrhenian Sea), are undergoing sea level rise, variable land subsidence, coastal erosion and retreat of beaches and high coasts due to gravitational instability. To assess the expected coastal changes by 2150 according to the climatic scenarios reported in the AR6 Report of the IPCC (www.ipcc.ch), that predict a global sea level rise even more than 1 m, a detailed evaluation of the potential coastal flooding has been estimated in the frame of the PANDCOAST project, funded by the INGV.

Here we focus on the use of Unmanned Aerial Vehicles (UAVs) imagery combined with GNSS and high-resolution multibeam bathymetry data collected in different years for the generation of the very high-resolution Digital Terrain and Marine Model (DTMM) of the Panarea Island and its archipelago.

Scenarios are based on accurate high-resolution Digital Surface Models, vertical land movements and climatic projections released by the Intergovernmental Panel on Climate Change (IPCC) for the SSP2.6 and SSP5 climatic scenarios for this area, are used to map the expected multi-temporal sea level rise scenarios up to 2150.

In the analysis have been incorporated the effects of the vertical land movements (VLM) as estimated by local GNSS geodetic network located in the archipelago. Assuming constant rates of VLM for the next years, relative sea level rise projections provide values between 31±11 cm by 2050 and 104±27 cm by 2100 for the IPCC AR6 SSP8.5 scenarios and at 27±10 cm by 2050 and 73±24 cm by 2100, for the IPCC AR6 SSP2.6 scenarios, with small variations for the individual islets of the archipelago, depending on their VLM rates.

Moreover, detailed studies on Dattilo Island also show the importance of regional tectonic structures to enhance gradual island dismantling.

With the above scenarios, the low-lying sectors of Panarea Island and its archipelago are exposed to increasing coastal retreat that continuously threatens the stability of coastal areas (pocket beaches and cliffs) and local infrastructure.

Coastal hazard in tuffaceous high coast in the Gulf of Naples (South Italy)

Tursi M.F.*[1], Matano F.[2], Fortelli A.[2], Sacchi M.[2] & Aucelli P.P.C.[1]

[1] Dipartimento di Scienze e Tecnologie, Università di Napoli "Parthenope".
[2] Consiglio Nazionale delle Ricerche CNR, Napoli.

Corresponding author email: mariafrancesca.tursi@assegnista.uniparthenope.it

Keywords: high coasts, coastal hazards, Gulf of Naples.

Italy boasts numerous volcanic regions along its coasts. In these areas, scientific interest is mainly focused on volcanic and seismic hazards, while natural hazards related to landslide phenomena and coastal erosion suffer less attention from the scientific community. Therefore, this study aims to identify the main predisposing factors to landslide phenomena (rockfall/rockslide) in tuffaceous coastal cliffs in the Gulf of Naples volcanic area (Southern Italy), to evaluate possible relations between the different predisposing factors (e.g., weathering, geomechanical characteristics of the rocks, ground deformation, etc.), and the triggering factors (e.g., seismicity, sea storms, rain, temperature, etc.).

In this area, pyroclastic deposits and fractured volcanic tuff form the coastal cliffs giving rise to significant erosion and landslide processes, such as the large one that affected the right side of Miseno promontory on March 25, 2015. The event resulted in the detachment of about 90.000 m3 of material from the slope reshaping the morphology of the coastline.

In order to determine and understand the predisposing factors for the occurrence of these large events a multistep analysis considering different datasets was carried out. The analysis started with a comprehensive literature review to obtain information regarding the number of events that previously occurred in the area, followed by a thorough geological and geomorphological field survey to identify and map key indicators of slope instability.

In a third step, a meteorological database was used to obtain accurate measurements of various meteo-climatic parameters (temperature, rainfall, wind, humidity, atmospheric pressure), with a time-frequency of 10 minutes over a four-year period (2014-2017). In the following step, the analysis provided a comparison with UAV survey carried out in different parts of the coastal sector and to define the failure mechanism of the tuffaceous cliff, field data from meso-structural stations were selected since discontinuity systems characterizing rock masses play a fundamental role in predisposing rocky slopes to failure processes. Finally, the morphological changes that occurred in the area in the last 200 years were analysed, by using ancient topographic maps, observing that large landslide phenomena have already been reported in the area since the 17th century.

The results of this research provide important advances in the knowledge of coastal hazards in volcanic high coasts in the Gulf of Naples area, leading to an accurate zonation of these coasts *i.e.* the division of the coastal area into sectors, and the relative ranking according to degrees of actual or potential hazard of coastal landslide occurrence. In addition, the analysis of the correlations between the different influencing factors could prove highly valuable for early warning actions and policies, especially considering that it is a densely urbanized area.

The drowned physical landscape of Porto Cesareo coastal area (southern Apulia, Italy)

Vitale A.*[1], Sansò P.[1] & Giaccari E.[2]

[1] Dipartimento di Scienze e Tecnologie Biologiche ed Ambientali, Università del Salento.
[2] Il Dipartimento delle Culture Europee e del Mediterraneo, Università della Basilicata.

Corresponding author email: vitaleandrea@inwind.it

Keywords: LIDAR, collapse dolina, Salento.

The LIDAR survey of Porto Cesareo area (Ionian coast of southern Apulia) realized in the 2013 by Ministero dell'Ambiente allowed the morphology of the submerged physical landscape of this coastal area to be analysed in great detail.

As already surveyed by Sanso' et al. (2020), the present sea level reaches the outer margin of the lowest marine terrace, stretching from about 4 to -1 m above sea level. A submerged steep scarp divides this partly emerged terrace from a lower, submerged one placed stretching from -10 m to -26 m which roughly follows the present coastline. A wider marine terrace is recognizable at about 30 m of depth, bordered by two steep WNW-ESE trending scarps; as the higher one, also this surface shows a gently southestward dipping. The upper portion of the lowest platform has been surveyed at about 45 m of depth.

The LIDAR survey reveals a number of short river valleys which cut the scarp placed between the second and the third platform. More interestingly, a number of deep morphological depressions can be detected on the third platform; they cluster in an area close to the outer margin of the platform and in its northwestern sector. These depressions show a maximum length of 1250 m and the maximum depth from the marine surface of about 6 m.

These peculiar submerged landforms can be interpreted as collapse dolinas or bedrock collapse sinkholes (Waltham et al., 2005), similar to those ones which characterize the emerged part of this coastal area, locally named "*spunnulate*". The genesis of these landforms is due to effective solutional processes in the Pleistocene calcarenites. According to Bruno et al. (2008) solutional processes are related to the mixing of saltwater encroaching from the sea and fresh groundwater from the aquifer, that increases the aggressiveness and the dissolution capability of water. Furthermore, cavity roofs collapse may be also promoted by chemical and biological action at the surface due to the coastal swamp fauna and flora hosted in the topographic depressions which fill the surface karst features such as solution pans and grooves with soil and vegetation. This leads to three different types of erosion of the carbonate rocks: secretion of chemical substances, physical disintegration, and chemical processes caused by the decay of organic matter. These processes are responsible for the shaping of tabular cavities whose roof collapse produced subcircular, coastal lakes.

The morphological analysis of Porto Cesareo submerged physical landscape reveals that collapse dolinas similar to the present ones formed several time during the Middle – Upper Pleistocene underlining the necessity to achieve a better understanding of "*spunnulate"* genesis since they produce a significant geomorphological risk along this coastal area.

Characterization and use of biochar, a sustainable material, for water purification and carbon storage

Animali L.*[1], Corrado S.[1], Bartoli M.[2], Mitillo N.[1], Tuccimei P.[1] & Giorcelli M.[2]

[1] Dipartimento di Scienze, Università di Roma Tre.

Keywords: carbon, sustainability, water.

Biochar is the solid material obtained for the thermal decomposition of biomass through pyrolisis. Its production process allows concentration of carbon in a very stable form. It is therefore a viable mean of carbon storage to support green transition. Due to its physical and chemical characteristics it has also been proven to be compelling adsorbent for contaminants in aqueous solution, such as heavy metals. Despite its potential little data are available about application in real case studies. Moreover, such data are often related to biochar produced solely for the sake of research.

The project aims to innovate, employing a hands-on approach based on the usage of widely available commmercial biochars for water purification in real scenarios. Characterization of nine different biochars through routine and novel analytical techniques acts as a tool to point out benficial properties to the selected application (e.g., removal of heavy metals).

The case study concerns the Malagrotta landfill area in the Lazio region, central Italy. A chemical survey on surface waters has been performed to assess their quality and evaluate remediation potential through biochar usage. Testing biochar in real case scenarios allows assessment of real world performance, hence promoting a sustainble alternative to traditional activated carbon for water purification.

The use of raw materials and residues for the manufacturing of sustainable lime mortars

Arizzi A.* & Cultrone G.

Departamento de Mineralogía y Petrología, Facultad de Ciencias, Universidad de Granada, España.

Corresponding author email: arizzina@ugr.es

Keywords: lime mortar, raw materials, natural additives.

In ancient times, building systems and technologies were constrained mainly by the geographic situation, the climatic conditions of the area and the availability of the appropriate raw materials. Since the 20th century, almost all building materials are globally produced by means of contaminant industrial processes, whilst most of the natural and locally available raw materials have fallen into oblivion. Modern construction promoting the use of cement and synthetic polymer-based materials has become expensive for the society, unhealthy for people and contaminant for the environment. The environmental impact associated with the construction sector is high, especially if we consider that demolition and new construction still constitute a better economical option than rehabilitation. We believe that minimising the need for the production of synthetic and cement-based materials, replacing them with lime-based mortars is the initial breakthrough in sustainable construction.

Mortar is one of the most ancient and traditional artificial materials manufactured and used by man throughout history. A simple mix of three basic ingredients, binder (e.g. lime, gypsum), water and aggregate, gives rise to a huge variety of mortar types, due to the existence of binders and aggregates with different chemical, mineralogical and textural features. The variability of properties and characteristics typical of composite materials, achieved by adjusting the component types and proportions, is a distinctive feature of mortars, for example compared to natural stone or cob.

Despite lime has been largely neglected in the last century, in recent years its use is being recovered due to its unique properties: versatility, workability, breathability, low thermal conductivity, self-healing and durability, among others. As an additional strongpoint, using lime involves important environmental benefits, since it can be manufactured locally and on a small-scale (especially in specific cases such as developing countries, remote areas, and small local demand). Moreover, it is produced at lower temperatures with respect to other more common binders (e.g. cement), which implies less energy consumption, less pollution and reduced CO_2 gas emissions. Definitively, lime mortar is a versatile, traditional and sustainable building material. Even so, our commitment to sustainable development compels us to find even more sustainable solutions for the manufacturing and use of this material. To this end, we present the most recent investigations on lime pastes and mortars in which different kinds of raw natural materials and residues such as hemp shives, and waste shells of commercial bivalve mollusc species (as additives, admixtures, secondary binders and/or sands) have been used. The mineralogical and textural changes induced in the mortars by the use of these components are discussed in relation to their inorganic and/or organic nature, among other factors.

Application of pigmented geopolymers in Cultural Heritage conservation and aging studies on a geopolymer mock-up

Bertino A.*[1-2], Caggiani M.C.[1], Fugazzotto M.[1], Portale S.[1-2], Starinieri S.[3], Mazzoleni P.[1] & Barone G.[1]

[1] Dipartimento di Scienze Biologiche, Geologiche e Ambientali, Università di Catania. [2] Dipartimento di Scienze Umanistiche, Università di Catania. [3] Piacenti S.p.A., Prato.

Corresponding author email: antonella.bertino@phd.unict.it

Keywords: conservation, geopolymers, mock-up.

Geopolymers are inorganic products made from powders of various types, mostly alumino-silicate, mixed and dissolved in an alkaline environment (Leonelli & Romagnoli, 2013). These materials are undergoing rapid development at the industrial and commercial level in recent years, proving to be very promising. The versatility of geopolymers makes them suitable for various applications in a wide variety of fields, including Cultural Heritage. Studies attest their application on polychrome surfaces of historical value and artistic interest, with various functionalities (Barone et al., 2020; Fugazzotto et al., 2023). In the past few months, thanks to the collaboration with the conservation company Piacenti S.p.a, it was possible to carry out a conservation work on the mosaic apparatus of the Cefalù Cathedral, which entered the UNESCO World Heritage List (UNESCO World Heritage Convention) in 2015. This Cathedral is famous for its magnificent Byzantine mosaic, considered one of the most beautiful in Italy. Piacenti S.p.A, recently carried out an extensive conservation intervention on the *lacunae* of the mosaic apparatus, and in this context it was possible to test the feasibility of conservation interventions based on geopolymer *tesserae*. Several formulations of pigmented geopolymers were preliminarily studied in the laboratories of the University of Catania, with the aim to obtain materials suitable to the original ones. The slurries were synthesised by using commercial metakaolin as geopolymeric precursor and by adding different kinds of commercial pigments, in different percentages. After a multi-analytical characterization of the raw materials, the cured geopolymers underwent colorimetric analysis at regular intervals of time, chemical and physical stability tests, and were characterized through a combination of spectroscopic and diffractometry techniques. Promising results are registered, particularly in terms of pigment stability in geopolymers and surface homogeneity. Inspired by one of the many decorations of the Cefalù Cathedral, a mosaic mock-up was made entirely of geopolymer *tesserae* and exposed to natural weathering for six months. A study of the aging was conducted to test both its physical-mechanical stability and its aesthetic performance over time. At the same time, among all the pigmented geopolymer sets, for the *in situ* application it was decided to select those that, after a curing time of 28 days, presented color coordinates most similar to the original *tesserae*, in order to ensure a good aesthetic compatibility. Then, the selected pigmented geopolymer *tesserae* were applied, with the help of the restorers, on the original mosaic apparatus of the Cefalù Cathedral to replace missing original *tesserae*, with an excellent result in terms of aesthetic performance.

Role of the application method in the calcium phosphonate consolidation of pyroclastic rocks used in the environmental heritage

Brodu G.*, Murgia S., Norio N., Arca M., Aragoni M.C. & Columbu S.

Dipartimento di Scienze Chimiche e Geologiche, Università di Cagliari.

Corresponding author email: g.brodu@studenti.unica.it

Keywords: pyroclastite, silicate rocks, chemical treatment.

The various degradation processes affecting the geomaterials that make up the environmental heritage (historical and contemporary buildings) are usually due to their interaction with environment. Among the intrinsic features of materials, compositional and microstructural/textural characteristics can affect this process; in particular, porosity can increase the active surface. Due to their excellent workability, pyroclastites - volcanic rocks generated by explosive eruptions and consisting of a cineritic matrix in which crystal-clasts, pumices, cognate fragments, xenoliths and lithics are immersed - have been widely used as a building material. However, their high compositional heterogeneity results in a high porosity, especially in poorly welded facies which can reach up to 50 vol.%. Although pyroclastites feature a silicate composition, and are therefore more resistant to chemical alteration with respect to the carbonate rocks, they show low resistance to physical degradation. In this context, the study and research of new protective/consolidating agents capable of preserving this material, especially in the field of cultural heritage, become of fundamental relevance. So far, the progress made on the research of innovative consolidating agents has focused on lithoid substrates of carbonate origin (e.g., marbles, limestones, calcarenites, sandstones) (Columbu et al., 2017; Aragoni et al., 2021), while less has been done on pyroclastic materials.

In agreement with Norio et al. (2023), who focused on the protective/consolidating treatment of pyroclastites through the application by immersion of ammonium phenylphosphonate, in this study the implications of a possible method of field application (brushing) of the consolidant and the effect of an enrichment of the system with calcium ions are evaluated. In fact, although the results of Norio et al. (2023) shown that the treatment improves several physical-mechanical characteristics of the samples, the application of the consolidant by immersion is not feasible in situ. Regarding the new results, compared to the untreated samples, a decrease in porosity was observed (i.e.: -0.38% ΦO He, -0.43% ΦO H_2O), especially in the most altered samples. As compared to the samples treated by immersion, the open porosities to water and helium are larger in the brush-treated samples by 4% and 2%, respectively.

Lastly, the mechanical strengths measured by compression uniaxial tests shown a marked improvement (~22%) with respect to the samples treated by immersion-method, showing the positive effect of an addition of calcium ions towards the precipitation of calcium phenylphosphonate, thus favouring the consolidating action of the product.

Metakaolin - Blast furnace slag geopolymers as catalyst support for water treatment

Clausi M.*[1], Girardi G.[1], Savino S.[2], Manica M.[2], Attrotto R.[3], D'Accolti L.[2] & Pinto D.[1]

[1] Dipartimento di Scienze della Terra e Geoambientali, Università di Bari "Aldo Moro". [2] Dipartimento di Chimica, Università di Bari "Aldo Moro". [3] Dipartimento di Ricerca e Sviluppo, Acciaierie d'Italia S.p.A., Taranto.

Corresponding author email: marina.clausi@uniba.it

Keywords: geopolymers, blast fournace slag, catalysts.

Metakaolin-based geopolymers resulted promising support for heterogeneous catalysis finalized to the recovery of industrial waters (Clausi et al., 2023). However, for fulfilling the principles of *sustainability* ever more practices are necessary to support the efficient exploitation of natural resources and the conversion of wastes into resources.

This work is aimed at the study of geopolymer catalysts for wastewater treatments obtained from the partial substitution of a natural kaolinite clay with an industrial by-product, i.e. blast furnace slag.

To this purpose, a set of six different geopolymers was prepared using a heat-treated (700°C) kaolinitic clay and blast furnace slag in 1:1 ratio, varying the type of alkaline activator (NaOH or sodium silicate solutions) and the polymerizations modes. Porous geopolymer samples were also prepared using hydrogen peroxide (3 wt.%) as foaming agent.

A combination of characterization techniques (XRPD, FTIR, SEM-EDS) showed quite compact geopolymers microstructures, mainly characterized by N,C-A-S-H gels. Diffraction patterns showed the predominance of amorphous structures in which large humps, in the 20-35° 2θ range, were distinguished in addition to quartz, calcite and in some cases sodium carbonates. Samples showed a chemical and physical integrity after 10 days of soaking in water. Mechanical tests, performed on selected samples, achieved values ranging between 12 and 22 MPa.

Based on the obtained results metakaolin-slag geopolymers can be considered as promising supports in photo Fenton process for the removal of pollutants from water.

It is worth noting that the substitution of blast furnace slag to the clay, beside halving the use of natural resources and reducing the energy required for the thermal treatment of the clay, reduces up to 25% the consumption of alkaline activators.

Clausi et al. (2023) - Pollutants abatement in aqueous solutions with geopolymer catalysts: A photo fenton case. Chemosphere, 344, 140333, https://doi.org/10.1016/j.chemosphere.2023.140333.

The use of olive oil-modified geopolymers for municipal wastewater treatment

Cofano V.*[1], Clausi M.[1], Pannu D.S.[2], Mathew J.[2], Barkhordari D.[2], Khorshidi Nazloo E.[2], Santoro D.[2] & Pinto D.[1]

[1] Dipartimento di Scienze della Terra e Geoambientali, Università di Bari "Aldo Moro".

Corresponding author email: vito.cofano@uniba.it

Keywords: geopolymer, wastewater, depuration.

Municipal wastewater treatment plays a critical role in safeguarding public health, preserving ecosystems, and sustaining water resources. As the urban population increases, the volume of wastewater produced, laden with harmful contaminants to humans and the environment, also increases. Effective treatment processes are essential to remove pollutants, pathogens and nutrients from wastewater prior to its discharge into water bodies. In this perspective, absorption methods offer several advantages in water purification compared to conventional treatments and, in particular, activated carbon and geopolymers were found excellent sorbent for a a wide range of contaminants, including heavy metals, ammonium and organic pollutants, with respect to other sorbent materials such as activated alumina, zeolite, polymeric adsorbents, etc., which may struggle with selectivity, efficiency, or sustainability (Luukkonen et al., 2019). Activated carbon and geopolymers are both effective sorbent materials for wastewater treatment, each offering distinct advantages and limitations. Activated carbon, derived from organic sources, boasts a high surface area and pore structure, fostering high adsorption capacity for several contaminants. Its versatility and well-established performance in water purification processes have made it a stronghold in wastewater treatment over the years. However, activated carbon's higher cost and limited regeneration capabilities, pose economic and sustainability issues. Geopolymers are composed of inorganic precursors, possess adaptable properties such as porosity and chemical stability, making them efficient adsorbents. They can be tailored to specific treatment needs and may exhibit long-term durability in hostile environments (Amran et al., 2021). In this study porous geopolymers were engineered using hydrogen peroxide and a combination of hydrogen peroxide and olive oil. The materials underwent batch experiments in the laboratory to assess their performance concerning specific pollutants. Subsequently, their efficacy was evaluated in column studies using wastewater samples. Despite the use of vegetable oil for the preparation of porous geopolymers has been already documented in literature (Bai et al., 2016; Lertcumfu et al., 2020), the application of oil-modified geopolymers in wastewater treatment remains relatively unexplored. To ensure robust and reliable results, the synthesized geopolymers were systematically compared during the test with activated carbon, a well-established benchmark in wastewater treatment. This comparative assessment highlights the efficacy and potential of the geopolymers as a viable alternative to activated carbon in wastewater treatment applications. Such outcomes underscore the significance of this research in advancing sustainable and effective solutions for wastewater remediation, while also exhibit the promising capabilities of geopolymers in substituting conventional materials in environmental engineering contexts.

Hydrated borates at non ambient conditions: pivotal experiments in the production of neutron-shielding concretes

Comboni D., Lotti P.*, Gatta G.D., Battiston T. & Pagliaro F.

Dipartimento di Scienze della Terra "A. Desio", Università di Milano.

Corresponding author email: paolo.lotti@unimi.it

Keywords: hydrated borates, neutron shielding, phase transition.

Hydrated borates (e.g., colemanite, kernite, ulexite, borax, tincalconite) are the most common ore minerals of boron, an important geochemical marker, in pegmatitic and granitic systems, for petrogenetic processes and a strategic element in a series of technological applications. Hydrated borates have been listed as critical raw materials by the EU (EU Commission, 2017), and they could be used as aggregates in neutron-shielding Sorel or Portland concretes, enhancing their adsorption towards thermal neutrons. The main structural units in hydrated borates are Bφx fundamental building blocks (i.e., tetrahedra and planar trigonal groups where φ is an anion, O^{2-} or OH^{-}), connected in such a way to form clusters of polyions connected to alkaline/Earth alkaline (mainly Na^{+}, K^{+}, Ca^{2+}, Mg^{2+}) polyhedra. In these structures, H_2O molecules and OH^{-} form a complex and pervasive hydrogen-bond network, which reinforce the connection between the polyions clusters and the cations coordination polyhedra, playing a paramount role in the stability of the crystalline edifice (Pagliaro et al., 2021; Comboni et al., 2021). In the last 4 years, a number of studies have been performed at high temperature and pressure unveiling the occurrence of phase transitions driving deformation mechanisms that lead to the formation of their high-pressure polymorphs. Critically, the pressure at which hydrated borates undergo a phase transition is related to the water content of the mineral itself. The aim of this contribution is to provide insights on the high-pressure behavior and structure evolution of selected hydrated borate minerals. These studies at non ambient conditions are pivotal to produce neutron shielding tiles of Sorel concretes.

Inderborite: a comprehensive reinvestigation of its technological features

Comboni D.*, Lotti P., Gatta G.D., Battiston T. & Pagliaro F.

Dipartimento di Scienze della Terra "A. Desio", Università di Milano.

Corresponding author email: davide.comboni@unimi.it

Keywords: inderborite, neutron shielding, phase transition.

Inderborite is a hydrated borate (ideal formula: $CaMg[B_3O_3(OH)_5]_2(H_2O)_4 \cdot 2H_2O$) often found in lower fractions alongside with the five most important boron commodities (i.e., colemanite, kernite, ulexite, borax, tincalconite) in Turkish mines which, nowadays produce more than 70% of the worldwide B-minerals (e.g., Sarikaya borate deposits, Baysal, 1973). Hydrated borates have been listed as critical raw materials by the EU (EU Commission, 2017), and, because of the high neutron cross-section of B-10, they could be used as aggregates in neutron-shielding Sorel or Portland concretes, enhancing their adsorption towards thermal neutrons. In the forthcoming decades, with the advent of fusion power plants, it is predicted that substantial quantities of neutron-activated elements (e.g., beryllium or tungsten), will be produced (Gonzalez de Vincente et al. 2022). The main goals of this projects are to: *i)* re-investigate, by means of a multi-methodological approach, the crystal chemistry (with a focus on the B isotopic composition and trace elements) and structure of inderborite (even based on a single-crystal neutron diffraction experiment), *ii*) assess the stability range of inderborite with respect to pressure and temperature even for potential industrial utilization of this borates, *iii*) describe the structural evolution of inderborite, at the atomic scale, with increasing pressure and temperature.

Keywords: carbon capture utilization and storage, mineral carbonation, brucite single crystals.

In the last decades, many studies have been focussing on carbon capture utilization and storage (CCUS) as possible solution to reduce the increasing of anthropogenic CO_2 concentration in the atmosphere. Among all, mineral carbonation (MC) has been recognized as the most promising route to achieve a long term almost irreversible carbon sequestration. In this respect, brucite [$Mg(OH)_2$] and layered Mg-bearing minerals containing brucite-like sheets, such as serpentine [$Mg_3Si_2O_5(OH)_4$], are targeted as best candidates for CCUS by water-mediated MC (e.g. Boschi et al., 2017; Rausis & Ćwik, 2021; Campione et al., 2024).

This reaction consists in a former dissolution step with formation of Mg^{2+} solvated cations, and a subsequent step with precipitation of Mg-carbonates and/or hydroxy-carbonate hydrates (Campione et al., 2024). Although spontaneous in nature, this reaction is hindered by activation barriers, reducing its capability to permanently store carbon, and consequently its exploitation in profitable applications.

All the above studies used powdered samples as starting materials to increase the reaction surface. In this work, we present preliminary results regarding brucite single crystals carbonation, used as model system for the reactive component of serpentine to better understand the mechanism of the carbonation reaction at the macroscale. The experiments have been carried out with the aid of a microwave-driven apparatus under controlled reaction time, temperature and pressure of a mixture of CO_2 and N_2 and water vapor.

Brucite single crystals surfaces are characterized before and after the experiments in order to identify any change occurred during the treatments. Optical microscope images are collected on the entire surface; on some selected areas, Atomic Force Microscopy (AFM) analysis in acoustic mode is acquired to identify dissolution features and/or incipient Mg-carbonate phases at micro/nano-meter scales. Moreover, these areas are analyzed with Raman spectroscopy and Scanning Electron Microscopy (SEM) to get both chemical and morphological information on the carbonate phases.

Keywords: Sardinia, bentonite, montmorillonite.

Bentonite is a rock composed mainly of smectite, usually of the montmorillonite-beidellite series, which results from the in-situ alteration of volcanic material (usually pyroclastic products, more rarely effusive rocks), or followed by transport and re-sedimentation. Because of its physical and chemical characteristics, it is widely used in ceramics, foundry, water purification and clarification, wine clarification, refining of petroleum products, manufacture of transparent and translucent films, paper mills, soap factories, etc. In this study, the geological and mineralogical characteristics of the bentonite deposit of Sa Pigada Bianca, a deposit that is part of the bentonite basin of Northwest Sardinia, has been analyzed. The survey site is located 15 km southwest of Sassari, in the municipality of Ittiri, on a structural high formed by Cenozoic volcanic succession. The stratigraphy consists of glassy ignimbrite at the top and bentonite bank up to 50 meters thick below, which can be divided into two sub-banks according to the colour of the bentonite, pink at the top and red at the bottom. According to a detailed geological survey two mutually orthogonal fault systems are present, dislocating the mineralized succession. Twenty samples were taken, of which 6 subjected to clay fraction separation and XRPD analysis, both under open-air drying conditions and after treatment with ethylene glycol. The mineralogical assemblage includes Ca-bentonite, mica, kaolinite, and zeolite, with the occasional presence of quartz, calcite, and plagioclase. This preliminary study indicates, for this deposit, a continental genesis with in-situ alteration of tufitic flows, affected successively by distensive tectonics. Mineralogical analyses emphasize a classic mineralogical assemblage, resulting from the interaction between parent material and fluids in the system.

From field to laboratory: geo-inspired strategies for the enhancement of the water-mediated mineral carbonation for the reduction of its energy and environmental impacts

Keywords: carbon capture utilization and storage, mineral carbonation, microwave chemistry.

Mineral carbonation (MC) plays a crucial role in Carbon Capture Utilization and Storage (CCUS), which is a technology approach aimed at better managing anthropogenic CO_2 emissions, also promoting the use of captured CO_2 for the production of secondary raw materials, in a system of Circular Economy. MC involves the chemical reaction in aqueous environment between CO_2 and magnesium and calcium rich minerals, in which CO_2 is converted into a stable and solid form.

In nature, listvenite rocks, mainly composed of Mg-bearing carbonates, quartz and Cr-muscovite (i.e., fuchsite), document a mechanism for natural CO_2 sequestration, potentially significant to develop effective geo-engineering strategies and mitigate CO_2 emissions (Hinsken et al., 2017). Listvenite rocks are the result of the extensive alteration of ultramafic rocks by CO_2-bearing fluids (i.e., carbonatation), which involved the substitution of olivine, pyroxene or serpentine by Ca and Mg enriched carbonates and silicates (Boskabadi et al., 2020).

Serpentinites from Zermatt-Saas Zone, in Western Alps of Aosta Valley (Italy), are natural samples studied in this work. These rocks might have undergone carbonation, which promoted the formation of carbonate-bearing lithologies (i.e., carbonated serpentinites and listvenites). Therefore, they represent valuable records of CO_2 sequestration, enhanced by fluid-rock interaction, observable in structural features from macro scale to micro one.

The aim of this work is the identification of accessory mineralogical phases and reaction mechanisms characterizing natural samples rich in carbonates, to recreate natural processes in laboratory, and enhance their efficiency through the use of microwaves (MW). Natural samples were characterized with optical microscopy and scanning electron microscopy (SEM), to identify phases and their mutual structural relationships. These results can improve the comprehension on performing MC experiments in laboratory. We studied MW effects on MC reaction of brucite [$Mg(OH)_2$], a model system of magnesium rich minerals, made of only two components ($MgO + H_2O$) (Campione et al., 2024). Though thermodynamically spontaneous for magnesium and calcium rich minerals in natural systems, MC reaction can be hindered by activation barriers. This limitation can be overcome by the use of MW, which promote a faster reaction rate compared to conventional heating methods.

Moreover, several combinations of temperature and reaction time, and chemical additives were explored, to fully exploit MW effects and fix the conditions of crystallization of magnesite [$Mg(CO_3)$] and magnesium hydroxide-carbonate hydrates (MHCH: i.e., nesquehonite [$Mg(HCO_3)(OH)\cdot 2H_2O$] and hydromagnesite [$Mg_5(CO_3)_4(OH)_2\cdot 4H_2O$]), minimizing energy expenditure.

Thanks to these MC products, considered secondary raw materials storing captured CO_2, a minor environmental impact can be achieved, also with a more eco-friendly outlay, compared to energy-intensive industrial settings.

Keywords: restoration mortars, compatibility, pozzolana.

This study aims to enhance the understanding of compatibility criteria for restoration mortars, which are crucial for preserving ancient and traditional buildings. Given the various substrates encountered in restoration projects and the wide-ranging functions required of restoration mortars, a fundamental question arises: can mortars with varied properties in the fresh and hardened state be formulated using exclusively traditional components but with a deliberate scientific approach?

This inquiry underscores the vital role of consciously utilizing traditional materials to optimize them, enabling tailored mortars to meet diverse restoration demands. The choice of the constituents was informed by ancient mortar knowledge and historical references, such as Vitruvius, who highlighted the effectiveness of mortar comprising pozzolana from *Fondi di Baia* and lime, preferred by the Romans. Therefore, traditionally produced lime putty (CL90-S PL) was chosen as the binder, while a *Phlegraean* pozzolana was selected as the aggregate. An extensive preliminary characterization was conducted on both materials to elucidate the correlation between the raw materials and the mortars properties from minero-petrographic and physico-mechanical perspectives. Subsequently, to formulate restoration mortars, the approach involved varying binder-to-aggregate (B/A) ratios and grain size distributions. Based on detailed analyses of the mineralogical and chemical composition of the pozzolana particles, which revealed no substantial differences in the composition of the pozzolana itself, three fractions were identified: fine (< 0.425 mm), coarse (≥ 0.425 mm) and the total pozzolana. These three granulometric fractions were utilized to formulate mortars with B/A ratios of 1:2 and 1:3 by volume. Water content was maintained constant at 15% by weight of the total mass. The resulting six formulations were characterized at 28 days of curing using chemical, mineralogical and petrographic techniques (PLM, SEM-EDS, XRPD, XRF, FTIR, TG-DSC) and physical-mechanical tests (MIP, flexural and compressive strength, apparent density, hydric tests, ultrasounds). This systematic approach yielded encouraging outcomes for formulating mortars with diverse strengths, workability, and other properties, all accomplished using only two traditional components and without any additives. Thanks to the properties of pozzolana, which offer a wide range of characteristics in mortars due to its hydraulic properties and varying reactivity based on grain size. Furthermore, the study emphasizes enhancing compatibility through the critical substrate-mortar interface. To achieve this, composite specimens structured as substrate-mortar-substrate layers were developed, using bricks and tuff stones as substrates, and are currently under study. These tailored formulations met specific requirements for various functions and substrates, thereby making a significant contribution to the preservation of ancient buildings.

New materials for civil engineering through solidification and stabilization processes

Keywords: solidification and stabilization, green material for civil engineering, waste utilization.

Contaminated soils as residue from old brownfield sites are a widespread problem today. Over the years, it has become apparent that through the solidification and stabilisation (S/S) process, it is possible to treat contaminated sediments (Wilk, 2004) and redevelop the interested areas. Specifically, the stabilisation phase serves to reduce the hazardousness of the waste by generating a change in chemical properties and the solidification phase provides a change in physical properties by modifying the waste. This work shows that the S/S process can be usefully employed to obtain new civil engineering materials, treasuring from previous studies that have proved it is a valid technique for the recovery of marine sediments (Todaro et al., 2023), and including in the process recycling materials such as, e.g., fly ash (Liang et al., 2024).

The proposed methodology involves several steps: the taking of soil samples, the application of the stabilisation and solidification treatment in the laboratory, the formation of the new materials and finally the testing phase during which the materials will be subjected to impact tests. The work presents some very promising initial results related to the use of the S/S process to form new materials to be employed in the construction of road surfaces (Salzano et al., 2022).

Investigations on simultaneous Sb and As removal from mining drainages by Layered Double Hydroxides (LDHs)

Dore E.*, Biddau R., Fancello D., Frau F., Medas D., Musu E. & Podda F.

Dipartimento di Scienze Chimiche e Geologiche, Università di Cagliari.

Corresponding author email: elisabetta.dore@unica.it

Keywords: Sb-As pollution, sorption processes, layered double hydroxides.

Layered Double Hydroxides (LDHs) are minerals characterized by a layered structure made up of brucite-like sheets ($[M_{1-x}^{2+} M_x^{3+} (OH)_2]^{x+}$), positively charged due to the partial substitution of bivalent metals (Mg^{2+}, Zn^{2+}, Ca^{2+}, etc.) with trivalent ones (Al^{3+}, Fe^{3+}, etc.), alternating with negative interlayers ($[(A^{n-})_{x/n} \cdot mH_2O]$) (Mills et al., 2012). Thanks to their structure, LDHs are able to trap anionic pollutants in solution by either anion exchange (untreated LDHs) or incorporation in the interlayer during reconstruction of the structure after calcination (the so-called *memory effect*).

Antimony (Sb) and arsenic (As) are considered pollutants of priority interest due to their toxicity for human health and the adverse effects for the environment. In the last decades, extensive investigations have been carried out in order to assess the LDHs removal capacity of these pollutants from waters. Several works show that both untreated and calcined LDHs with different composition can efficiently remove As, by incorporating the oxyanion (e.g., AsO_4^{3-}) in the interlayer (Wang e al., 2018). On the other hand, in the case of Sb, the cationic composition of LDHs affects the removal process; in fact, the hydrotalcite-like compound $Mg_6(Al_{0.5}Fe_{0.5})_2(CO_3)(OH)_{16} \cdot 4H_2O$ removes $Sb(OH)_6^-$ through the formation of the brandholzite-like compound (a non-LDH layered mineral, with general formula $Mg[Sb(OH)_6]_2 \cdot 6H_2O$), whereas the zaccagnaite-like compound $Zn_4Al_2(CO)_3(OH)_{12} \cdot 3H_2O$ removes Sb by means of the reconstruction of the zincalstibite-like compound (an LDH with general formula $Zn_2Al(OH)_6[Sb(OH)_6]$) (Kameda et al., 2011; Dore & Frau, 2018).

In the context of the project PRIN-PNRR2022 (MOLIERE - antiMony resOurce itaLy envIronmental Exploration cRitical matErial) we studied the simultaneous removal of dissolved Sb and As from a highly contaminated slag drainage sampled in the abandoned mine of Su Suergiu (SE Sardina, Italy) by calcined hydrotalcite-like and zaccagnaite-like compounds. Drainage water chemistry is characterized by oxidizing conditions, slightly alkaline pH (8.0 - 8.3), Ca(Na) – SO_4 composition and high concentration of both Sb (up to ~13 mg/L) and As (up to ~5 mg/L). Preliminary results are encouraging (more that 90% of Sb and As were removed), but showed that the removal capacity is affected by the competition effect of anions in solution and can be influenced by the precipitation of secondary phases (e.g., $CaCO_3$). Therefore, further investigations are needed in order to assess the most effective removal conditions (e.g., liquid/solid ratio, contact time, etc.).

Keywords: layered double hydroxide, compressive strength, cement hydration.

Ensuring the sustainability of cement production holds significant importance within the construction sector. A key method to enhance this is by incorporating suitable additives and materials into traditional cement mixes. Essentially, understanding the physical and chemical mechanisms involved in the hydration of blended cement is crucial (Wu et al., 2018). Layered double Hydroxides (LDHs) present promising potential as additives, due to their capacity to capture CO_2, thereby enhancing the carbonation resistance of cement, and eliminate CO_2, SO_4 and Cl^- ions, which can compromise the durability of the cement paste. They are classified as ionic solids with layered structure and known as anionic clays with controllable supramolecular structure and unique physicochemical properties (e.g. anion exchange), which make them very interesting in the field of cementitious materials (Yazdi et al., 2023; Mishra et al., 2018). Nano Mg-Al-NO_3/$HCOO^-$ LDHs were synthesized by direct and ultrasonic precipitation methods. The nanometric size and purity of the LDHs were verified by X-ray powder diffraction (XRPD), transmission electron microscopy (TEM), scanning electron microscopy (SEM), dynamic light scattering (DLS) and Fourier-transform infrared spectroscopy (FTIR). The LDHs were mixed with Portland cement in different weight percentages (wt.%), ranging from 1 to 10 wt.%. First, the mixed dry cement powders were analysed using DLS, FTIR, XRPD and SEM to verify the actual homogenization of the powder that ensures the dispersion of the nano LDHs. The influence of LDHs on the hydration process of the cement paste as well as on the morphology and porosity of the hydrated samples is going to be studied after 1-, 7-, 14- and 28-days curing times, and analysed by XRPD, SEM, thermal (TGA/DTG) and spectroscopic analyses. This method makes it possible to explore the chemical impact of LDHs on the formation of calcium silicate hydrate (C-S-H) and calcium aluminate hydrate (Afm) phases, as well as the potential anion exchange process during hydration. In addition, ongoing mechanical compression and flexural tests aim to assess the physical effects on the mixed cement paste. The initial results presented here help to understand the precise role of selected nanomaterials in the cement hydration process. They also highlight potential adverse effects and facilitate the refinement of the appropriate procedure for their incorporation into cement pastes. In addition, the use of waste material rates, such as construction and demolition waste, as additional additives will be investigated. The goal is to develop engineered cement with minimal environmental impact while respecting strict physical and mechanical standards.

Optimization with slaked lime of alkali-activated pastes based on Mt. Etna's volcanic ash: rheological and physical-mechanical assessment

Finocchiaro C.*[1], Occhipinti R.[1], Barone G.[1], Mazzoleni P.[1], Andreola F.[2], Romagnoli M.[2] & Leonelli C.[2]

[1] Dipartimento di Scienze Biologiche, Geologiche e Ambientali, Università di Catania.

Keywords: alkali-activated materials, recycle, volcanic ash.

In recent years, innovation in the development of sustainable alternatives in the construction material industry has increased exponentially, in line with the EU policies aimed at limiting the exploitation of natural resources and emissions in the manufacturing process. In this context, Alkali-Activated Materials (AAMs) have emerged as a viable solution thanks to their synthesis process without energy consumption (e.g., generally at room temperature) or the use of waste products (e.g., industrial by-products and natural materials), in line with the principles of the circular economy. The activation process requires the mixing of aluminosilicate powdered precursors with alkaline reactants.

Recently, volcanic ash from Mt. Etna, which would otherwise be considered as solid municipal waste if not used in innovative and safe processes, has been valorised through the alkaline activation process for different purposes, such as the realization of lightweight or fire-resistant pastes or restoration mortars (Finocchiaro et al., 2022; Fugazzotto et al., 2023; Occhipinti et al., 2023; Scanferla et al., 2023). The latter were realized and applied to restoration interventions carried out on a vertical mosaic area of the Cathedral of Monreale in Sicily (Italy), within the completed project "Advanced Green Materials for Cultural Heritage". Several in-situ applications were carried out in order to optimize the standard formulations prepared in the laboratory, which had a tendency to drip, thus hindering the engraving for the reproduction of the mosaic. The modification consists of adding 2 wt.% $Ca(OH)_2$ in the form of slaked lime to the standard mortar formulation.

This work provides experimental insights into the optimization of pastes applied in-situ during the restoration works of the mosaics of the Monreale Cathedral. A comprehensive comparison between the standard and modified pastes was carried out by evaluating their setting time and rheology, as well as by determining the microstructure of consolidated samples in terms of mineralogy, morphology and mechanical performance.

The results showed an accelerated setting times, alongside superior mechanical strength and rheological properties in the modified pastes. No relevant mineralogical difference was observed due to the negligible addition of slaked lime. Furthermore, the latter induced marginal changes in the gel morphology without affecting the chemical composition of the Na_2O-CaO-Al_2O_3-SiO_2-H_2O (N,C-A-S-H) type. These results have great potential for the development and improvement of building materials, especially for restoration works requiring specific and better physical and mechanical characteristics.

"Cradle-to-cradle": waste geopolymers as precursors for new geopolymers in the restoration and construction sectors

Fugazzotto M.*, Barone G. & Mazzoleni P.

Dipartimento di Scienze Biologiche, Geologiche e Ambientali, Università di Catania.

Corresponding author email: maura.fugazzotto@unict.it

Keywords: geopolymers, ceramics, waste.

Geopolymers are recognized as promising eco-sustainable alternative to traditional materials for construction and restoration. Geopolymers, indeed, offer exceptional mechanical performance, making them ideal for use in construction, as well as their versatility in terms of both technical properties and aesthetic characteristics renders them the perfect choice for monument restoration. Furthermore, their aluminosilicate nature guarantees chemical compatibility with silicate substrates, which represent one of the most prevalent materials in cultural heritage.

However, as extensive research on geopolymers continues, the generation of geopolymer waste is on the rise. A new kind of global waste arises, that add to the huge volumes of industrial waste already in existence.

It becomes important to anticipate solutions for their management, in order to reduce the waste environmental impact. Nevertheless, few studies are available on geopolymer waste recycling. They are used as aggregates (Mesgari et al., 2020) or only partially replacing precursors for the production of new geopolymers (Hattaf et al., 2021). So far, little was the exploration of the possibility of creating new geopolymer materials by recycling up to 100% of geopolymer waste (Wu et al., 2023).

The present work aims to evaluate the feasibility of using ceramic-based geopolymer waste as precursors for new geopolymer products, suitable for the conservation of ceramic-based cultural heritage or as new potential building materials (blocks, tiles, bricks…). According to the principle of "cradle-to-cradle", various ceramic-based geopolymers resulting as waste from previous researches were as geopolymer precursors, solely or in binary mixtures with metakaolin. Following the mineralogical characterisation of the geopolymer waste, they were ground and employed in the synthesis of novel formulations. The synthesis parameters, including the type and ratio of activators and consolidation temperature, were maintained consistent with those of the original formulations. The evolution of the new geopolymer gel was confirmed by ATR-FTIR spectroscopy and X-ray diffractometry. Compressive tests showed strength values comparable to those of the geopolymers from which they originate, that are suitable for the desired applications. For restoration purpose, furthermore, colorimetric investigations were also carried out. Some applicative examples were realized, as tiles, blocks, decorative elements, reintegration mortars applied on pottery, fillers, etc.. The research demonstrates the recyclability of geopolymer waste, specifically of those obtained by ceramic waste. The promising results encourage further researches for the development of these innovative green products.

Acknowledgments: The work has been supported by MUR in the framework of PNRR Mission 4, Component 2, Investment 1.3 under project CHANGES, Spoke 6 (CUP E63C22001960006).

Tadelakt: a thousand-year-old technique for the production of special plasters with unique properties

Gambino F.*[1], Longhitano N.[2], Tazzini A.[1], Mancini S.[1], Ghignone S.[1] & Dino G.[1]

Keywords: Tadelakt, lime, sustainable geomaterials.

Tadelakt is an ancient Moroccan lime-based decoration technique that has been handed down for over 5 centuries and which has evolved and perfected over time.

In particular, the lime used by Tadelakt is produced starting from the carbonate rocks of the quarries in the Marrakech area and has long been an essential conventional material in Moroccan buildings.

Marrakech lime was used to produce a special mortar with waterproofing and antibacterial properties. In fact, the particular processing of Tadelakt gives the material a high resistance to water, making it suitable for waterproofing cisterns and for decorating bathrooms, facades, hammams and fountains.

The installation of Tadelakt is a meticulous operation and the Moroccan master craftsmen, Maalem, undergo training that lasts many years in order to master the technique.

The Tadelakt technique has the particularity of being finished with cut and smoothed river pebbles which allow the finish to be closed and making it completely smooth, and of being treated with natural black soap of a pasty consistency, obtained from olive oil, which makes the surfaces of the material perfectly water-repellent and gives it a soft and fine appearance.

The materials used for Tadelakt essentially consist of lime, water, natural pigments for the mixture and of black soap deriving from olive oil residues and dust and natural bees wax to confer water resistance.

This traditional technique is conquering architects and designers to create bathrooms, SPAs, walls and environments with soft and warm tones.

There are not many studies in the literature on the properties and characteristics of the traditional Marrakech lime. This study is focused on the characterization of Moroccan limestone rocks and Marrakesh lime.

In particular, various characterization techniques were used: optical microscope of thin sections of original rock and of the plaster, tests physical and mechanical for performance evaluation, X-ray diffraction (XRD) and mineralogical analysis using scanning electron microscopy (SEM) for composition analysis.

Tadelakt can be considered a “sustainable” technique as it uses low-carbon construction materials and waste materials. It is for this reason that in recent decades, this technique has been reevaluated for the contemporary architecture.

The role of temperature on the pressure-mediated adsorption in natural zeolites: the case of leonhardite

Gatta G.D., Comboni D.*, Chiappella L., Battiston T. & Lotti P.

Dipartimento di Scienze della Terra "A. Desio", Università di Milano.

Corresponding author email: davide.comboni@unimi.it

Keywords: zeolites, leonhardite, in-situ P-T X-ray diffraction.

While the high-pressure and high-temperature behavior of natural zeolites has been intensively studied in the last decades, to the best of our knowledge, no in-situ X-ray diffraction studies have been performed combining the effects of both. Experiments at these conditions could have crucial geological implications and potential applications at the industrial level (e.g., high-P/T adsorption of alcohols compounds in zeolites to promote methanol to olefins reaction). In this study, we present the results from the first pilot experiments, obtained with an easy and reproduceable experimental set-up, performed with one of the most common natural zeolite, i.e., laumontite ($[(Ca_{4-x}Na_x)K_x][Al_8Si_{16}O_{48}]\cdot(H_2O)_n$, with $n < 16$). This zeolite occurs in a wide range of natural environments, including sedimentary deposits or volcanoclastic sequences interested by burial diagenesis/metamorphism, as well as in hydrothermal vugs of volcanic rocks. Partially hydrated laumontite (i.e., with 15 H_2O molecules per unit cell) is often referred to as "leonhardite". The behavior and adsorption mechanisms of these minerals have been (already) well characterized at high-pressure by several authors (Gatta et al., 2018; Comboni et al., 2018), leaving unexplored the effect induced by temperature increase. In-situ high-pressure+high-temperature single-crystal synchrotron X-ray diffraction experiments were performed at the ID15-b beamline, at the ESRF, Grenoble (France). Saltwater (0.35 wt.% NaCl) was used as hydrostatic pressure-transmitting fluid. The DAC was placed in a resistive heater, which allowed to increase the T up to 100(2)°C. Temperature was defined using a thermocouple placed very close to the P-chamber; T value was consistent with what obtained by the analysis of the Au-powder pattern. In leonhardite, the temperature seems to enhance the H_2O adsorption, giving rise to a volume expansion at $P < 5$ kbar. Above this pressure, the compressibility becomes similar to that of fully hydrated laumontite (Comboni et al., 2018). Previous experimental findings proved that leonhardite experiences a full hydration, at ambient PT conditions, only after about 24 hours, whereas each data-point at high-PT required not more than 20 minutes: this further highlights the role played by temperature on the kinetics of the P-mediated adsorption process (i.e., speeding up the adsorption process).

Keywords: sustainable material, C&D waste, geopolymeric mortar.

Geopolymers, derived from a precursor composed of aluminosilicate-rich materials combined with alkali activators, represent environmentally friendly alternatives to ordinary Portland cement. Clay brick waste (CBW) serves as excellent reactive materials for producing geopolymer binders, given their chemical and mineralogical properties.

In this study, we explored the potential of reusing CBW to produce geopolymer mortars as an alternative to conventional fired bricks. Experimental work focused on producing geopolymer bricks using metakaolin (MK) as the raw material and sodium hydroxide (NaOH) and sodium silicate (Na_2SiO_3) as activators. Samples were prepared with various formulations, incorporating CBW both as aggregate and as a replacement for MK, up to 100%. Following molding, the geopolymer bricks were cured at 60°C for one day. Subsequently, demolded materials were sealed in plastic bags and maintained at room temperature in the laboratory for 7, 14, and 28 days before conducting physical and mechanical property measurements.

The results of this study demonstrate that geopolymer mortars produced using crushed brick waste exhibit favorable properties in terms of open porosity, water absorption, and mechanical strength compared to conventional brick materials.

First insights on the synthesis of cordierite from Sardinian raw materials

Mameli P.*[1], Martucci A.[2], Alberti A.[2]†, Mancinelli M.[2] & Oggiano G.[1]

[1] Dipartimento di Scienze Chimiche, Fisiche, Matematiche e Naturali, Università di Sassari.
[2] Dipartimento di Fisica e Scienze della Terra, Università di Ferrara.

Corresponding author email: mamelip@uniss.it

Keywords: cordierite, synthesis, raw materials.

Cordierite, $Mg_2Al_4Si_5O_{18}$, is a ternary compound within the MgO-Al_2O_3-SiO_2 system. It is a widespread commercial material due for its unusually low coefficient of thermal expansion, low thermal mass, low dielectric loss factor, low density, volume resistivity and high resistance to thermal shock. These physical-mechanical properties give this mineral phase a high industrial value. Particularly high grade cordierite is widely used in various industrial fields such as automotive, catalysis, electrical devices, etc..

Cordierite can be synthesized from natural raw materials (e.g. talc, stony kaolinite, andalusite) or synthetic powders, which have high purity and are readily available (Gonzalez-Velasco et al., 1999; Khabas et al., 2003; Cao et al., 2016).

In this study, to synthesize cordierite, natural raw materials quarried in Sardinia and available at low commercial cost were used in the following first series of 15 syntheses:

1) talc + low iron bauxite + opal at 1250°C and 1300°C;
2) talc + low iron bauxite + quartz at 1250°C and 1300°C;
3) talc + low iron bauxite + opal + quartz at 1250°C and 1300°C;
4) talc + low iron bauxite + kaolin 1 at 1250°C and 1300°C;
5) talc + low iron bauxite + kaolin 1 + opal at 1250°C and 1300°C;
6) talc + low iron bauxite + kaolin 1 + quartz at 1250°C and 1300°C;
7) talc + kaolin 1 at 1300°C;
8) talc + low iron bauxite + kaolin 2 + opal at 1300°C;
9) talc + low iron bauxite + kaolin 2 at 1300°C.

The raw materials were milled to powder, placed into a closed crucible and sintered in an oxidizing furnace for 2h at designed temperatures (Succi, 2007).

To maximize the cordierite content in the synthesis product, both mineralogical and chemical analyses of the starting phases were carried out in order to precisely balance the chemical composition of the starting mixture for the synthesis.

The XRD patterns of the synthetized material specimens were analyzed by Rietveld method which allowed us to highlight the most reactive phases and the optimal mixtures, among the tested ones. Cordierite content exceeding 75% was obtained in the most promising synthesis.

Keywords: flue gas desulfurization, 13X zeolite, semi-dryer system.

The reduction of sulfur dioxide emissions has led to significant research into gas desulfurization methods. Techniques for reducing sulfur dioxide emissions can be classified into dry, semi-dry, and wet flue gas desulfurization (FGD). Limestone is widely used in FGD due to its availability and cost-effectiveness, but its reactivity is often insufficient for effectively removing sulfur dioxide. Lime, a byproduct material, is an environmentally friendly option due to its abundance and low cost. Zeolites, microporous crystalline materials with thermal and chemical stability, catalytic properties, and a high specific surface area, are commonly used for gas separation and as catalysts.

The study aims to investigate a semi-dry system operating at low concentrations that is designed to address challenges in practical gas desulfurization. Porous materials, specifically slaked lime and a selected synthetic 13X zeolite are evaluated as adsorbents. The efficiency of the adsorbents is evaluated using microgas chromatography. A model calculation detailing gas mobility, X-ray powder diffraction, thermal analysis, and scanning electron microscopy are used in the integrated approach to elucidate the mechanisms governing gas desulfurization and propose an experimental prototype setup for the absorption of SO_2 in semi-dry and low concentrated systems.

Hydration processes of geomaterials for green and sustainable applications

Massa M.*[1-2], Vola G.[1], Ardit M.[3], Bresciani P.[1] & Colombari V.[1]

[1] Cimprogetti S.r.l., The Green Edge of Lime Technologies, Dalmine (BG). [2] INSTM e Chemistry for Technologies Laboratory, Dipartimento di Ingegneria Meccanica e Industriale, Università di Brescia.

Keywords: lime hydration, double hydrated dolomitic limes, flue-gas desulphurization.

This work introduces and validates diverse hydration assessment methodologies utilizing a developed and tailored fully integrated planetary mixer engineered for Cimprogetti's Technological Laboratory. This specialized apparatus is engineered to consistently hydrate different calcined limes, encompassing high-calcium lime (quicklime), magnesium-rich lime (dololime), and magnesium oxide (periclase). The aim is to produce fully hydrated materials, even those exhibiting low reactivity, to yield final products with specific properties for different industrial applications such as construction and building materials and flue-gas desulphurization (FGD). Different hydration protocols were optimized to produce enhanced high calcium-hydrated lime, double-hydrated dololime, and magnesium hydroxide coming from calcination of pure limestones, pure dolostones, and pure magnesites of various Italian and foreign geological provenances. It is well-established that the calcination process is primarily affected by burning temperature and retention time, which significantly impact the reactivity of the burned compounds with water (Vola et al., 2019; Huang et al., 2020). Consequently, hydration can be a challenging process, depending on the degree of over-burning or sintering of Ca-Mg limes.. However, the complete conversion of periclase (MgO) into brucite ($Mg(OH)_2$) in dolomitic limes is often hardly achievable under ambient conditions (Lanas & Alvarez, 2004). Therefore, hydration kinetics have been increased using high temperature, and naturally generated steam pressure. Effectively, the new planetary mixer, insulated and pressurized to withstand up to 3 bars, is also equipped with a heating system capable of reaching up to 200°C. Furthermore, enhanced hydrated limes, presenting high BET surface area and pore volume (PV) for acid gas treatments, were synthesized with specific recipes employing high water-to-lime ratios coupled with TEA fluidizing additive. In this research, several types of lime products, previously calcinated in-lab to simulate different industrial kilns, were investigated before and after hydration tests. Additionally, the materials were characterized using the Whole Pattern Profile Fitting (WPPF) on X-ray powder diffraction (XRPD) data analyzed by the Rietveld method for microstructural and quantitative phase analyses. Porosimetric investigations were conducted using nitrogen gas adsorption, employing BET and BJH methods. These techniques facilitate the identification of the complete conversion of oxides into hydroxides, as well as the determination of crystallite size, BET-specific surface area, and BJH pore volume of hydrated products. The materials obtained are suitable for various industrial applications, including modified activated binders, flue gas desulphurization, flame retardant, neutralizer of water pollutants, and chemical sensors for ethanol.

Keywords: pozzolans, lime reactivity, C-S-A-H.

This paper describes the pozzolanic reactivity with aerial lime of two volcanic materials with high zeolite content from Central and Northern Sardinia (Palomba et al., 2006; Naitza et al., 2006). The zeolites are represented by predominantly clinoptilolite and subordinate mordenite. These materials were preliminarily micronized, sieved low < 63 μm and then dry-mixed with aerial lime (CL90), followed by addition of water in a 0.5 (solid/liquid) by weight ratio in order to create a paste system without the use of aggregate. The volcanic materials and paste systems were analysed by SEM scanning electron microscopy, Differential Thermal Analysis (TG-DTA) and XRPD Diffraction at the different time: 1, 3, 7, 14, 28, 60, 90 days under two different curing conditions: limited CO_2 input from outside, and in air at ordinary temperature. In addition, for comparison, homologous systems were prepared with the same weight proportions, using silica fume as a pozzolanic additive. These last is considered a hyper-pozzolan agent because of its marked reactivity with lime. The results obtained for the systems matured with limited CO_2 input showed appreciable reactivity by both samples investigated. The hydration kinetics of these systems appears to be slower, compared with that of the homologous system containing silica fume. In the case of zeolitic systems cured under normal atmospheric conditions (in air), the reaction between the lime and the zeolitic additive is slower, compared with that of systems cured with limited CO_2 contribution and the reference system containing silica fume, because the effect of carbonation is prevalent. Therefore, the curing process is critically influential on the development of any hydraulic products (C-A-S-H). The results obtained as part of the research, provide a preliminary scientific basis for the possible use of zeolitic materials in the field of the production of hydraulic mortars, characterized by greater sustainability, as it excludes a treatment of geomaterials by thermal or chemical activation.

Tripoli Formation rocks as new resources in alkaline-activation technology: a feasibility study

Occhipinti R.*[1], Bertino A.[1-2], Barone G.[1] & Mazzoleni P.[1]

[1] Dipartimento di Scienze Biologiche, Geologiche e Ambientali, Università di Catania.
[2] Dipartimento di Scienze Umanistiche, Università di Catania.

Corresponding author email: roberta.occhipinti@unict.it

Keywords: geopolymers, alkali-activated materials, natural precursors.

Alkali-activated materials (AAMs) are inorganic compounds formed by dissolving solid aluminosilicate precursors in a strongly alkaline liquid medium. Well-designed, AAMs can be considered a valid alternative to substitute Ordinary Portland Cement (OPC) due to their notable energy efficiency and reduced environmental impact compared to traditional cements (Palomo et al., 2021). These binders reduce the CO_2 emission, primarily attributed to their production at room temperature, bypassing the necessity for high-temperature thermal treatments. Moreover, their production can exploit a diverse range of natural raw materials, including volcanic ash, rocks, and rock processing waste, thereby minimizing transportation costs related to the materials.

This study aims to utilize the diatomite of the Tripoli Formation, previously unexploited as a natural precursor for AAMs, particularly in niche applications such as cultural heritage restoration. In particular, this natural raw material has been selected both for its local availability and for its mineralogical composition, since it includes phases such as calcite, gypsum, silica, and clay minerals, which are important in alkali-activated materials technology and commonly used in cementitious materials. The investigation of Tripoli diatomite reactivity in an alkaline environment was conducted through selective chemical attack with an 8M sodium hydroxide (NaOH) solution, representing conditions closest to alkaline synthesis. This test aimed to dissolve amorphous phases and slightly affect crystalline ones. The total amounts of soluble phases were determined gravimetrically. Subsequently, feasibility studies involving the synthesis of alkaline-activated materials using Tripoli Formation rock alone or in binary mixture with metakaolin yielded promising results in terms of workability and mechanical properties. Samples were subjected to X-ray diffractometry, FT-IR spectroscopy, scanning electron microscopy and uniaxial compressive testing for a complete mineralogical, textural and physical-mechanical characterization to provide insights into their properties and potential applications.

The present contribution falls within the research activities of the PNRR project CHANGES - Spoke 6 - History, Conservation and Restoration of Cultural Heritage. The main focus of the spoke is to develop and apply integrated methodologies, strategies and approaches to support the processes of historical understanding, conservation, restoration, monitoring, sustainable and participatory planning in multi-layered contexts of cultural heritage.

New method to quantify fluorite in geo-complex material: the case of Pianciano mine (Central Italy)

Parlapiano F.*

Dipartimento di Scienze Psicologiche, della Salute e del Territorio, Università "G. d'Annunzio", Chieti.

Corresponding author email: francescaparlapiano51997@gmail.com

Keywords: carbonatites, mine, complex geo-materials.

Geo-complex materials consist of mixtures of two or more different raw materials, requiring the definition of ad hoc beneficiation methods for their characterization. In this case, the products studied, marketed by So.Ri. Co.M. Srl - Società Ricerche Coltivazioni Minerarie, consist of two different mixtures from the Pianciano mine: carbonatite and clay fluoritite. The mine is located 3 km southwest of Lake Bracciano, near Castel Giuliano (Rome, Italy). The Pianciano-Castel Giuliano carbonatite-fluoritite sequence was first described by Mastrangelo (1976) as the main deposit in the Sabatini Mountains area, covering about 6-8 km^2 and characterized by the presence of four different mineral facies: white carbonate material; yellow carbonate material; white fluoritite material and grey fluoritite material. The latter represents the source of CaF_2. The deposit has since been extensively studied (Stoppa et al., 2016; 2019), and its facies have been interpreted by Stoppa et al. (2016) as carbothermal residual carbonatites.

The Pianciano's geo-complex materials are heterogeneous, with fluorite being mainly f < 200 µm, therefore their CaF_2 grading it's difficult to assess. The new proposed method relies on differentiation of granulometric spindles and their evaluation. After primary quartering, the material is homogenized using hydrogen peroxide (H_2O_2) at 120 vol. the solution obtained is sieved and dried (T < 80°C). Both 200 µm passing and retained is dried and quartered for quantitative analysis using X-Ray Powder Diffraction. SEM EDS Analysis control is performed on the qualitative characterization of this geo-complex material. Each spindle is represented by different proportions of contained minerals, with the < 200 µm fraction being as semi-pure materials with only fluorite, calcite, and barite. This griding procedure allows the efficient assess of the real mineralogical content the different mixing ready for marketing. Fluorspar is currently used in clinker production to reduce CO_2 emissions. Due to its importance, it is necessary to accurately assess the fluorspar content in geo-complex materials to use them as raw materials and limit industrial waste.

Comparative trace element concentrations in carbonate lithologies used for the production of lime and their washing muds

Piepoli L.*[1], Grieco G.[1], Della Porta G.[1], Marinoni N.[1], Govoni D.[2] & Fumagalli L.[2]

[1] Dipartimento di Scienze della Terra "A. Desio", Università di Milano. [2] Unicalce S.p.A., Lecco (LC).

Corresponding author email: luca.piepoli@unimi.it

Keywords: trace elements, Critical Raw Materials, lime.

Numerous raw materials are of increasingly high importance in many industrial fields, while at the same time presenting high risks in their supply chain. The European Union has, with the Regulation (EU) 2024/1252, also known as the Critical Raw Material Act, updated the list of these essential materials and laid out policies to increase production in European countries. This study in accordance with the new policies and in collaboration with UNICALCE S.p.A., a leader company in lime production and part of an international group, focuses on the characterization of washing muds produced during stone processing, while also comparing them with the original carbonate rocks (limestone and dolostone) from which they derive. Facies character, petrographic and diagenetic features and trace element concentrations were preliminarily analysed from two quarries, Vaiolo Alta (LC) and Costiolo-Forcella (BG), both of which extract material from the Lower Jurassic shallow-water, partially dolomitized, carbonates of the Albenza Formation. The two localities differ in the abundance of diagenetic dolomite both as subhedral dolosparite mosaics completely or partially replacing the original limestone or as hydrothermal dolomite cement in fractures, with Vaiolo Alta expressing more extensive and advanced dolomitization of the observed facies compared with Costiolo-Forcella. The methodologies adopted for this study were optical microscopy for the facies analysis, and ICP-MS for the trace elements. The results show low but varied concentrations, with relatively high contents of strontium (27-723 ppm) and uranium (0.10-0.84 ppm). As the lime industry involves in Europe hundreds of quarrying sites and produces millions of tons of fine-grained sub-products even relatively low amounts of metals and especially CRM metals, eventually identified as associated with specific facies, could be potentially of interest for recovery. The difference in trace element patterns between source rock and washing muds serves as an important starting point in the future considerations and potential recycling of these sub-products.

Recovered silt filled geopolymers for low-strength concrete applications in road construction

Ranellucci F.*[1], Ulian G.[1], Moro D.[1], Sangiorgi C.[2], Tataranni P.[2] & Valdrè G.[1]

[1] Dipartimento di Scienze Biologiche, Geologiche e Ambientali, Università di Bologna.
[2] Dipartimento di Ingegneria Civile, Chimica, Ambientale e dei Materiali, Università di Bologna.

Keywords: geopolymers, metakaolin, waste silt.

Geopolymers are inorganic polymeric materials derived from the reaction between a solid aluminosilicate and an alkaline activating solution. Geopolymers have shown remarkable qualities compared to Ca-based cements, such as excellent mechanical strength, durability, high thermal and chemical resistance to acidic and alkaline environments (Lyon et al., 1997), with the additional quality of requiring lower temperatures and contributing with 80% less CO_2 emission during their production. Among the wide variety of applications these products may be found in construction industry as they have been studying for their similarities with Ordinary Portland Cement (OPC) (Davidovits, 2008). A wide variety of raw materials are employed as precursors in the geopolymer synthesis to obtain materials for different applications. Moreover, significant research has been conducted on the effect of incorporating industrial by-products as additives in the geopolymeric matrix aiming at improving the properties of the composites, e.g., mechanical, fire-resistance and high durability (Solouki et al., 2021). In this study, a novel composition employing metakaolin (MK) as raw material coupled with a quarry derived by-product silt, as filler, is presented (Valdrè, 2023). The present research has both economic and environmental goals, potentially facing greener and low-cost sustainable concrete production, while preserving suitable mechanical properties in low-strength concrete applications. The mechanical properties of MK-based geopolymer with Si:Al ratio equal to 2, namely Na,K polysialate-siloxo binder, and its composite have been studied in depth. The geopolymer samples were synthetized varying the ratio of NaOH/KOH in the activating solution, but keeping fixed both the M^+O ratios and the water content (Davidovits, 2008). The binders were cured at different temperatures, i.e., 85°C for 2 hours, 60°C for 3 hours and 40°C for 4 hours. The mechanical properties, the structural, morphological and microchemical characterization of metakaolin, silt powder and the geopolymers were carried out by means of unconfined compression tests (UCT), X-ray diffraction and ESEM-EDS analysis. Results have underlined that the curing process at 40°C generally improves the mechanical performances of the mixed Na^+/K^+ geopolymers compared to higher curing temperatures products. The maximum fracture stress obtained was approximately 21 MPa at 40°C. The use of a filler resulted in composites with mechanical properties similar to those of the sole binder, meaning that the performance was not degraded by adding the waste silt. ESEM imaging showed the presence of some inhomogeneities (cracks and voids of few micrometers) in the products. The proposed material that safely uses a waste by-product (end-of-waste) and reduces the carbon footprint by geopolymerization could be suitable for low-strength concrete applications, such as in semi-rigid or rigid road pavements.

Multi-methodological analysis of orpiment As_2S_3 and related possible applications in bidimensional optoelectronics

Ulian G.* & Valdrè G.

Dipartimento di Scienze Biologiche, Geologiche e Ambientali, Università di Bologna.

Corresponding author email: gianfranco.ulian2@unibo.it

Keywords: orpiment As2S3, 2D minerals, optoelectronics.

Orpiment, whose chemical formula is As_2S_3 (space group $P2_1/n$), is a well-known mineral since ancient times because of its use as yellow and golden pigment, hence its Latin name after *auripigmentum* (Bonazzi & Bindi, 2008), which can be commonly found in veins and hot-spring deposits (Gaines et al., 1997). Besides its use in artwork and in the extraction of arsenic, As_2S_3 is a very important phase in materials science and optoelectronics for its semiconducting properties. Furthermore, from the crystallographic perspective, orpiment is made of layers of arsenic sulphide stacked along the [010] direction, thus the mineral presents a heterodesmic structure with strong covalent in-plane As–S bonds and weak van der Waals interactions between the As_2S_3 layers. It is worth noting that the cited layers are not atomic-flat like, for instance, as graphene or mica, but present a puckered surface.

Considering the growing interest in bidimensional, easily cleavable minerals and materials presenting peculiar electronic and optical properties, orpiment could be an important candidate for advanced use in optoelectronics and other related physical applications.

In the present work, we report a detailed experimental and theoretical characterization of the crystallographic, physical (electronic and optical) and vibrational properties of orpiment. On the experimental side, we performed X-ray powder diffraction (XRPD), environmental scanning electron microscopy (ESEM) with energy-dispersive microanalysis (EDS) and confocal Raman microspectrometry on a natural sample of orpiment provided by the "L. Bombicci" Mineralogy Museum (Bologna). This knowledge was corroborated by theoretical simulations carried out within the Density Functional Theory (DFT) with the CRYSTAL code (Dovesi et al., 2018) to provide further data at the atomic scale and help the interpretation of the results. We employed throughout the work all-electron Gaussian-type orbitals basis sets on As and S atoms and hybrid functionals (B3LYP and HSE06), including long-range interactions in the physical treatment via the DFT-D3 correction (Grimme et al., 2015). We also simulated the exfoliation of orpiment, considering different models with decreasing thickness (i.e., number of layers). The results show that the bulk mineral has a semiconducting behaviour, with band gap energy Eg = 2.44 eV, which increases up to 3.17 eV when it is exfoliated down to a single layer. The surface formation energy, which is directly related to the cleavage, is almost constant, meaning that the exfoliation of flakes with different thicknesses is not hindered by energy contributions. The phonon dispersion relations calculated for the bulk and layered mineral did not show any imaginary phonon band, hence all the structures are thermodynamically stable. All the measured and calculated properties provide further insight into orpiment as a suitable large-band semiconductor mineral for optoelectronics and other advanced technological applications.

Keywords: alkali-activated materials, sawing sludge, circular economy.

In recent years, a growing awareness of environmental issues has risen, leading to the promotion of actions aimed at reducing the negative human impact of on our planet. These attempts have led to set ambitious goals to lower CO_2 emissions, with a view to a greener and more sustainable future (Ramón-Álvarez et al., 2023). In order to accomplish this target, a significant management of natural resources is necessary to protect the ecosystems and biodiversity. The stone industry, crucial for the development of the construction field, has to deal with different issues such as high production costs, energy and water consumption as well as its large amount of derived wastes, among them sawing sludge. This latter, constituting approximately 30% of the total sawn block volume, represents important environmental and health issues when improperly managed and disposed in landfills (Coppola et al., 2020). Within this context, Alkali Activated Materials (AAMs) offer a promising deal through the recycling of wastes to use as precursors for the synthesis of new materials in a sustainable process, which takes place at room temperature. Some attempts by other authors have already successfully explored and validate the feasibility of producing AAMs starting from different sawing sludges, including basalt and marble powders, to be applied in the fields of construction and restoration (Portale et al., 2023; Salihoglu & Salihoglu, 2018).

In this work, the potentiality of using Cuasso al Monte sawing sludge (FC), sourced from late-Hercynian granitic plutons renowned for their ornamental and structural properties, as a precursor for AAMs production was explored. Moreover, metakaolin was added to FC enhancing the reactivity of the system in turn activated using solutions made of sodium silicate (Na_2SiO_3) and 8M sodium hydroxide (NaOH). Cubic samples (2x2x2 cm) were cured at room temperature for 28 days. Mineralogical analysis was carried out by X-ray diffraction method (XRD) on both raw materials and synthesized binders, while uniaxial compressive strength (UCS) tests on consolidated binders. The XRD results showed the formation of an amorphous phase on the consolidated samples, testifying the occurrence of the polycondensation reaction.

Moreover, the AA-binders recorded an average compressive strength up to around 30 MPa, demonstrating the suitability of using FC as a precursor for the development of alternative materials for the construction field, in a perspective of eco-conscious construction practices.

Keywords: alkali-activated materials, recycle, waste materials.

In light of escalating ecological and climate challenges, there is a shift towards mitigating the environmental footprint of the construction sector. Therefore, the development of alternative materials is crucial. This study aims to explore the potential of utilizing waste materials such as nonrecyclable glass from Johns Manville company (*E*-fiber glass producer, Slovakia) and volcanic ash from Mt. Etna (Italy) in the process of alkaline activation. Waste glass, which amounts to an annual production of about 200 tons, poses a significant environmental challenge (Xiao et al., 2022). Similarly, volcanic ash from Mt. Etna is considered solid municipal waste and disposed of in landfills if not used in a safe and innovative and process. Previous research demonstrated the feasibility of using similar materials for AAMs production with interesting properties (Adesina et al., 2022; Scanferla et al., 2023). In particular, this work aims to realize AA-pastes using mixtures of volcanic ash and waste glass from glass fibers in borosilicate system as precursors, with two mix proportions (40-60 wt.% and 20-80 wt.% of waste glass and volcanic ash respectively) activated with 7M and 9M potassium hydroxide solution and cured at 60°C for 4 days. A multidisciplinary approach was performed, including: a feasibility study to assess if the final materials could withstand up to 3 hours in boiling water; XRD to investigate the differences in the crystalline phases between raw materials and the final samples obtained; FT-IR and SEM-EDX analysis to evaluate the gel formation and the surface morphology; Inductively coupled plasma mass spectrometry to investigate the potential for heavy metal release; compressive strength tests and helium pycnometer measures to quantify and evaluate the influence on the mechanical properties of the different reactants involved in each mix design related to the samples porosity. The results have shown that all formulations studied are feasible, with enhanced mechanical performance for the mixtures with lowest volcanic ash content, for both molarities of KOH, achieving values of approximately 20 MPa. Porosity decreased with the increase of alkali concentration, from approximately 25% for 7M to 21% for 9M. Carbonated and hydrated phases were identified from both XRD and FT-IR analysis, sign that the reaction among glass, ash, and alkali took place to form a stable gel. Grains of glass and ash are visibly embedded into an Al-Si-Ca matrix, as highlighted by SEM and EDX. These outcomes lay the groundwork for potential using of these mixtures in additive manufacturing process for the production of building elements made mainly of waste-based materials.

In the last years, United Nations are paying much attention to sustainability's theme, with several environmental targets to be reached. One of these targets is aimed at taking action for a responsible consumption and production, preserving as much as possible the extraction of natural raw materials as well as to limit the disposal of manufacturing subproducts and wastes (Zanelli et al., 2021).

In light of this, we have explored the possible reuse of fired ceramic scraps (FCS) into the ceramic production (at 12 and 21 wt.%), with particular focusing to the sanitary-ware cycle (Bernasconi et al., 2011), in partial substitution of natural raw materials such as quartz and feldspar. The results show that FCS reuse is feasible because the largest part of technological constraints are respected with the exception of the alpha linear thermal expansion of the fired body (αL, body), whose value tends to a progressive diminution as FCS content in the recipe is increased, with deleterious outputs if the ceramic body is glazed (Plesingerola & Kovalcikova, 2003).

Application of diffraction techniques (both RIR-Rietveld - Gualtieri, 2000 - and in-situ experiments) demonstrated that the body thermal expansion reduction is mainly addressed to phase fraction changes, with the largest effect due to the decrease in quartz content. Differences in the glass thermal expansion coefficient have been also highlighted as well as some residual stress at the quartz-glassy matrix interface.

These findings are important to figure out a possible slip composition that maintains the αL, body within tolerances also in presence of FCS, possibly with the introduction of other waste materials.

Bottom ashes from MSWI in ceramics: a higher value reuse of waste

Bernasconi A.[1], Mantovani L.[2] & Tribaudino M.*[1]

[1] Dipartimento di Scienze della Terra, Università di Torino.
[2] Dipartimento di Chimica, Scienze della Vita e della Sostenibilità Ambientale, Università di Parma.

Keywords: MSWI, bottom ashes, tiles.

In Europe about 30 Mtons of bottom ashes (BA) from incineration plants are produced every year. Not more than half is reused, most after quality-upgrade treatments as a substitute for natural aggregates in road building or other construction related activities (Chen et al., 2023). Higher value applications are being sought, such as in the production of ceramic tiles, where careful processing and mixing are required to ensure compatibility with the ceramic matrix and to meet the necessary quality standards. However, research in this field is still in the preliminary stages (Namkane et al., 2016). The criticalities in the addition of BA in ceramics are: 1) the detrimental effect on the rheology of the paste from Cl and sulphates, 2) the behaviour under high temperature furnace heating, and the effect on technological properties 3) the release of potentially toxic elements in the manufactured product.

In this investigation, we explored the possible use of BA in sanitary ware ceramics. Sanitary ware is challenging due to strict technological and aesthetic constrains. BA were added to a standard industrial (SI) paste, used in sanitary ware production. We observed that the use of BA negatively affects rheological properties, likely for the dissolved salts. An improvement was observed if the BA were therefore sieved, and the coarser fraction was used (> 8 mm), after milling and repeated washing. Heating through a ceramic route produced the samples of interest. Each sample was analysed by XRD and XRF before and after each run; leaching tests were done, and ICP-MS were performed on the leachate.

Preliminary results show that addition of coarse and washed BA is not detrimental to rheological and technological properties of the paste and products. However, leaching tests on heated BA alone showed that increasing the heating temperature not all elements are efficiently immobilised. Elements such as Cr and V are strongly immobilized, Ti, Mn, Fe, Co, Zn and Pb increase their concentration in the leachate while for Ni, Cu, and Cd their behaviour is not clear. Leaching tests on sanitaryware ceramics with added BA are in progress. The reuse of BA in sanitary ware ceramics is a strong opportunity in circular economy, but upgrade treatment are required, as simply heating BA may not guarantee the immobilization of potentially toxic elements.

The CLEAN project: a sustainable methodology to reduce the environmental impact of MSWI fly ash and to recover strategic metals

Caviglia C.*[1], Bernasconi D.[1], Destefanis E.[1], Wehrung Q.[1], Brombin V.[2], Mancinelli M.[2], Martucci A.[2], Mantovani L.[3], Bonadiman C.[2] & Pavese A.[1]

[1] Dipartimento di Scienze della Terra, Università di Torino. [2] Dipartimento di Fisica e Scienze della Terra, Università di Ferrara. [3] Dipartimento di Scienze Chimiche della Vita e della Sostenibilità Ambientale, Università di Parma.

Corresponding author email: caterina.caviglia@unito.it

Keywords: MSWI FA, steam washing, heavy metals absorption.

Municipal solid waste fly ash (MSWI FA) is classified as hazardous waste due to its high metal and soluble salt content, giving rise to environmental risks upon its reuse. Multi-step washing proved highly effective, notably in chloride removal, yet often requires substantial water volumes (Ferraro et al., 2019). Therefore, water washing poses challenges including high water consumption, substantial wastewater generation, heavy metal enrichment, and potential secondary environmental contamination. The CLEAN project, funded by the Ministry of the Environment and Protection of Land and Sea, introduced the steam washing (SW) to reduce chloride and metal concentrations in FAs, exploiting the steam available in waste-to-energy plant, as a sustainable solution to decrease the volume of these residues and make them more suitable for stabilization, since the reduction of alkali chlorides (including KCl, NaCl) can improve fly ash mechanical and geotechnical properties as mechanical strength. While SW wastewater is rich in trace elements, investigations were conducted to recover heavy metals (Cr, Ni, Cu) for the raw-secondary materials market.

Detailed elemental characterizations of solid matrices (pre- and post-SW) and liquid matrices (leachates, wastewater) were carried out, by X-ray fluorescence (XRF), X-ray diffraction (XRD), and inductively coupled plasma mass spectrometry (ICP-MS). The results of leachates analyses of samples treated by SW show that steam washing was efficient in removing especially water-soluble chlorides including sodium chloride, potassium chloride (up to 80%) and sulfates (by 30%); while for heavy metals, like Cd, Zn, Pb, the removal was up to 80%, even at short time of treatment (15-30 minutes). It was noted a decrease of concentration all for trace elements, excluding Sb, (only 70% and higher than the legal limits), which still requires particular attention and study. Results about solid residues indicate metals like Cr (300 mg/kg), Ni (65 mg/kg), Cu (1500 mg/kg), and Sb (1800 mg/kg). After a 40% weight loss of FAs post-washing, there is a 80-90% surge in these elements per kg of ash. Residual washing water has high metal concentrations: 6000 mg/L Zn, 400 mg/L Pb, and 250 mg/L Cd, corresponding to approximately 15%, 10%, and 70% extraction from FAs (considering SW uses a 1.5-2.0 liquid-solid ratio).

Analyses for the elemental characterization of wastewater are underway after absorption and recovery of metals by minerals like zeolites. Three synthetic zeolites and a natural zeolite has already tested showing that Zn, Cd and Pb are successfully removed (reduction by about three orders of magnitude), using zeolites with low Si/Al (Si/Al~ 1.3; 1-2); whereas Cd is better adsorbed by more alkaline zeolite.

Complexity of the system and plethora of crystal phases in fly ashes: a careful investigation of processes and products from cooling of the flue gas in the MSW waste-to-energy incinerators

Curetti N.*, Bernasconi D., Servetto G.P., Vigliaturo R., Tribaudino M. & Pavese A.

Dipartimento di Scienze della Terra, Università di Torino.

Corresponding author email: nadia.curetti@unito.it

Keywords: fly ashes, melted drops, waste management.

The chemical-physical complexity of the material recovered from filters located along the path of the flue gases in the municipal-solid-waste incinerators (fly ashes - FA) is well known. FA are materials composed of a significant easily-soluble fraction, carrying highly volatile heavy metals, chlorides and sulfates, and classified as "hazardous" (Bernasconi et al., 2022). The samples investigated in this work were collected at the waste-to-energy plant of Turin (Orbassano - Iren Group Company). In this plant, the fly ashes deposited in the empty pass, in the boilers and in the electrostatic precipitators (EA, BOA and ESTA in Wolffer et al., 2021) are not differentiated, so that the samples under study are a mixture of them.

We have performed a preliminary characterization of the bulk original and washed ashes, using X-ray powder diffraction (XRPD) and transmission electron microscopy (TEM), with a focus on the detection and evaluation of the amorphous portion.

Then, we have attempted a new approach, which is to simplify the system by analyzing small portions of sample separately, and using XRD, SEM and EDS. More than 30 samples were selected on the base of optical features, glued to the tip of a capillary and analyzed by X-ray diffraction. Three main types of materials were classified:

I) isolated crystals SC of variable size (up to about 200 μm). Some of them show an idiomorphic habit and the morphological forms are well recognized. In most cases, the crystals are irregularly shaped and include impurities that make them opaque in transmitted light;

II) porous particles PP formed by aggregated of loosely cohesive crystalline phases (up to about 800 μm). The porous particles and the crystals forming them have variable size, color and aspect. Some of the crystals forming the aggregates exhibit an idiomorphic shape, presumably because of the inter-crystal voids that enable development of faces;

III) more compact spheroidal particles MD with smooth and shiny surface (up to about 500 μm). Specimens of such a type often show one or more spherical cavities within. The spheroidal shape, the smooth surface and the occurrence of "bubbles" point to them being products of a solidification from molten drops bearing dissolved gas. The MD can be viewed as a "closed" system (no exchange of matter) and their crystals can form an equilibrium paragenesis.

A noticeable number of crystals have been identified: quartz, cristobalite, anhydrite, feldspar, olivine, pyroxene, gypsum, hematite, gahnite, chromite, merwinite, monticellite, aluminum, corundum, periclase, perovskite, gehlenite-akermanite, calcite, ettringite, halite, sylvite, grossite, apatite, merrillite-whitlockite, Si-carbide, Ba-sulfide. This approach highlighted that FA is a very complex material, not only as a result of the many chemical species involved, but also because several crystallization processes take place, leading to different products, each one related to its conditions of formation.

Keywords: inertization, industrial by-products, geopolymers.

In the framework of the circular economy, the recovery, processing, and reuse of industrial byproducts are topics that stakeholders support to achieve environmental targets such as resource management efficiency, industrial process optimization, and the reduction of environmental impact (including waste output, gas emissions, and sustainable use of raw materials).

A case study is represented by the secondary aluminum industry, which deals with special hazardous waste from screening, pyrolysis, and fusion processes. According to European Union regulations, such materials cannot be disposed of in normal landfills due to the high concentration of toxic substances and the potential development of hydrogen-enriched gases that can form explosive mixtures with air.

Experimental studies (Ercoli et al., 2021) were developed for a procedure that leads to a full chemical neutralization driven by the oxidation of metallic components in a stainless-steel batch mini reactor. Firstly, by controlling the process in an alkaline solution to study gas generation. Secondly, identifying correlations between the change in mineralogical phases and specific parameters such as loss on ignition (LOI) of the residues after the experiments.

Additionally, further procedures were planned to dilute and trap the pollutants within innovative inorganic materials called geopolymers to demonstrate the possibility of reusing them as foaming agents (Nguyen et al., 2022). The influence of foam generation on the density of geopolymers was deeply investigated, highlighting the physical properties, such as mechanical strength, thermal conductivity, specific heat, and thermal diffusivity (Ercoli et al., 2022). Leaching tests were performed to obtain preliminary results on the interaction and affinity of toxic elements with the structure of the geopolymer.

Processing these types of by-products represents a sustainable approach to waste management, thereby avoiding the risks associated with direct storage before chemical neutralization and the long-distance transportation to landfills for hazardous waste materials. Incorporating the industrial by-products into geopolymers provides a potential solution for their reutilization. It offers a promising alternative to Portland cement manufacturing, which demands large amounts of energy and emits approximately 80% more CO_2 (Krishna et al., 2020).

In conclusion, this experimental research aims to provide significant insights into waste management, offering economic and environmental benefits based on thorough mineralogical and physicochemical characterization of the products, exploiting advanced analytical techniques.

Keywords: by-products, ashes, fertilizer.

Various industries are paying growing attention to the importance of sustainability and environmental responsibility. This entails efforts to reduce waste, optimize resource usage, and minimize environmental impacts. Particularly, there is increasing interest in finding innovative ways to repurpose industrial by-products and waste materials, transforming them into valuable resources. This aligns with regulatory frameworks such as Directive 2008/98/EU, which promotes efficient waste management practices.

In the mineral fertilizer industry, there is a reliance on non-renewable mineral resources to produce fertilizers that support agricultural productivity. However, there is a growing recognition of the need to transition towards more sustainable practices by incorporating waste materials and implementing processes to transform them into valuable products.

One notable area of focus is the recovery and utilization of cogeneration ashes, which are generated from the incineration of biomass for electricity production. These ashes have been recognized for their potential as sources of essential plant nutrients, such as potassium, phosphorus, magnesium, and calcium. Additionally, due to the presence of basic cations in the form of oxides, hydroxides, and carbonates, these ashes can be an effective soil amendment (Freire et al., 2015; Maresca et al., 2017; Cruz et al., 2023).

From this perspective, this study aims to investigate the potential, from a mineralogical and chemical point of view, of cogeneration ashes in order to recover elements and minerals useful for plant growth and, at the same time, to reduce the landfills disposal in accordance with the principles of the Circular Economy.

In this study, eight samples of vegetal biomass ashes, comprising four fly ashes and four bottom ashes from different cogeneration plants, producing electricity through the combustion of agroforestry residues, were characterized using a multi- methodical approach. Various chemical, mineralogical, and microstructural analysis techniques, along with physical-chemical treatments, were applied to evaluate their content of phytoavailable components, occurrence of harmful substances, and viability as a sustainable resource for mineral fertilizer production.

Results reveal significant physical and chemical variability in fly and bottom ashes derived from various agroforestry residues. This variability is associated with factors such as the type of incinerator, combustion temperature, ash type and particle size of ashes. However, chemical analyses indicate the presence of substantial concentrations of K_2O, CaO, and MgO in all investigated samples, while leaching tests and mineralogical analysis reveal relevant water-soluble mineral phases that may be available to plants. Furthermore, investigations show the occurrence of basic cations in the form of oxides, hydroxides, and carbonates, which could be an excellent amendment to deal with soil acidity and compensate for the loss of nutrients.

Keywords: solid waste residues, characterization, pandemic, radionuclides, radiation hazard.

Municipal Solid Waste Incineration (MSWI) plants generate significant amounts of solid wastes such as Fly Ash (FA) and Bottom Ash (BA). These MSWI residues have received attention due to the presence of potentially toxic elements and significant isotopic fractionation (Funari et al., 2016). Knowledge and data coverage on activity of naturally occurring radionuclides such as polonium (^{210}Po), uranium (^{235}U, ^{238}U), radium (^{226}Ra), and potassium (^{40}K) in MSWI residues (e.g., Janković et al., 2011) is limited so far, even though such a kind of exploration is necessary to evaluate the potential of radiological hazard and environmental impact fully. Here, available types of BA and FA included samples from bag filters treated with soda additive (FAS) and lime additive (FAL), and quenched BA samples from grate-furnace MSWI plants, located in Northern Italy. Both BA and FA were sampled during pre- (2013) and post-pandemic period (2022). In this study, the main objectives were to determine and compare the radionuclides (^{210}Pb, ^{40}K, ^{226}Ra, ^{232}Th, ^{137}Cs, ^{241}Am, ^{131}I) concentration in MSWI samples to evaluate their abundance by Enrichment Factor (EF), and total radionuclide emissions with radiological impact. Gamma spectrometric analyses results showed that naturally occurring radionuclides (^{210}Pb, ^{40}K, ^{226}Ra, and ^{232}Th) were higher for FAL rather than FAS and BA, while the anthropogenic radionuclides (^{137}Cs, ^{241}Am, and ^{131}I) were comparatively low in all ashes for both periods. The EF showed that radionuclides were enriched in FA and BA with low to high enrichment level, as ^{40}K and ^{210}Pb being the most elevated nuclides. Activity Concentration Index (ACI) results of all radionuclides were found below the permissible limit (< 1), as recommended by the European Commission (1999), suggesting no potential radiological hazards in the external environment. The total emission factor of natural radionuclides based on regional estimation point to a potential risk of radiological hazard.

Keywords: MSWI-BA, environmental mineralogy, PTE.

The ever-increasing production of waste on a local and global scale is driving scientific research to investigate and deeply understand materials for their potential reuse in a circular economy. In this context, bottom ash (BA) from Waste-to-Energy (WtE) plants plays a paramount role, as it not only represents the majority (about 80% by weight) of the plant's output but can also be considered a valuable resource for new materials. Indeed, currently, BA has been used for various applications such as filler material in road construction and foundation material in noise barriers. However, in many regions, it is still mostly left unused and ends up in landfills (Gooi, 2020). Bottom ash is largely composed of silico-aluminates of Ca, Fe, Na, and K, both as amorphous and crystalline structures. The main problem associated with their use lies in the strong heterogeneity of the material, especially regarding the minor elements that these residues may contain and release into the environment over time during their utilization (Mantovani et al., 2023). The release mainly concerns heavy and potentially toxic elements (PTE), which are commonly leached even when BA is incorporated into other materials and subjected to heating processes (i.e., ceramic processes)(Ardit et al., 2022).

In this work, BA from the Parma WtE plant is treated at different temperatures (from 200 to 1250°C) and characterized using in-situ techniques (XRPD) and ex situ techniques (XRPD, SEM-EDS, Raman spectroscopy and XRF) to investigate the modifications of the material under different treatments. Additionally, leaching tests were conducted after each treatment to assess the release of elements. Preliminary results have shown that: a) the bottom ashes begin to melt at a temperature of 1150°C, releasing various gases and exhibiting a highly vesicular structure, b) despite the high-temperature firing process, all samples from 200 to 1150°C exhibit significant heterogeneity, especially at the microscopic level, c) the increase in temperature promotes the formation of wollastonite, melilites, pyroxenes, and feldspathoids together with amorphous materials, but small agglomerates of metal compounds are still present, d) leaching tests showed that the increase in heating temperature strongly immobilizes certain elements such as Cr and V, while Ti, Mn, Fe, Co, Zn, and Pb increase their concentration in the leachate. Other elements such as Ni, Cu, and Cd do not show a particular trend. The main outcome is an outlook about reuse of BA after treatments. The high temperature treatments of BA can be a way to reuse them as they are or combined with other materials, but it's necessary to assess in details the heterogeneity of the material, especially regarding the behaviour of the metallic phases and alloys.

Keywords: phosphorus, fertilizer, microwave heating.

The majority of phosphorus (P) supply within the European Union originates from Morocco, while the demand for fertilizer continues to escalate. These dynamics raise significant concerns regarding supply stability and market volatility (Schoumans et al., 2015). This study aims to characterize sewage sludge ashes resulting from mono-combustion of municipal sewage sludge, identifying them as a potential resource for P recovery and fertilizer production, in line with circular economy principles. The ashes underwent comprehensive analysis, including chemical analysis via ICP-MS for total P and heavy metal (As, Cd, Cr, Cu, Hg, Ni, Pb, and Zn) composition, X-ray diffraction, and quantitative phase analysis (QPA) to examine phosphatic crystalline structures and to highlight the amorphous content. SEM-EDS analysis facilitated the identification of various P-compounds within the ash, enabling correlation between quantitative data from QPA and ICP-MS regarding crystalline and total P content. The as-collected ash samples contained P in various crystalline compounds such as whitlockite ($Ca_{9.5}Mg_{0.5}(PO_4)_7$), hydroxyapatite ($Ca_5(PO_4)_3(OH)$), monetite ($CaHPO_4$), and tetra-potassium pyrophosphate ($K_4P_2O_7$), with total crystalline P ranging between approximately 3-4 wt.%, while the total P content ranged between approximately 4-8 wt.%. However, the bioavailability of P in both crystalline and non-crystalline states was found to be low or absent, as typical of sewage sludge ashes (Kasina et al., 2023). Subsequently, the ashes underwent thermochemical treatment at various temperatures using an innovative approach utilizing microwaves (MWs) instead of conventional heating sources. The treatment involved mixing the ashes with two reagents - an additive and a reducing agent - in specific proportions. This treatment aims to enhance P bioavailability, following the AshDec® process mechanism, and to generate new crystalline P compounds, such as buchwaldite ($NaCaPO_4$) or $KCaPO_4$ orthophosphate, with higher bioavailability. Concurrently, the treatment led to a reduction in heavy metal content, volatilizing them due to their higher vapor pressure at the working temperatures (Xu et al., 2023). The treated ashes underwent a thorough characterization process, mirroring the earlier approach, ICP-MS, QPA, and SEM-EDS analysis. This comprehensive analysis aimed to evaluate the formation of new crystalline compounds and track the concentration trends of P and heavy metals following the treatment. Subsequently, several leaching tests were conducted to achieve the maximum solubility of P and the reduced solubility of the non-volatilized heavy metals. The results achieved through this new MW-technology are promising for the production of P-based fertilizers from sewage sludge ashes.

Functional recovery of Provincial Road no. 2 and management of waste materials: from waste to by-products. Experiences of the Province of Southern Sardinia in the reuse and cold recycling of geomaterials

Mureddu A.*

Provincia del Sud Sardegna.

Corresponding author email: mureddu.alessio@tiscali.it

Keywords: geomaterial reuse, recycling, cold recycling methods.

As part of the extraordinary maintenance and safety activities of the road heritage scheduled for the years 2022 and 2023 by the Road Service of the Province of Southern Sardinia, two functional lots of intervention were designed and carried out on Provincial Road no. 2, a four-way section travel lanes that connect the Municipality of Carbonia with the Municipality of Villamassargia.

The design parameters have been set in advance in order to optimize the "best practices" during the design phase, capable of reducing the production of intervention waste as much as possible in favor of the reuse of by-products of materials from milling and excavation. In this way, by reducing as much as possible the transfer of waste to landfill, it was possible to design an intervention capable of recovering the waste materials typical of traditional processes, in favor of less exploitation and supply of new natural resources.

The first design phases were set both through an in-depth analysis and overall study of the entire road axis, and with the recovery of previous prospecting and indirect investigations, carried out by the former Province of Carbonia Iglesias, which had carried out deflectometric and laser profiler tests on the entire road platform in previous interventions, starting from 2008.

These data were then compared with those acquired with the "Falling Weight Deflectometer" surveys carried out in May 2022. All the data concerning the elastic modules of the first layer (bituminous conglomerate), the second layer (granular or stabilized mix) and finally the background layer.

The parameters of the indirect investigations were compared with the stratigraphic ones acquired through a campaign of direct micro-cores carried out in May 2022, carried out within the first meter of depth, in order to calibrate the stratigraphic data present in situ with those of the indirect investigations. Subsequent processing concerned the verification of the load-bearing capacity of the stratigraphy of the pavements, as well as verification of the continuity and regularity of the seismic parameters developed for geotechnical purposes.

Compared to a "standard design" approach, by comparing various design hypotheses, the design hypothesis with cold recycling methods was chosen, then carried out with lime and cement treatment of the materials present in situ. This execution led to a decrease in excavation activities by 45%, a decrease in landfill disposal by 34%, the elimination (-100%) of the items regarding a new foundation layer, in addition to a 75% decrease in the bituminous conglomerate of basic.

The (less impactful) design approach carried forward, however, resulted in the obtaining of excellent functional results, verified with the execution of plate tests which highlighted exceptional results, thus being able to see how it is actually possible to match the functional needs of the project and reduction of the impacts of intervention on the environment.

Recycling of surgical masks into green products for the building sector

Ossoli E.[1], Ercoli R.*[2], Stabile P.[1] & Paris E.[1]

Keywords: surgical masks, geopolymers, circular economy.

The MASKVERDE project aims to explore the feasibility of incorporating surgical masks into geopolymer-based matrices to produce building materials. Initiated by Fondazione TIM in response to the COVID-19 pandemic, the project addresses the need for a sustainable method to dispose of surgical masks, whether unused or expired, which would otherwise end up in landfills. This approach aims to fulfill various environmental, social, economic, and industrial needs.

Surgical masks, provided by a collaborating school, underwent shredding using a Retsch Knife Mill SM 100 to produce fractions characterized by different sizes (1 and 2 mm lengths) of the three polypropylene layers, including nose wires and elastic bands.

Geopolymer samples were created by mixing various precursors such as metakaolin with sodium and potassium-based alkaline solutions. Different amounts of mask fragments (ranging from 1 to 5% by weight) were added to the mixtures, incorporating varied fiber grain sizes. Examination of the samples using optical and scanning electron microscopes revealed excellent textural characteristics, particularly in samples containing smaller fibers.

Leveraging the exceptional chemical and physical properties of geopolymers allows for tailoring specific technical attributes to meet diverse application requirements. Comprehensive physical-mechanical testing, including compressive and flexural strengths, density and porosity measurements, and various durability tests, has showcased promising attributes for integrating these materials into a wide array of construction products. These applications span both external and internal uses, as well as specialized panel preparation. In this regard, Life Cycle Assessment (LCA) will be of interest to determine the environmental impact.

Preliminary data indicate the feasibility of implementing an upcycling process for surgical mask waste, thereby diverting it from landfills and transforming it into a green material. Advancing understanding of these materials and their potential applications can play a significant role in promoting circular economy principles and fostering synergies among local industries.

Sustainable binders for the stabilisation of subgrade layers of road pavement by recycling of biomass ash, municipal solid waste incineration ash and concrete demolition waste

Pandolfi Balbi E.*[1], Comodi P.[1], Fastelli M.[1], Zucchini A.[1], Cambi C.[1], Corradini A.[2], Mantovani L.[3], Cerni G.[2], Bou Farhat H.[4] & Snellings R.[4-5]

[5] Department of Materials Engineering, KU Leuven, Belgium.

Corresponding author email: eliapando1@hotmail.com

Keywords: supplementary cementing materials, subgrade layers stabilisation, composite cement.

Road subgrade layers have the important task of absorbing and redistributing external loads from the more superficial and bituminous layers of the pavement. Low load-bearing capacity and large void variations in the subgrade can cause cracking and deformation of the road structure. During road construction, it is sometimes not possible to avoid soils with low bearing capacity, such as inconsistent soils, which do not meet the conditions required by technical regulations. Nonetheless, quarry materials are becoming scarce, and they are not considered environmentally friendly since the expansion of quarries implies many environmental problems and quarries are often located far from construction sites, consequently increasing costs and environmental concerns. For these reasons, this kind of lands are often treated with cement able to improve their physical and mechanical characteristics. However, the production of this stabilising agent is very harmful to the environment as it generates a large amount of CO_2, which then has a negative impact on the Earth's climate processes. Thus, to avoid this, the utilization of supplementary cementitious materials (SCMs) for the partial or total substitution of cement could represent a pragmatic solution to mitigate the CO_2 emissions of its production (Habert et al., 2020). Thus, this work concerns a mineralogical study for the stabilisation of subgrade layers belonging to road pavements through a complete replacement of Portland cement (PC) by combinations of natural pozzolan (NP) or metakaolin (MK) in association with waste materials coming from Italy, including wood biomass ash (WBA), municipal solid waste incinerator bottom ash (MSWI), calcined concrete demolition waste (cCDW) and not calcined concrete demolition waste (CDW). In this way, binders with a much lower CO_2 footprint and higher recycled content were formulated. In a first step, this study investigated the binding potential of the selected waste materials based on their physical, chemical, and mineralogical properties, as well as their reactivity using the R3 testing (Avet et al., 2016). In a second step, the total substitution of PC by various combinations of MK-NP-SCMs was studied in terms of impact on the cement hydration kinetics and phase assemblage by using of X-ray diffraction, thermogravimetric and calorimetric analyses. Results of R3 testing show that WBA and MSWI in addition with portlandite, calcite and a potassium solution, present significant reactivity. However, the mineralogical and thermogravimetric results show that WBA, needs to presence of an aluminosilicate source to allow the growth of new cement hydration phases. Results about MK-NP-SCMs blends demonstrate that mixtures subjected at 90 days of maturation, containing WBA and cCDW, have a considerable reactivity and formation of new cement phases such as ettringite, hemicarbonates and monocarbonates. Finally, on the most promising mixtures, proctor and unconfined compressive strength test are underway to confirm the binder formulation results.

Habert G. et al. (2020) - Environmental impacts and decarbonization strategies in the cement and concrete industries. Nat. Rev. Earth Environ., 1, 559-573, https://doi.org/10.1038/s43017-020-0093-3.

Wood biomass ash: a possible alternative to free lime and cement as stabilizing agent in clayey subgrade of road pavement

Pandolfi Balbi E.[1], Corradini A.*[2], Cambi C.[1], Fastelli M.[1], Cerni G.[2], Cotana F.[2], Zucchini A.[1] & Comodi P.[1]

Keywords: clayey soil stabilisation, mechanical analyses, supplementary cementing materials.

EU countries agreed upon increasing the use of renewable energy, which strongly stimulates the usage of biofuels for reducing CO_2 emissions. Following these goals, an increase in thermoelectric power plants powered by biomass is expected, which will cause an exponential increase in waste produced, thus making necessary their disposal. This work is aimed at researching and recycling wood biomass ashes (WBA) coming from the Umbria region (Italy), to be used as stabiliser for clayey soil belonging to the same area.

Based on the results of the initial lime consumption test (ICL), several samples were prepared by adding to the clay soil the amounts of lime and biomass ash that result in a pH value of 12.4. Furthermore, densification properties of studied mixtures were investigated carrying out standard Proctor compaction test. Data collected from these tests, performed on both the raw soil and the stabilized blends, made it possible to relate the Optimum Moisture Content to the dry density achieved in each mixture and to create mixes initially characterized by the same dry density and water content.

Such samples were then subjected to different curing time and analysed by mechanical tests such as UCT (unconfined compression test) and swelling tests to perform a comparative analysis among studied samples. At the same time the chemical-mineralogical evolutions of the different blends were monitored using X-ray powder diffraction (XRPD), thermogravimetric (TGA) and energy dispersive X-ray spectroscopy analyses coupled with scanning electron microscopy (EDS-SEM).

The results of ICL test showed that WBA provides a sufficiently alkaline environment, therefore two mixtures were prepared by adding two different WBA to a clayey soil, which needs stabilization as it is not suitable for any purpose construction in its natural state. The addition of ash causes a reduction in both soil plasticity and maximum dry density, an increase in optimal moisture content and a shift towards coarser size of grain distribution. Furthermore, the addition of ash to clay soil provides a positive impact on bearing capacity and swelling, as well as both short-term and long-term compression parameters. The chemical-mineralogical characterization of the treated soil, together with TGA, show the formation of new cementitious phases as the curing time increases. The results obtained indicate the possibility of reducing the use of traditional binders on road pavements (lime and cement) by incorporating WBA which are widespread and readily available in many geographical areas. This translates into a reduced environmental and economic impact as no extraction, processing or transport of raw materials is necessary.

Petrographic variation of CDW in an industrial plant: a case from Central Italy

Radica F.[1-2], Iezzi G.*[1-2-3], Piccioni R.[4] & Bernardini V.[4]

[1] Dipartimento di Ingegneria e Geologia InGeo, Università "G. d'Annunzio" di Chieti-Pescara. [2] UdA-TechLab, Research Center, Università "G. d'Annunzio" di Chieti-Pescara. [3] Istituto Nazionale di Geofisica e Vulcanologia, Roma. [4] S.A.M.I.C.A., Martinsicuro (TE).

Corresponding author email: g.iezzi@unich.it

Keywords: CDW (construction and demolition waste), concrete, petrography.

Construction & demolition waste (CDW) accounts for over a third of the continental end of life (Eurostat, 2020). CDW are mainly made up of ceramic-like solids such as concretes, mortars, cementitious bindings (attached mortars or isolated cement pastes), bricks, perforated bricks, tiles, gypsum and rocks (CER-17.01). In addition, variable and relatively low levels (< 10/15 wt.% or vol.%) of ferrous and non-ferrous metals (CER-17.04) plus plastics, woods, and glasses (CER-17.02) can be present. Today, CER-17.01 waste is separated on-site or at the entrance of the plants from the other two categories CER-17.02 and CER-17.04; eventually, further treatment can liberate the CER-17.01 from these different materials (Serranti & Bonifazi, 2016). The ceramic-like CDW (CER-17.01) is then crushed into different grain size classes and resold for applications with low values and structural performance in the construction sector. The very low cost (a few euros per ton) of CDW is related to their extremely high petrographic and physical-mechanical variability, which determines downcycling reuses (embankments and fillings). Alternatively, a homogeneous stream of CDW with well-defined and stable physic-mechanical performance can be adopted even as aggregates for structural concretes. In this optic, several studies concerning the durability of recycled aggregate concrete (e.g. Silva et al., 2014) and also the Italian building regulation (NTC2018, DM 17/01/2018 Italy) fosters the reuse of certified recycled aggregates from concrete (RCA), provided that a conformity certification is provided (End of Waste, DM n. 278 15/7/2022 Italy). Moving from this appraisal, in this work, we monitor the petrographic variability of the products of a CDW processing plant sited in Martinsicuro town (Central Italy). For 6 months, the same aliquot of ~3 kg of representative CDW were sampled every 2/3 weeks; these crushed CDW are either from decommissioning a nearby building or from the leftovers from concrete pours. Thus, they are strictly RCA. Each of the 8 sampled aliquots was first examined according to its mesoscopic attributes; these specimens have good to excellent segregation of the most significant aggregate fragments (size commonly ≥ 2 mm) from the cement paste. A representative fraction per each of the 8 aliquots was selected and then finely milled for XRPD (X-ray powder diffraction) characterization. XRPD results unveil that CDW have low mineralogical variations through time since most of the crystalline part of the samples is made of calcite (≥ 60/70 wt.%), followed by moderate to abundant quartz (≥ 10 wt.%), plus a few of feldspars and sheet silicates. Other spectroscopic and micro-chemical facilities will investigate the poor to non-crystalline phases related to the cement pastes to quantify the possible enrichment and depletion of all these phases in defined gran-size ranges after the typical comminution and sorting by sieving processes.

Keywords: circular economy, construction and demolition waste, materials characterization.

Cement manufacturing contributes to 7% of global CO_2 emissions, mainly from clinker production due to, on the one hand, the combustion of carbon coke and/or pet coke in firing kilns at temperatures around 1450°C, and, on the other hand, the decarbonation process of the raw materials. The decarbonization of cement industry and the reduction of its huge carbon footprint is a priority for the cement industry, to align with the EU's "net zero" goal by 2050. The main objective of this work is to optimize the recycling of construction and demolition wastes (CDW) through a process of thermal reactivation. The materials used come from the 2016 Umbria-Marche earthquake and are managed by Valle Umbra Servizi (VUS) of Norcia (PG). The procedure here texted, aims to dehydrate, and partially decompose the hydration phases of cement in concretes, generating a material with binding properties and with the mineralogical phases present in clinker so that it can be used as a partial replacement for cement. The range of reactivation temperature used was from 600 to 700°C, with an attempt to limit CO_2 emissions. The CDW before and after the heat treatment were characterized by a multi-analytical approach, using techniques such as X-ray powder diffraction (XRPD), field emission scanning electron microscopy (FE-SEM), X-ray fluorescence (XRF), thermogravimetric analysis (TGA), and calcimetry. Starting from a complete mineralogical characterization of concrete wastes, where the most abundant phases were calcite, quartz, and some C-S-H and C-A-H phases, the analytical protocol was conceived to evaluate the amount of the transformations of C-S-H and C-A-H phases and verify the quantitative presence of typical clinker phases (alite-C3S, belite-C2S, celite-C3A, ferrite-C4AF) after thermal reactivation, as a function of time and temperature of the heat treatment. Results show the presence of clinker phases in the treated samples, particularly C2S and C3A, in addition to portlandite (CH) and lime (CaO) at 700°C. The effect of different proportion addition of reactivated CDW (20 wt.%, 30 wt.% and 40 wt.%), in place of traditional cement in a mortar, on the mechanical properties will be presented as obtained by flexural and compression tests, according to UNI EN 196-1. Optimizing the recycling of CDW would have a positive impact on the environment: far lower thermal reactivation temperatures than those used for clinker firing would be used and CO_2 emissions related to clinker production would be reduced. Their reuse would promote the recycling of waste materials that would otherwise end up in landfills, in line with the principle of a circular economy. Finally, the recovery of the waste materials would be optimized by producing a new second-generation binder for being used both in geotechnical applications and in the construction industry.

Time-temperature-crystalline behavior of thermally treated MSW bottom ashes

Stabile P.*, Ercoli R., Paris E. & Carroll M.R.

Scuola di Scienze e Tecnologia, Dipartimento di Geologia, Università di Camerino.

Corresponding author email: paola.stabile@unicam.it

Keywords: bottom-ashes, thermal treatments, crystallinity.

The crystallization behavior of municipal solid waste (MSW) bottom ashes thermally treated at 1000°C and 1100°C for 1, 2,4, 8, 16 h has been investigated by powder X-ray Diffraction, Scanning Electron Microscopy (SEM) and Raman spectroscopy to distinguish between the crystalline and the amorphous phases.

The MSW bottom ashes considered for vitrification treatments fall within (~80-95 wt.%) the CaO- Al_2O_3-SiO_2 (CAS) system (Caurant, 2017; Karamanov, 2009), with relatively high CaO (17.20 wt.%), FeO_{tot} (16.31 wt.%) and Al_2O_3 (9.31 wt.%), and low SiO_2 (46.05 wt.%) and alkali content (ca. 5 wt.% Na_2O+K_2O). Minor elements composition (ppm) accounts for Cl (8730), Cu (6595), Ba (1458), Pb (1335), S (1000), Cr (915), Ni (277) (Stabile et al., 2019).

The main mineralogical phases present in the starting BA samples are quartz, gehlenite and calcite. The crystalline phases that usually form in the waste-based glass ceramics produced by thermal treatments are, therefore, silicates: typically, calcium-bearing silicates and aluminosilicates and sometimes spinel (including magnetite) (Isa, 2011). In fact, X-ray diffraction (XRD) analysis carried out on the treated samples revealed that the most abundant phases were high-T Ca-rich phases, like wollastonite ($CaSiO_3$), gehlenite ($Ca_2Al_2SiO_7$) and diopside ($MgCaSi_2O_7$). In particular, the crystalline phases were mainly identified as quartz and gehlenite and wollastonite in samples treated at 1000°C and diopside in samples annealed at 1100°C. XRD also indicated a variable degree of crystallinity (DOC) in the range of 30-50% in bottom ashes treated at 1000°C and 1100°C. Additional treatments at 1200°C for different durations (2, 4, 24 h) resulted in homogenous and completely glassy products as macro- appearance. SEM observations confirmed from completely to extensive vitrified areas of the products treated at the highest T. On the other hand, in the crystalline sample (in BAs treated at 1000 and 1100°C) the morphology of crystals has been investigated by SEM images; in particular, needle-shaped morphology of wollastonite and common tabular habit of gehlenite were observed in products obtained at 1000°C. The tendency of specific phases to crystallize, their distribution and crystallization rate is the focus of this study.

The comprehension of factors controlling the crystalline behavior of thermally treated bottom ashes is, in fact, important for the manufacturing of these glassy materials, whose physical properties can be of application in various fields, from the glass and ceramic industry to technological applications.

Vitrification processes can represent an important solution to avoid storage of this type of waste in landfills, also producing valuable glass or glass -ceramic materials, chemically stable, useful for the immobilization of potentially harmful heavy metals eventually present in them. In this regard, leaching tests, that can give useful insights, are in progress.

Keywords: waste-based glasses, Raman spectroscopy, polymerization/viscosity.

Among different waste treatments, vitrification has been considered one of the most promising, producing a chemically stable material, which can immobilize toxic elements in its vitreous structure (Sanito et al., 2022).

Here, mixtures of different waste materials, e.g. ceramic and glass waste, incinerator bottom and fly ashes, added to construction and demolition waste (CDW), were subjected to vitrification experiments at 1200°C, ambient pressure and 8 h duration in a chamber furnace (Stabile et al., 2023).

The obtained products were mineralogically and chemically characterized by EMP, SEM-EDS and XRPD, exploring the distribution of the mineralogical phases as a function of the waste used at increasing amounts (from 30 to 70 wt.% of different waste materials added to a starting CDW fraction). The resulting vitrification products present a maximum amorphous content (i.e. 100 wt.%) in mixes made of CDW added with 70 wt.% ceramic waste materials (e.g., roof tile, ceramic powder). Referring to the CAS system, the best vitrification results were obtained when the waste mixture composition fell in the area close to the thermal minimum at 1170°C (Stabile et al., 2023).

The waste-based glasses or glass-like products were also characterized by micro-Raman spectroscopy to investigate the crystalline and the glassy content. By increasing the content of the waste added to CDW, the amorphization of the products emerged, exhibiting the typical Raman features of glass. On the other hand, in the products with higher content of CDW, crystalline phases were also detected, including mineral phases already present in the precursor materials (like calcite or gypsum) and newly formed high-T phases (like gehlenite, pseudowollastonite and minor amount of sulphates).

The distribution of Qn species (tetrahedrally coordinated cations with n bridging oxygens) was estimated from the Raman bands of glass features, by deconvoluting the stretching vibrations of the Qn units. Raman spectroscopy allowed us to describe the degree of polymerization of the different products. Some products, i.e. CP70, (containing 70 wt.% of ceramic added to CDW) showed higher content in Q3 and Q4 than Q1 and Q2, resulting in more polymerized glasses.

Further, a differential scanning calorimetry (DSC) approach has been adopted to retrieve the viscosity of these products (Di Genova et al., 2020; Stabile et al., 2021).

These results can be of relevant importance for the waste reuse in the glass industry, with particular attention to specific glass manufacturing processes (fining, molding, annealing) where viscosity plays a key role.

Keywords: circular economy, 3D printing, cultural heritage.

Every year in Italy, several thousand tonnes of eggshells, mollusc shells, fish bones and animal bones are stored as food waste (Food and Agriculture Organization of the United Nations, 2021), creating problems in their disposal. These biowastes are an important reserve of carbonate and phosphate that could be used as potential precursors in the production of useful biomaterials, limiting the exploitation of geological ones (De Angelis et al., 2017). In line with the Circular Economy Action Plan and the 12th goal of the 2030 Agenda, BIO-DUST project aims at producing a new green product starting from the recycle of food waste to be used in 3D printing. Indeed, carbonates and phosphates of geological origin are the most used fillers in the 3D printing technique called Fused Deposition Modelling (FDM) (Zárybnická et al., 2022). In a sustainable perspective, these inorganic fillers will be synthetized starting from food industry waste (Mignardi et al., 2020), consequently limiting the supply of natural resources. They will be mixed with algal-derived polysaccharides, to create safe, green, and nontoxic 3D printable biopolymers. The use of this product in the culture industry, not only as gifts in museum shops, but also for filling missing pieces of statues and to reproduce copy of artworks, will be fundamental for research, documentation, restoration and for educational purposes in an idea of wide accessibility and inclusive perspective. Reintegrating touch and other senses into the cultural experiences will have great benefits in accessibility, increasing the involvement in culture of persons with learning difficulties, children, elderly, blind or visually impaired visitors. Furthermore, a complete characterization of the new product, from the raw materials and during the whole production process, using both static and dynamic techniques as FT-IR, XRPD, SEM-EDS, TGA, NMR, will allow the evaluation of possible applications in other fields, such as engineering, medicine, food, and industries, further boosting the impact of the research. The first step of BIO-DUST project involved the collection of eggshells, mollusc shells and animal bones as raw materials from food waste. From these raw materials, inorganic additives (i.e., hydroxyapatite and biochar) were synthesized using different procedures, such as precipitation method by acid and by calcination and microwaves irradiation. Parameters such as calcination temperature and time, power and exposure time to microwaves, have been optimized in order to develop a sustainable production process. Both hydroxyapatite and biochar were characterized using the diagnostic techniques mentioned above.

Keywords: thermodynamic modelling, waste management, cement.

The current extraction rate of raw materials corresponds to over 100 billion tonnes (Gt) per year and, according to business-as-usual scenario estimates this will increase to over 170 Gt by 2050. About 35% of the overall stock of extracted resources is classified as unrecoverable waste upon processing, and only about 7% is obtained by recycling. These numbers demonstrate a broad scope for improving the circular approach to materials sourcing and waste management. Construction materials play a key role in this scenario, considering that they incorporate about 40% of the total extracted raw materials and the majority of extracted industrial minerals. On the other hand, cement-based materials can: a) safely incorporate different types of wastes, and b) be utilized for the stabilization of specific wastes.

This contribution will provide an overview of the role of thermodynamic modelling in devising appropriate strategies for waste management and reutilization in sustainable binders. Thermodynamic modelling can provide a tool to unravel the control of complex geochemical equilibria in aqueous solution in determining both the macroscopic properties of waste-based cement binders and the specific interactions between hazardous wastes and cement binders used for stabilization purposes. A series of specific examples from real applications will be illustrated.

Biotechnological potential of marine extremophiles in the treatment of valuable anthropogenic materials like spent car catalysts

Keywords: waste management, PGE, biohydrometallurgy.

The metals supply market is facing a critical period because of the high demand for primary raw materials. In search of alternative sources of critical metals, spent automotive catalytic converters (SACC), an increasing waste category, represent a diversified source of supply of platinum group elements (PGE) and other elements of economic interest. Utilizing traditional methods from Solid Earth Sciences (ICP-MS, ESEM, XRD, etc.) in conjunction with marine biotechnology, we aim to develop a bio-hydrometallurgical process for treating SACC and recovering PGE. Marine sediments selected for bacterial isolation represent extreme environment for life survival and are from extreme marine environments such as offshore anthropogenic contamination (near river drainage), on volcanic/ophiolite rocks occurrence or the deep-sea (below 600 m isobaths).

Bacteria were isolated through a specific enrichment with SACC sample materials or its hydrochloric acid leachates for strains' targeted selection. Strains selected as best candidates for SACC bio-treatment are those best tolerant to extreme pHs, metal concentrations, including several potentially toxic elements and PGEs like Pt, and pulp densities. Some microorganisms such as *Pichia sp*. and *Rodococcus sp*. could tolerate impressive concentrations of 800 and 200 ppm of Pt and Pb, respectively. In the context of SACC bio-treatment experiments, *Pichia sp*. and *Microbacterium sp*. are best performing for Pt(II) bio-recovery.

A novel in-situ method to continuously monitor the aqueous carbonation degree of high calcium (chloro)(hydr-)oxide content-industrial alkaline waste through gas flow sensors

Wehrung Q.*, Pastero L., Bernasconi D., Cotellucci A., Bruno M., Destefanis E., Caviglia C. & Pavese A.

Keywords: carbonation, monitoring, IAW.

Industrial Alkaline Waste (IAW) carbonation integrates Carbon Capture, Utilization, and Storage (CCUS) with waste management, addressing ecotoxicological challenges and carbon emissions. Despite its perceived scalability and commercialization examples, efficiently monitoring IAW carbonation remains a challenge. The most common method, thermal gravimetric analysis (TGA) (Martín et al., 2019), is widely applicable but has drawbacks. These include a lack of real-time data due to its ex-situ nature, complex interpretation and limited accuracy. An additional option was proposed by (Brück et al., 2018), but is limited to closed systems as it relies on pressure drop measurements. Alternative approaches were recently suggested by Mario et al. (2021) and Sorrentino et al. (2023).

The present study outlines a complementary methodological sequence to accurately monitor the carbonation degree of various IAW containing high Ca(chloro)(hydr-)oxide (CaClOH) content**.** Typical IAW concerned includes Air Pollution Control residues (APCr) from Municipal Solid Waste Incineration (MSWI), Cement Kiln Dusts (CKD), High-Calcium Coal Fly Ashes (HCFA), Waste Paper Fly Ashes (WPFA), and Calcium Carbide Residues (CCR).

In general, CaClOH species predominantly control CO_2 uptake and kinetics in direct accelerated aqueous carbonation of IAW, with limited contribution from Ca/Mg-bearing silicate dissolution. Utilizing gas flow sensors (GFS), this study shows how to compare CO_2 absorption vs. time patterns ($\eta(t)$) in the pure $Ca(OH)_2$ aqueous carbonation (CAC) with that of any IAW listed above, under similar operational conditions. The proposed monitoring method, successfully applied to multiple APCr and FA samples, can be summarized as follows:

Calibrating the CO_2 volume and mass uptakes through GFS measurements by using CAC as a standard. A preliminary study showed that in CAC, $\eta(t)$ displays four distinct rate-controlling mechanisms, denoted as step 1: maximum absorption; step 2: first downfall; step 3: secondary absorption; step 4: secondary downfall. Step 4 should be excluded as it corresponds to the CO_2 dissolution capacity of the water. $Ca(OH)_2$ reprecipitation in $CaCO_3$ at the completion of step 3 can be both observed and verified through sampling and X-ray Powder Diffraction. A calibration factor *k* is obtained. Performing carbonation experiments under consistent operational conditions with any of the aforementioned IAW samples and converting the CO_2 volume to mass uptake using the calibration factor *k*. This process will yield a comparable $\eta(t)$ pattern enabling the identification of the completion time for step 3. Finally, the total carbonation degree achieved (gCO_2/kg of IAW) can be determined.

Further research is necessary to adapt this method to Mg systems, given the diverse mineral phases encountered in MgO carbonation, which can influence the overall stoichiometry of the process.

Carbonation performance of waste incinerator air pollution control residues (APCr) under wastewater reuse conditions - Towards a sustainable stabilization process

Wehrung Q.*, Pastero L., Bernasconi D., Cotellucci A., Bruno M., Destefanis E., Caviglia C., Cavagna S. & Pavese A.

Keywords: carbonation, waste, incineration.

Carbonation of alkaline feedstocks is considered as the most scalable strategy for CO_2 utilization and long-term storage in useful mineral byproducts (Baciocchi & Costa, 2021). This study explores the carbonation potential of Municipal Solid Waste Incineration (MSWI) Air Pollution Control residues (APCr) to divert them from landfilling, reduce carbon emissions, and mitigate rising landfill costs. APCr, classified as hazardous waste, are typically the only solid residue not extensively reused after MSWI, unlike bottom ashes for which solutions exist (Schnabel et al., 2021). An average MSWI plant generates approximately 3-4 wt.% of APCr from the MSW mass incinerated. When lime is utilized as additive for acid gas removal, APCr collected in baghouse filters typically contains elevated levels of calcium (chloro)hydroxide and Potentially Toxic Elements (PTEs) like Pb, Cr, Sb and V (Phua et al., 2019).

The novelty of the study lies in utilizing a high liquid-to-solid ratio (L/S) to simultaneously carbonate and wash the APCr, while regenerating the wastewater through distillation to reduce water consumption and separate the most soluble PTEs. Fresh APCr samples were collected in France to assess temporal and spatial variability in residue composition. Laboratory-scale tests using scrubbers from 1.5 to 5L coupled to a rotoevaporator successfully carbonated over 10 kg of APCr through 50 tests including 30 cycles at CO_2 flow rate of 0.4-2 L/min, L/S 10-50, T ranging between 283-363K, achieving carbonation degree exceeding 300 gCO_2/kg of APCr.

High-precision gas flow sensors generated CO_2 absorption rate vs. time patterns ($\eta(t)$). Solid-liquid phases characterization was conducted using XRPD with Rietveld refinement, SEM-EDS, ICP-MS, XRF and BET analysis. EN 12457-2 leaching tests were performed on both raw and carbonated waste residues.

Key findings include sustained high CO_2 absorption rates $\eta(t)$ under wastewater reuse conditions, with the accumulation of dissolved sodium, potassium, chloride, and calcium. Water recovery efficiency exceeded 90% during solution settling and supernatant separation. Pb, Cu and Zn were efficiently immobilized by carbonation, while chloride and the most soluble oxy-anions forming metals (Cr, Sb and V) were removed by carbonation washing and subsequent distillation during water regeneration. Optimal carbonation temperatures ranging from 323K to 343K were identified, with higher temperatures yielding a higher calcite/vaterite ratio. Process intensification experiments using a gas-liquid static mixer showed that $\eta(t)$ can exceed 90% during APCr aqueous carbonation. Calibration between $\eta(t)$ and pH enables continuous in-situ pH monitoring via gas flow sensors, minimizing heavy metal leaching.

By integrating the proposed process into the workflow of MSWI plants, APCr could achieve the necessary stabilization for incorporation into concrete blocks or the production of lightweight aggregates (Gunning et al., 2011).

The Mo-LREE-(W) greisen and F-LREE-(Mo) hydrothermal mineralisation in the Oschiri - Alà dei Sardi area (N Sardinia)

Attardi A.*, Cossu D., Deidda M.L., Fancello D., Sedda L. & Naitza S.

Dipartimento di Scienze Chimiche e Geologiche, Università di Cagliari.

Corresponding author email: attardi.geo@gmail.com

Keywords: CRMs, granitoid-related mineralisations, fluorite.

The Gallura region hosts widespread outcrops of metamorphites intruded by Variscan granite units. Granite-related ores were rarely exploited, but due to the interest in Critical and Strategic Raw Materials (C-SRMs) the potential of Sardinia as a prospect for W-Sn-Mo-Bi and F-REE granite-related deposits has been recently suggested.

We studied three granite-related ores in the Oschiri - Alà area: the Su Laccheddu (SLU) greisen, located about 3 km SW from the Giacone (GIA) granite- and greisen-hosted hydrothermal vein system, and the Monte S'Abbagana (MSA) greisen, spatially associated to pegmatites, located about 30 km eastward from the others.

The greisen facies include muscovite, sericite, quartz and relics of K-feldspar, plagioclase and biotite. Titanite and rutile are associated with altered biotite. The ore mineral assemblages are: a) molybdenite dry veins and disseminations, with interstitial Bi-Te phases and scattered hematitized pyrite; b) scheelite, with wolframite-columbite relics, at the grain boundaries of muscovite crystals. The MSA ore minerals include LREE phosphates and fluorocarbonates, such as xenotime-Y and synchysite-Ce, and Nb-Y-F phases like columbite and euxenite-Y. Zircon is common and associated with thorite/uraninite.

At GIA a fluorite-quartz veins system occurs within the granitoids striking NE-SW at low-angle, with multi-decimetre thickness and banded texture. Stockworks of fluorite veinlets depart from thicker veins, spreading in the host-rock. The veins are cut by a vertical fault breccia made of metamorphites and greisen clasts cemented by fluorite and subordinate quartz and molybdenite.

Brecciation is associated with a high-angle fault system revealed by fault mirrors on quartz veins, displaying sub-vertical slicklines and argillic alteration. It hosts fluorite veins, molybdenite spreadings, and greisen breccia blocks.

The three ores are seemingly part of an "F-rich open system" (Pirajno, 2009): greisening took place at deeper crustal levels and higher T (400-300°C), whereas hydrothermal fluids circulation occurred at lower T (< 300°C) along faulting at shallower levels. Fluids had a strong HF-rich signature and caused: a) pervasive alteration of biotite and feldspar; b) Ti-W-Nb and Ca-REE remobilisation; c) rutile, titanite, wolframite-scheelite, columbite, fluorite and REE fluorocarbonates precipitation. The high HF concentrations in the hydrothermal fluids caused extensive Y mobilisation and precipitation of xenotime-Y and euxenite-Y.

Hence, we propose that the SLU and MSA Mo-LREE-(W) greisen ores represent the roots of a unitary mineralising system that evolves towards the shallower GIA F-LREE-(Mo) hydrothermal veins. However, the Nb-Y-F signature of MSA (columbite, xenotime-Y, euxenite-Y, fluorite) suggests an affinity with NYF pegmatites. In conclusion, the area is of potential interest for further C-SRMs investigations and modelling that may serve as a guideline for other granite-related deposits of Sardinia.

Distinct magma evolution processes control the formation, endowments and metal ratios of porphyry Cu-Au deposits in thin and thick arcs

Chiaradia M.*

Department of Earth Sciences, University of Geneva, Switzerland.

Corresponding author email: Massimo.Chiaradia@unige.ch

Keywords: porphyry copper deposits, thick arcs, thin arcs.

Porphyry Cu-Au deposits (PCGDs) are the major global source of copper, an essential metal for the green transition, and a significant source of gold. They occur both in thick continental and thin oceanic arcs at depths of ~1-6 km above ~5-15 km deep parental magma chambers. Although metal precipitation processes for these deposits are similar in thin and thick arcs, it is not clear why porphyry deposits in these two environments display different Cu and Au endowments and different Au/Cu ratios, i.e., Au/Cu ~14 in thick arcs and ~80-120 in thin arcs. Using mass balance petrological modeling, I argue that PCGDs in thick and thin arcs form by two distinct magmatic evolution precursors (Chiaradia, 2022).

In thick arcs, PCGDs and their metal endowments and metal ratios can be explained by a two-stage process: (i) lower crustal accumulation of large volumes of hybrid magmas, fluids and metals during several Ma and (ii) subsequent transfer of these H_2O-undersaturated magmas to shallow levels where they exsolve aqueous fluids and metals. The decoupling between Cu and Au in thick arc deposits is due to the early magmatic sulfide saturation occurring at the deep crustal levels of a thick crust. Because Au is much more chalcophile than Cu, the loss of Au in the deep hybrid magma is nearly quantitative. In contrast, Cu remains in the magma in concentrations sufficient to form behemothian (> 31.16 Mt Cu) porphyry Cu deposits, because the Cu loss is compensated by the large magma volumes accumulated at deep crustal levels. Further decoupling may also occur due to different precipitation efficiency at variable shallow crustal levels.

In thin arcs, PCGDs form by little differentiated mantle-derived magmas that rise directly to shallow crustal levels where they exsolve fluids and metals. This process optimally exploits two advantages of the thin-intermediate arc environment to form giant to supergiant porphyry Cu deposits (> 5 and up to 30 Mt Cu) with the largest Au endowments (~500-2600 t Au) and highest Au/Cu ratios (~80-120) among all PCGDs known. The first advantage is the significantly higher Cu and Au contents of intermediate magmas in thin versus thick arcs, due to delayed magmatic sulfide saturation in thin arcs. The second one is the exsolution of fluids at an earlier stage of magma differentiation than in thick arcs before Cu and especially Au are removed by sulfides.

These two distinct magmatic pathways of PCGDs generation are ultimately controlled by the different arc thicknesses in the two environments, even though the processes of metal precipitation in the actual deposits of the shallow crust are similar. The model discussed here may stimulate the development of new tools for the exploration of porphyry deposits in the distinct environments of thick and thin arcs.

Chiaradia M. (2022) - Distinct magma evolution processes control the formation of porphyry Cu-Au deposits in thin and thick arcs. Earth Planet. Sci. Lett., 599, 117864.

Trace elements and REYs signature of ore and gangue minerals in the Zn-Pb(-Cu-Fe) mineralization of Longobucco and Fonte Argentila (Sila Massif, Calabria, southern Italy)

Ciccolella A.*[1], Festa V.[1], Ruggieri G.[2], Schingaro E.[1], Tursi F.[3], Ventruti G.[1] & Fregola R.A.[1]

Keywords: sphalerite, Zn-Pb(-Cu-Fe) mineralization, REYs and trace elements.

Here we illustrate key mineralogical and geochemical features of some Zn-Pb(-Cu-Fe) mineral deposits of the Sila Massif (Calabria, southern Italy) that were historically exploited (Fregola et al., 2023), unveiling their hidden genesis. We have collected and analysed samples from apparently vein-type mineralization associated with fault zones affecting the granodiorite of the Sila batholith at Longobucco (LGB) and Fonte Argentila (FAR). The mineral association comprises sphalerite (Sp) as primary ore mineral, along with galena (Gn), quartz (Qz) and calcite (Cal) in both areas. Samples from FAR site also contain chalcopyrite (Ccp), pyrite (Py) and fluorite (Flr). Mineral composition and microstructures were determined by petrographic observation, SEM, EPMA, and μ-Raman spectroscopy. Trace element distribution in sphalerite and chalcopyrite, as well as REY contents in calcite and fluorite, were also analysed through LA-ICP-MS. Sphalerite exhibits colour and chemical zonings mainly due to variations in Fe contents (up to 11.3 wt.%; 0.21 mol FeS). Trace elements identified in sphalerite include Mn, Co, Cu, Ga, Ge, Ag, Cd, In, Sn, Sb, Hg, Tl, Pb, and Bi. The reconstructed paragenetic sequence comprises five growth stages for both areas. Stages 1 and 2 register the main mineralization event, with the formation of Sp1, Sp2, and Qz1. In stage 3, following brittle deformation, massive precipitation of calcite (in LGB) and fluorite (in FAR) occurred. The REYs concentrations in Cal and Flr suggest mixing between two different fluids, one of likely igneous origin and the other diagenetic, also indicating a change from reducing to oxidizing conditions of the system. In LGB, calcite hosts synchysite with grain sizes in the range 20-60 μm, and LREE-Y contents from 2.40 to 42.6 wt.%. Furthermore, colourless Sp3 formed as a result of the recrystallization of Sp1 and Sp2 due to oxidizing conditions. A diffuse recrystallization of Qz2 occurred in stage 4 while, in stage 5, almost pure Gn formed along with Ccp and Py at the expense of previous minerals. Formation temperatures derived from Sp1 and Sp2 using the GGIMFis geothermometer (Frenzel et al., 2016) range between 170 and 220°C. This temperature range is in good agreement with that obtained from preliminary fluid inclusion analyses. In addition, the Zn/Cd (195-267), Ga/In (190-596), and In/Ge (0.24-1.20) average ratios in sphalerite, are indicative of a low-temperature ore-forming fluid. Our geochemical data indicate an MVT-SHMS ore formation, with no evidence of hydrothermal processes involved in the system, contrasting with the apparently vein-type character of the mineralization observed in the field. A genetic model connecting the paragenetic stages and geochemical data obtained from ore and gangue minerals for LGB and FAR Zn-Pb(-Cu-Fe) mineralization is presented here.

Keywords: vanadium, hyperspectral remote sensing, PRISMA.

In recent years, the intensification of vanadium-dependent technologies has resulted in the growing economic importance of vanadium as a critical raw material. Economic concentrations of vanadium are most commonly found in specific types of ore deposits hosted either in mafic-ultramafic igneous systems or sedimentary or metamorphic rocks (Boni et al., 2023).

This contribution aims to study the applicability of spectral reflectance in the investigation of V-bearing mineral assemblages for the exploration of V-ores. Study areas include the Mibladen district in Morocco, consisting of stratabound karstic V-bearing Pb-Zn mineralizations hosted in Mesozoic carbonates, and the Otavi Mountainland in northern Namibia, hosting base metals sulfide and nonsulfide deposits in Neoproterozoic platform carbonates (Boni et al., 2007; Yaagoub et al., 2021). The surface-exposed areas were investigated through hyperspectral images acquired by the Italian satellite mission "PRecursore IperSpettrale della Missione Applicativa" (PRISMA). Additionally, the mineral assemblage in the samples was identified and mapped using Headwall Photonics hyperspectral cameras. Both the satellite and laboratory sensors cover the nominal 400-2500 nm range of the electromagnetic spectrum where absorption features of the target minerals exist (Laukamp et al., 2021). XRPD and SEM-EDS analysis were used to validate the results obtained.

The hyperspectral analysis allowed the identification of host rocks (dolomite and calcite), minor alteration minerals (phyllosilicates and Fe-oxy-hydroxides), and vanadates (vanadinite, descloizite-mottramite series). In addition, it was observed that changes in the chemical composition of vanadates and carbonates caused shifts in the absorption feature towards shorter or longer wavelengths. Specifically, vanadates had a variation in wavelength from 2397 nm (descloizite, ZnO > 18 wt.%) to 2426 nm (mottramite, ZnO < 2 wt.%). Similarly, dolomite shifts from 2311 nm to 2321 nm based on Ca content, while calcite shifts from 2330-2340 nm due to Mg content.

In conclusion, hyperspectral analysis can provide specific targeting information for follow-up in situ surveys and drilling campaigns for this type of ore deposits.

Keywords: Sardinia, bentonite, montmorillonite.

Bentonites are a group of rocks formed essentially by smectites, mainly belonging to the montmorillonite-beidellite series. Bentonites derive from the alteration of volcanic and/or sedimentary rocks, with a prevalent siliceous-vitreous component, by aqueous fluids that operate at temperatures between 90°C and 120°C. During the alteration, chemical elements are remobilized and the composition and structure of the minerals are modified. The resulting mineral assemblage depends on the nature of the protolith and the composition of the altering fluids (Cuadros et al., 1999). Bentonites have a wide range of properties (CEC, thixotropy, swelling, viscosity, water absorption) which make them a very important industrial mineral, which are periodically tested also by the EU for the possible inclusion in the list of critical raw materials. S'Aliderru bentonite deposit is located in the northern Sardinia bentonite (Tertiary) basin (Italy). The deposit derives from the alteration of calcalkaline pyroclastic rocks of Oligo-Miocene age, which fill a structural depression occurring in the Mesozoic carbonate basement. The present work has the aim to define geological and mineralogical features of the S'Aliderru deposit and define its genesis. S'Aliderru deposit extends for 0.8 km N-S, 0.4 km E-W, with an average thickness of 50 m. The orebody consists of multiple bentonite lenses of variable colour, interbedded with moderately to strongly altered pyroclastic rocks, travertine bodies and sandy-to-conglomeratic lenses, and is locally dislocated by faults. The study was based mainly XRPD analysis of the samples, which were subjected to various processes (AD, EG, DMSO, heating) to identify the occurring mineralogical phases to understand the geological processes that led to the formation of the deposits and possible genetic differences at the basin scale. Petrography analyses and SEM analyses were also carried out. The XRPD analyses showed a classical mineralogical assemblage. In detail, the S'Aliderru bentonites are composed mainly of Ca-montmorillonite, with the accessory presence of kaolinite, chlorite, muscovite and biotite. Quartz, calcite, plagioclase and glass are also present. The petrographic analyses and SEM analyses have made it possible to state that the formation of smectite occurs at the expense of the glass and plagioclase present in the original tuffs and led to the identification of an unreworked marine fossil within the bentonite. The use of SEM also allowed the identification of hollandite and xenotime. The studies conducted confirm that the deposition of tuff flows and their subsequent alteration occurs in a transitional marine environment, but the presence of minerals such as kaolinite, chlorite, hollandite and xenotime suggest that one or more hydrothermal stages contributed to the development of the deposit.

Corresponding author email: alessandro.deleo@unimi.it

Keywords: lithium, pegmatite, geochemistry.

Spodumene rich pegmatites (SRP) represent a crucial source of lithium, a key critical raw material. In Brazil, the primary lithium deposits are represented by the SRPs in the Araçuaí Pegmatite District. These pegmatites have a high modal content (up to 30%) of coarse-grained spodumene crystals dispersed within a matrix of quartz, feldspars, and muscovite and form rather homogeneous ore bodies. In the Araçuaí Pegmatite District, SRPs have been interpreted as residual magmas derived from Cambrian two-mica granites associated with large barren pegmatitic bodies formed during the late tectonic stage of the Araçuaí Orogen. However, the relation between barren and mineralized pegmatites as well as the formation mechanism of SRPs in this region and elsewhere remains puzzling.

The analysed rock samples encompass the full range of inferred differentiation grades in the Araçuaí Pegmatite District, from two-mica granites to barren pegmatitic bodies, culminating in SRP. We present compositional data of muscovite and apatite, obtained with a combination of EMP and LA-ICP-MS analyses, to investigate the genetic relation among the different lithologies as well as the internal evolution of the SRP.

Except for minor biotite in the two-mica granite, all mica can be classified as muscovite. The muscovite from the SRP has higher Al and lower Fe contents than muscovite from other lithologies. In the spodumene zone of SRP muscovite exhibits the highest contents of incompatible elements Li, Cs, Mn, and Zn, negatively correlating with the K/Rb ratio. Li median contents varies from 783 μg/g in the border zone to 2619 μg/g in the spodumene zone of SRP, while median contents of 1204 and 1156 μg/g are measured in barren pegmatites and two-mica granite.

Apatite is a ubiquitous accessory phase in the samples, reaching up to 5-10% of modal content in the border zone of the SRP. Similarly to muscovite, apatite shows the highest contents of incompatible elements U, Th, Mn, and Zn in the spodumene zone of SRP, along with a drastic reduction in REE contents.

Both muscovite and apatite display an extreme evolution in composition within the SRP (one to two orders of magnitude for selected trace elements), suggesting the fundamental role of internal differentiation in the pegmatite to concentrate rare elements.

The presented data support the use of muscovite and apatite chemical compositions as indicators of the degree of differentiation and Li enrichment among various products of granitic magmatism. Even if the genetic relation between the different lithologies is still not defined, it is clear that they share the same fingerprinting enrichment in rare elements, supporting an origin from the same magmatic system. The association observed between muscovite and spodumene is recurrent worldwide in SRPs and highlights the system's relatively high alumina/low fluorine character, a crucial factor favouring spodumene as the primary Li bearing crystallizing phase over Li-F bearing mica.

Iron isotope systematics and ore forming processes: first results from the ophiolite-hosted, Tuscan Cu-Zn VMS deposits

Di Giuseppe P.*, Agostini S., Rielli A., Vezzoni S. & Dini A.

Istituto di Geoscienze e Georisorse, CNR, Pisa.

Corresponding author email: paolo.digiuseppe@igg.cnr.it

Keywords: iron isotopes, ore deposits, ophiolite-hosted VMS.

Ore forming processes still need to be improved, and new conceptual genetic models must be developed to help exploration of new ore deposits for the energy transition. Decarbonization and the switch to renewable energies will require increasingly large amount of Critical Raw Materials (CRMs) that must be provided by conventional and unconventional ore deposits.

The availability of copper, although considered as a common metal, will potentially limit the speed of the energy transition, because large amounts of this metal will be used in electric vehicles and power generation. For this reason, any implementation of genetic models regarding Porphyry-Cu and Volcanogenic Massive Sulphide (VMS) deposits is highly desirable. Ophiolite-hosted Cu-Zn VMS deposits from orogenic settings, with respect Porphyry-Cu deposits, represent a minor provider of copper, but their better understanding could shed new light on the mining potential at seafloor.

Stable isotopes of ore-forming metals, like Fe, can be used for the investigation of ore-forming processes, metal source(s), and water-rock interactions. The development of the High-Resolution Multi-Collector Inductively Coupled Plasma Mass Spectrometers (HR-MC-ICPMS), like that hosted in the Neptune-TIMS Laboratory (IGG-CNR, Pisa, Italy), given the opportunity to accurately measure Fe isotope ratios for ore deposit applications.

In the framework of the project "TEOREM - Deciphering Geological Processes using Terrestrial and Extraterrestrial ORE Minerals" (PRIN-MUR 2017AK8C32) and the project ITINERIS ISOTOPE VRE (IR0000032; PNRR; Next Generation EU), we developed the methodology for the Fe separation from different matrices, and the determination of Fe isotope ratios using HR-MC-ICPMS (Neptune Plus).

Determination of iron isotope composition was performed on samples of massive sulphide ore and gangue minerals from the ophiolite-hosted Cu-Zn VMS deposits of Tuscany (Italy). Samples of both primary chalcopyrite-pyrite-pyrrhotite stockworks and reworked nodular ores (bornite-chalcocite-chalcopyrite), were studied by SEM-EDS (Dini et al., 2024) and selected mineral separates were processed for Fe isotopic analyses.

First results show a significant variability of negative $\delta^{56}Fe$, consistent with the available data on copper sulphides from Mid-Atlantic slow-spreading ridge (Rouxel et al., 2004). The new data on Tuscan VMS deposits suggest that the nature of the oceanic crust hosting the ores (ultramafic vs. mafic) is likely to exert some control on the variation of $\delta^{56}Fe$.

The supergiant epithermal Hg district of Mt. Amiata (Italy): metal source and genesis

Dini A.*

Istituto di Geoscienze e Georisorse, CNR, Pisa.

Corresponding author email: a.dini@igg.cnr.it

Keywords: mercury, black shales, Mt. Amiata volcano.

Mercury is an extremely rare element in Earth's litosphere but hydrothermal processes concentrated Hg in monometallic, high-grade deposits. More than half of the global Hg production (ca. 1 Mt of metal) came from three supergiant districts (Almaden, Spain; Idrja, Slovenia; Mt. Amiata, Italy) that exploited high-grade cinnabar ores (1-8 wt.% Hg). These grades imply an ore/source concentration factor of ca. 10^6, one to three orders of magnitude larger than any other supergiant metal ore deposit. Why these huge, high-grade Hg ores are almost monometallic and how such extreme concentration factors were attained?

Since the early, modern, scientific contributions on epithermal systems, the existence of Hg-rich hot springs and the formation of mercury deposits was attributed to metal mobilization from sedimentary sequences driven by hydrothermal fluids. The affinity of mercury for organic matter is responsible for the extreme Hg concentrations measured in peculiar sedimentary rocks like black shales (100-5000 ng/g). The role of black shales as the most suitable terrestrial source rock for Hg was later supported by many other authors. In this model, magmas involved in the formation of epithermal Hg ores provide heat and, possibly, part of the fluids. Conversely, other authors have argued for a magmatic/mantle source of the mercury involved in some of the world's largest deposits. A hypothesis that would seem to be supported by the substantial Hg flux measured in many volcanoes worldwide.

The Middle Pleistocene supergiant Hg district of Mt. Amiata volcano (Italy), with its preserved epithermal characters, is the best candidate to address these questions (Dini et al., 2017; Rimondi et al., 2015). Hg concentration profiles in rocks below the deposits, down into the contact aureole of the magma chamber at 5 km depth, indicate that the ca. 100000 t of mercury mined in the district were thermogenically released from Late Permian black shales, transferred upward as gaseous phase, and scrubbed by shallow paleo-aquifers (< 200 m depth). The upward isotherm propagation, ca. 300-150 ky ago, coupled with the extraordinary volatility of mercury, allowed a selective metal transfer & deposition, well before the inception of the present-day, liquid-dominated, geothermal system.

Results open many questions about the meaning of volcanic Hg fluxes worldwide, their inter- intra-arc variability, and the role of subsurface igneous activity on the geochemical cycle of mercury at global scale (Svensen et al., 2023).

Keywords: Southern Tuscany, carbonate-hosted ore deposits, hydrothermal fluid evolution.

Antimony, a Critical Raw Material (European Commission, 2023) has been mined in Southern Tuscany until late ’80 of the last century from several carbonated-hosted Sb(±Au) mineralizations (Lattanzi, 1999). They are genetically linked to a widespread silicification of carbonate rocks (jasperoids) and have strong analogies with “Carlin-style” gold deposits (Sillitoe & Brogi, 2021). Even though these systems have been characterised through fluid inclusion and structural geology studies (Lattanzi, 1999; Brogi & Fulignati, 2012), there are still several open questions concerning sulfides geochemistry and the origin and evolution of the ore-forming fluids. The trace element composition of ore minerals is intricately connected to the redox state, pressure, temperature, and the source of mineralising fluids and thus can provide critical insights into ore-forming processes. Here we combine the trace element composition of sulfides (stibnite and pyrite) and stable isotope composition of quartz ($\delta^{18}O$) and calcite ($\delta^{18}O$, $\delta^{13}C$) associated with some of the main Sb(±Au) mineralisations of Southern Tuscany (Frassine, Cetine, Poggio Peloso, Campigliola, Micciano), to constrain the ore-forming process and concentration of precious metals in sulfides.

Keywords: CRMA, mining, database.

The issue of security in the supply of mineral resources essential for industrial development is now placed at the top of the political-economic agendas of all advanced countries. To limit the dependence of supplies on the hyper-concentration of resources in politically unreliable countries, the European Commission has developed a new regulation for the safe and sustainable supply of raw materials considered critical or strategic (Critical Raw Materials Act - CRMA) published in the OJEU on May 3, 2024 (EC, 2024). The ISPRA - Geological Survey of Italy already has activities underway that are perfectly in line with the provisions of the new European regulation, in particular the art.19 and 27. Article 19 of the CRMA requires each member state to equip itself with a National Mining Exploration Plan by 24 May 2025. The starting point for the implementation of the plan is the recovery and review of previous data. With this in mind, all available mining data is being collected and harmonized. Included are data relating to all deposits cultivated in the past and the results of various national and local research campaigns, with a particular focus on critical raw materials (CRM). All the information collected is entered into the national GeMMA database (Geological, Mining, Museum, Environmental). The DB is created in total coherence with the European Mintell4EU database and represents the access point to a series of specific databases already created or in the process of being created (disused mining sites, current research concessions and permits, digitalization of 1927 and 1973 mining maps, Mining parks and museums, RIMIN project, geological maps, geochemistry, geophysics, etc.). The database is designed to be able to implement the data deriving from the acquisition of information available from Ministries, Universities, Research Institutions, Regions/PAs, European projects and new mineral research projects for the realization of which appropriate investments will be necessary for new surveys, sampling and analysis.

Previous mining activities have left approximately 150 million cubic meters of extractive waste which represents a serious environmental problem and is the subject of expensive interventions to reclaim the territories from heavy metals. The recovery of these metals, in addition to having an important economic value, would solve an environmental problem. For this reason, the CRMA provides in art. 27 that member states should have a specific database of extractive waste that will be a specific part of GeMMA. For this aspect, a line of activity has been included in PNRR-RePowerEU to map, characterize and computerize all extractive waste deposits nationwide in terms of presence and potential recovery of MPCs. The Geolgical Survey of Italy will be member of European Critical Raw Materials Board.

EC (2024) - Regulation (EU) 2024/1252 of the European Parliament and of the Council of 11 April 2024 establishing a framework for ensuring a secure and sustainable supply of critical raw materials and amending Regulations (EU) No 168/2013, (EU) 2018/858, (EU) 2018/1724 and (EU) 2019/1020Text with EEA relevance. Re-use of granite quarry waste for REEs-recovery along the industrial production chain: results from pre-concentration tests

Gioiello S.[1], Santoro L.*[1] & Cazzaniga A.[2]

[1] Dipartimento di Scienze della Terra, Università di Torino. [2] Minerali Industriali Engineering S.r.l., Novara.

Corresponding author email: silvia.gioiello@unito.it

Keywords: Rare Earth Elements, circular economy, mineral processing.

Granite quarry waste from the "Serie dei Laghi" plutons in Piedmont (N-Italy) (Boriani et al., 1988) underwent several lab-scale beneficiation tests to enhance the recovery of Critical Raw Materials (CRMs) in the context of circular economy and sustainable mining, considering their pivotal role in the modern industry and the economic development strategies of the European Union (European Commission, 2023). Preliminary analyses by ICP-MS highlighted that the magnetic waste discarded during the industrial re-processing of granite for feldspar production is notably enriched in Rare Earth Elements (REEs), paving the way for simulating and refining a lab-scale treatment to optimise the concentration of REE-bearing minerals. SEM-EDS analyses allowed to identify monazite-(Ce) as the primary target mineral, predominantly locked within Fe-rich biotite (siderophyllite). The feed material was then milled to various grain sizes and subjected to multiple magnetic separation stages to determine the optimal conditions for REE mineral beneficiation. Results from recovery calculations indicate that approximately 90% of REEs are associated with the paramagnetic fractions at 75-150 µm and 150-250 µm grain sizes. According to ICP-MS, the 75-150 µm paramagnetic concentrate recovered at 1 A current intensity shows the highest enrichment to ~1800 ppm REEs + Y and Sc compared to ~200 ppm in the raw granite. However, significant REEs amounts remaining in the paramagnetic material at 0.4 A suggest possible incomplete liberation of monazite. Although grinding below 600 µm prior to magnetic separation favours the rejection of diamagnetic gangue minerals from the monazite-bearing siderophyllite, as confirmed by the quantitative phase analysis (QPA) on XRPD diffractograms, SEM-EDS observations and particle analysis by Automated Mineralogy reveal liberation issues for monazite particles above 100 µm due to their smaller size compared to siderophyllite. Further grinding below 100 µm was then applied to isolate monazite, but dry electromagnetic separation used on fine material demonstrated poor monazite recovery, possibly due to airflow influence, particle-particle adhesion, and particle-rotor adhesion (Park et al., 2021), indicating the need for alternative techniques for an effective recovery from the fine-grained pre-concentrate. Additional enrichment tests will consequently include wet magnetic separation and flotation, which is considered more suitable for materials with a grain size less than 100 µm (Jordens et al., 2013). This work underscores the potential of improving the beneficiation techniques to maximise the recovery of CRMs as by-products along the industrial production chain, advocating valorisation and sustainable management of mineral processing waste through its re-processing.

Keywords: mining and metallurgical wastes, CRMs, circular economy.

As the world's demand for raw materials increases with the growing global population and industrial applications, more raw materials are being listed as critical for Europe (critical raw materials - CRMs). Antimony is an important and not easily-replaceable metal that the EU Commission has classified as a CRM, as the EU supply is currently 100% reliant on import. The present study investigates the potential for Sb and other metals from the waste rock, tailings and slags dumped at the abandoned Villasalto and Ballao Sb mines in Gerrei region, SE Sardinia, aiming to their possible recovery. This region was for over one century the most important antimony-mining district in Italy. The Su Suergiu mine near Villasalto was mined for stibnite that occurred with some scheelite, pyrite and minor Pb-Zn-Cu sulfides in quartz-calcite veins within black shales and metalimestones. At the Corti Rosas mine in Ballao, 8 km to the north of Villasalto, the deposits take the form of veins and stockworks mainly hosted in metalimestones. The Sb ores from both mines were processed in the Corti Rosas plant; Sb concentrates underwent pyrometallurgy in the Su Suergiu smelter. Samples of mining waste, tailings and different types of slags were collected from Su Suergiu and Corti Rosas. The samples were analyzed for grain size, the mineralogical phases identified by XRD and the chemical composition analyzed by XRF and the ME-ICPORE method to obtain the concentrations of antimony in the different types of waste. Up to 33.2 wt.% Sb was found in slag samples, followed by tailings (up to 7.97 wt.% Sb), then waste samples (up to 0.64 wt.% Sb). In the slags, significant Zn (up to 1.9 wt.%) W (up to 0.38 wt.%) and Au (up to 53 ppm) contents are also reported. A positive correlation between Sb and Zn was found, especially evident in slag samples, which could mean a possibility of recovering zinc alongside antimony. Microdroplets of metallic Sb dominate in the glassy slags; other Sb-bearing minerals in studied materials were mopungite, melanostibite, schafarzikite, and valentinite, with quartz, calcite, and muscovite among the gangue minerals. Antimony contamination is high, as concentrations up to 1600 µg/L Sb were found in water samples for several km downstream of the mining areas. The metallurgical wastes of Su Suergiu are the most contaminating sources, also due to the presence of highly soluble Sb phases as mopungite. Overall, the study provides initial indications for the possible recovery of Sb (and other metals) from the materials studied, with the identification of the useful phases as well as the degree of liberation necessary for their valorization. Antimony recovery from the abandoned mine wastes of Gerrei region would provide a relevant secondary source for this critical metal and contribute to the solution for the problem of contamination in the area.

The antimony resource in Italy: evaluation of environmental impact and ore exploration of a Critical Raw Material under the MOLIERE project

Morelli G.*[1], Chmes H.[2], Costagliola P.[2], Dore E.[3], Frau F.[3], Gonnelli C.[4], Lattanzi P.[1], Medas D.[3], Nannoni A.[2], Regini G.[4], Ruggieri G.[1], Trumpy E.[1], Vezzoni S.[1] & Rimondi V.[2]

[1] Istituto di Geoscienze e Georisorse, CNR, Firenze. [2] Dipartimento di Scienze Terra, Università di Firenze. [3] Dipartimento di Scienze Chimiche e Geologiche, Università di Cagliari. [4] Dipartimento di Biologia, Università di Firenze.

Keywords: critical raw materials, ore geology, environmental geochemistry and mineralogy.

Antimony (Sb) is widely used in strategic sectors and is listed as a "Critical Raw Material" (CRM) by e.g. Europe, Canada, USA, Japan, and Australia. To support the increasing demand of this metal for the green energy transition, new ore bodies need to be exploited, along with the development of Sb recycling. On the other hand, Sb is classified as one of the 13 priority metal pollutants and can be dispersed into the environment through natural and anthropogenic processes, such as oxidation of primary sulphides and mine wastes. In the current Europe scenario, a sustainable mining approach should optimize mineral extraction, minimizing the environmental impact.

Italy hosts potential Sb resources, although not numbered by worldwide statistics. Extraction up to the end of 1980s from Tuscany and Sardinia, left a legacy of mineral waste and tailings on these territories, which vehiculate potentially toxic elements (PTEs, e.g., As, Tl, Hg, W) to freshwaters and likely to the Mediterranean Sea. The Sb districts of Tuscany and Sardinia are therefore exceptional areas for studying ore-forming processes, for the evaluation of potential resources of Sb and associated metals inside the national borders, and to jointly evaluate the environmental impact of extraction, and the potential of cost-effective remediation solutions to reduce Sb and associated PTEs in the environment.

Herein, we present an overview of the MOLIERE project (*The antimony resource in Italy: evaluation of environmental impact and ore exploration of a critical raw material*) funded by PRIN 2022 PNRR, which combines different expertise to provide: i) a geological investigation of Sb ore resources with implications on ore-genesis and exploration, ii) an updated picture of the natural Sb dispersion in the environment and on the long-term environmental impact of past Sb mining, iii) low-cost solutions to limit Sb (and other PTEs mobility) in the mining areas.

To define the characteristics of the primary Sb ores and of the secondary Sb sources (weathered soils, mine wastes), a minero-chemical characterization of the Tafone Sb ore body (southern Tuscany) and of the associated hydrothermal fluids (fluid inclusion study), a geochemical distribution map of Sb and other PTEs in soils and a 3D reconstruction of the ore bodies will be produced. The long-term environmental impact of Sb exploitation will be assessed analyzing Sb and associated PTEs in stream sediments and waters from the Tafone Creek draining the mining area, and providing an assessment of the mass loads of Sb and other PTEs transported by the surficial draining networks to the Mediterranean Sea. As a final aim, the processes that might limit PTEs mobility, such as natural attenuation processes in the vegetation cover and possible cost-effective techniques for remediation at the plant-soil interface, will be investigated. Antimony sorption mechanisms of trap minerals such as LDHs as removal of Sb from freshwaters will also be studied.

Petrogenetic and metallogenic constraints from dark micas compositions of late-Variscan post-collisional granite suites from southern Sardinia (Italy)

Keywords: granite petrology, dark micas trace elements, Sn-W-Mo ore deposits.

The Late-Variscan batolith of Sardinia displays numerous granitic intrusions emplaced at shallow crustal levels during post-collisional extension. In southern Sardinia they have been grouped in several rock-Units (AP, GS1, GS2, GS3, MM suites) resulting from partial melting of different crustal sources (Conte et al., 2017; Secchi et al., 2021). Granites show commonly a ferroan and F-bearing character and are either sub-aluminous (GS1) to peraluminous ilmenite, or metaluminous magnetite rock-series (GS2 and GS3). Remarkably, GS1 granites display a strong granophile metallogenic signature and are associated with numerous Sn-W-Mo mineral deposits. Dark micas are ubiquitous mafic minerals in all the studied rock-Units, thus representing suitable phases to constrain physicochemical conditions and metallogenic potential of granitic magmas. EPMA and LA-ICP-MS chemical analyses allowed identification of independent groups of primary dark micas corresponding to the each recognized granitic rock-Unit. Dark micas show low-Si contents (5.19 ÷ 5.77 a.p.f.u.) and range from Fe-biotite (MM) to siderophyllite (AP) and lepidomelane (GS2 and GS3). GS1 dark micas cluster at the boundary of lepidomelane and siderophyillite fields. In addition, except for the more sodic and alkaline GS3 rock-Unit, dark micas plot in the subalkaline up to calcalkaline field of the Mg/Al_{tot} diagram. Overall, dark micas exhibit low concentrations of Li, Rb, Sr, strongly variable amounts of Ba and very low values of Cs. Moreover, they show chondrite-normalized REE flat patterns and lower total REE average ppm contents compared to host rocks, in the range 0.2 (MM) ÷ 42.4 (GS1), with a peak value (79.3) in GS3 granite. The use of corrected F and Cl values [IVF/(IVF/Cl)] diagram confirms independent trends characterized by positive correlations with a marked F depletion in GS3 dark micas. In the Fe^{2+} - Fe^{3+} - Mg plot, dark micas from peraluminous rock-Units (i.e. AP and MM) show low oxygen fugacity conditions falling between the QFM and NNO *buffers*. More oxidized conditions are revealed by dark mica from GS3 granites which plot between the NNO and HM buffer. The oxygen fugacity can be also constrained from the calibrated curves in the $f(O_2)$-T space. Except for GS3, studied dark micas equilibrated at an oxygen fugacity between 10-15 and 10-17, which shows $f(O_2)$ conditions between NNO and QFM buffers for the temperatures of crystallization interval between 700°C and 750°C. The chemical characters of studied dark micas confirm the occurrence of independent magmas originated from different rock-sources and suggest low degrees of differentiation by crystal/liquid fractionation. The overall lack of correlation between physicochemical crystallization conditions of dark micas (i.e. temperature and reduced/oxidized conditions) and granophile Sn-W-Mo ore deposits confirm the prevalence of the nature of crustal sources in the metallogenic potential of Sardinian granitic magmas (Naitza et al., 2024).

Keywords: Amazon rainforest, mining tailings, supercapacitors.

The rapid development of global economy and the expanding industrialization have led to the depletion of fossil energy sources and to the extensive emission of carbon dioxide. In order to meet the demand for efficient energy storage systems, new electrochemical energy storage devices (EESDs) are currently under investigation. Supercapacitors (SCs), also known as electrochemical capacitors (ECs), have attracted wide attention as they are alternative to both conventional capacitors and secondary batteries. Indeed, SCs possess high-power density, long cyclic stability, good rate capability and fast charge/discharge. MnO_2 has been considered a staple of the research on SC electrodes, because of its low price, low toxicity, high theoretical capacity (1370 F g^{-1}) and good environmental compatibility, etc. Nonetheless the electronic conductivity and structural stability of MnO_2 are poor, limiting the performance and application of MnO_2-based electrode materials.

During mining, beneficiation, and transportation of high-grade Mn-bearing ores, up to 30% of the high-grade ore is turned into Mn tailings (i.e., equivalent to low-grade manganese ore) (Teng et al., 2019). Besides environmental issues, organized crime groups have been establishing (notably in South America) networks for theft, transport, and sale of tailings from legal or illegal exploitation sites. Therefore, directing mining tailings towards "recycling" should be the preferred choice, compared to storage in tailing ponds. Furthermore, reuse of mining waste may also be economically profitable. Indeed, materials science can allow mining tailings to be transformed into value added products: nanomaterials. Although millions of tons of manganese ore tailings are generated every year, mainly due to steel industry, studies concerning manganese recovery from low-grade ore/tailings and its application to electrochemical storage are still very scarce (Teng et al., 2019).

This contribute proposes the synthesis of a quasi-amorphous δ-MnO_2 (similarly to the commercially available "Permanox" (Euler & Helsa, 1979)) by exploiting mining tailings from a manganese (mainly cryptomelane) extraction site in the Brazilian Amazon rainforest. In particular, Mn recovery as potassium manganate (K_2MnO_4), and δ-MnO_2 synthesis were achieved through oxidative alkaline fusion with KOH and subsequent reduction using "low-end" reducing agents (H_2O_2 and ethanol) in solution. According to circular economy principles, highly alkaline liquor resulting from manganese oxide synthesis was recovered and used as electrolyte in supercapacitors. Conductivity and electrochemical properties of δ-MnO_2, electrolyte and supercapacitors were investigated.

"Low cost/low end" birnessite-like MnO_2 recovered from Amazon mining tailings as conversion anode for Li-batteries

Keywords: manganese, recovery, batteries.

Mining activities generate huge amounts of waste materials, often stored in tailings dams, posing serious environmental and social threats. In fact, extensive metal ore mining brings about land degradation, groundwater contamination, habitat destruction, and potential health hazards for nearby communities. Thus, sustainable mining solutions are called for.

Reconversion of mining tailings into harmless and value-added materials is regarded as one of the most promising options for "environmentally friendly" mining. In addition, tailings recovery allows the opportunity to turn waste materials into economically profitable products.

In this context, the present research focuses on the recovery of manganese (an E.U. critical raw material) from mining tailings sampled in an extraction site in the Brazilian Amazon rainforest (Carajás Mineral Province, Pará). The chosen mine represents a significant source of manganese-rich waste material.

Manganese typically occurs in minerals in association with iron as they have similar geochemical properties (Liu et al., 2019). Hence, this study takes advantage of alkaline (e.g. KOH) oxidative fusion to carry out manganese recovery from tailings (as potassium manganate, K_2MnO_4). By controlling fusion process parameters such as, temperature, duration, and tailings/KOH ratio, we aim to efficiently separate manganese from other elements, particularly iron.

Battery grade MnO_2 belonging to the birnessite (δ-MnO_2) family, was synthesized by directly reducing the manganate leachate recovered from Mn-tailings. Birnessite-like materials are well known for their unique properties such as layered structure, high specific surface area, and ion- exchange capabilities (Zhu et al., 2020). Reductant type (hydrogen peroxide, ethanol, manganese sulfate) effect on the morphology, crystallinity, and oxidation state of the manganese oxides was investigated. In addition, manganese oxides were incorporated as active materials into conversion anodes for lithium-ion (Li-ion) rechargeable batteries.

The efficiency of the recovery process is currently under evaluation, while batteries assembled with the recovered MnO_2 are being tested to assess their electrochemical properties, including specific capacity, cycling stability, and rate capability.

Keywords: phosphorite, Albania, carbonates.

The Mediterranean Phosphogenic Province includes numerous phosphorite deposits within sedimentary successions in North Africa, Southern Europe and the Middle East. (Notholt, 1985). This study investigates three uranium-bearing phosphorite deposits, occurring in the Jurassic to Cretaceous marine carbonate rock succession of Southern Albania, through petrographic, scanning electron microscope (SEM) and X-Ray powder Diffraction (XRD), and EMPA analyses. At Bogaz, uranium-rich phosphorites occur as authigenic fluorapatite cement in the interparticle space of hydraulic or tectonic breccia with clasts of Lower Jurassic (Sinemurian-Pliensbachian) shallow-water peritidal platform carbonates, containing *Siphovalvulina* foraminifers and *Palaeodasycladus mediterraneous* dasyclad algae. In Fushëbardha, the lower Toarcian (Lower Jurassic), carbonate facies rich in *Bositra*-like thin-shelled pelagic bivalves corresponding to the organic matter-rich "Posidonia" Shales of Austria and Germany, alternate with tabular phosphorite deposits. Gusmar deposit consists of pelagic calci-mudstone/wackestone with globotruncarid planktonic foraminifers indicative of Late Cretaceous (probably Coniacian) age, alternating with a few millimeters-thick layers of phosphates. SEM analysis was pivotal in identifying the euhedral morphology of calcium phosphate minerals with hexagonal basal section, often organized in radial spherulites and in confirming the presence of microbial organic remains, such as biofilm extracellular polymeric substances (EPS) and filaments.

The formation of phosphorite deposits within pelagic carbonates requires up-welling currents that contribute to increasing primary productivity, organic matter accumulation and expansion of the oxygen minimum zone. This allows the concentration of calcium phosphate associated with organic-rich sediments. Phosphorous and uranium migrate in the first few meters of sediments, from organic matter to pore fluids that precipitate apatite in suboxic conditions. The process described above is valid for the Toarcian Fushëbardha and the Coniacian Gusmar pelagic carbonate deposits both linked to global Oceanic Anoxic Event (OAE). As for the Bogaz fluorapatite in brecciated shallow, platform-interior carbonates, it was determined that a Toarcian or later hydraulic brecciation of the older and underlying Sinemurian-Pliensbachian carbonates was responsible for the formation of this secondary phosphorite deposit. Hydrothermal fluids percolating downwards into the carbonate sequence re-mobilized phosphates higher up in the stratigraphy and re-deposited them while brecciating the host carbonates.

This study is one of the first comprehensive investigations of primary sedimentary and secondary diagenetic phosphorites in Southern Albania.

Notholt A.J.G. (1985) - Phosphorite resources in the Mediterranean (Tethyan) phosphogenic province: a progress report. Sci. Géol. Mém., 77, 9-17.

Punta Corna five-element vein system (Italy): Late-Alpine hydrothermal circulation and metallogenesis

Santoro L.* & Domenighini G.

Dipartimento di Scienze della Terra, Università di Torino.

Corresponding author email: licia.santoro@unito.it

Keywords: cobalt, hydrothermal, alpine.

The Punta Corna Fe-Co-Ni-Ag-Bi deposit is located in the Lanzo Valleys, Piedmont (Italy). It consists of five-element mineralization exploited for Fe and Co until the 19th century and then abandoned. The global concern for strategic raw material supply, such as Co, has raised a renewed interest in old mining sites where economic potential was not fully investigated. Since 2018 the Junior Exploration Company AltaMin Ltd. owns the exploration license of the Punta Corna area for assessing the economic viability of the ore.

Mineralization consists of a complex vein system emplaced during the exhumation phases of the Alpine orogeny (Castelli et al., 2011). The veins are related to two sub-vertical faults systems, cutting all metamorphic structures since the Oligocene, in an extensional-transtensive regime (Perello et al., 2004). Various styles of brecciation, overgrowth and replacement indicate multiple hydrothermal pulses.

Hydrothermal activity started with silicification and sericitization of the host rock, followed by the precipitation of Fe-rich carbonates (siderite and ankerite), calcite, quartz and baryte. This first stage concludes with the deposition of base metal sulfides (pyrite, chalcopyrite, galena. The Fe-Co-Ni arsenides comprise nickeline, overgrown by safflorite, then euhedral skutterudite and final rammelsbergite in siderite and quartz gangue. Native Bi and As may be recognized in the core of skutterudite and safflorite (Moroni et al., 2019). The final hydrothermal stage is characterized by sulfides and sulfosalts such as tetrahedrite, chalcopyrite, sphalerite, galena, pyrite and bournonite. This stage, at the very end, also includes Bi-Sb sulfosalts such as the emplectite-chalcostibite solid solution, horobetsuite and wittichenite in siderite, quartz, ankerite and baryte.

Fluid inclusion studies employing microthermometry, cathodoluminescence, and micro-Raman spectroscopy revealed the presence of different fluid types, suggesting a mixing process as the cause of ore precipitation. These fluids exhibit distinct temperatures, salinities and composition, indicating diverse provenance sources. The evolution of fluids associated with Stage I mineralization and those linked to the arsenides align with existing models, stating that the transition from base metal sulfides to Fe-Co-Ni arsenides is triggered by a process of rapid reduction, caused by the oxidation of a reducing agent. The presence of Bi-Sb sulfosalts, appearing in the late stages of the mineralization, may represent a connection to the hydrothermal Au-Bi-Sb veins in the nearby Gran Paradiso Massif (Cevales et al., 1961).

Ore variability in five-element (Ni-Co-As-Ag-Bi) vein systems: insights from the As/S vs. S binary plot

Scano I.*[1], Moroni M.[2], Frau F.[1] & Naitza S.[1]

[1] Dipartimento di Scienze Chimiche e Geologiche, Università di Cagliari.
[2] Dipartimento di Scienze della Terra "A. Desio", Università di Milano.

Corresponding author email: iscano91@gmail.com

Keywords: five-element veins, ore variability, arsenides curve.

Five-element (Ni-Co-As-Ag-Bi) veins (Kissin, 1992) are a class of hydrothermal deposits characterized by complex mineral assemblages such as native elements, Ni-Co arsenides and base-metal sulfides/sulfosalts in quartz and carbonate gangue, sometimes in association to barite and fluorite. Many theories have been proposed to explain the origin of fluids, the sources of metals and ore precipitation mechanisms (Scharrer et al., 2019 and references therein), which require a reducing agent usually represented by 1) methane (Markl et al., 2016), and/or 2) oxydation of Fe^{2+} to Fe^{3+} in siderite (Kreissl et al., 2018). Temperature of fluids varies greatly between localities (50-400°C) and appears not to play an essential role in ore-formation mechanism (Scharrer et al., 2019). Although conditions of ore precipitation can be very different, textural features and mineralogical associations display evident, worldwide-scale similarities. Another typical feature of this kind of deposits is represented by the extreme compositional and mineralogical variability of the ore inside the same vein system. A simple way to explain the observed variations is represented by a linear-log scale binary plot comparing S content in wt.% versus As/S ratio in the arsenides. Plotted in this diagram, the worldwide arsenide mineral compositions (Scharrer et al., 2019 and references therein), lie on a potential "Arsenides Curve" (equation: $y = 28.382x^{-1.085}$; $R^2 = 0.9968$). Fluctuations in Sb contents, especially for mono-arsenides/antimonides and sulfo-arsenides/antimonides solid solutions, result in a shift from the curve due to a lower As/S ratio. The plot shows a continuous trend from monoarsenides to sulfarsenides which reflects the general paragenetic successions observed in many deposits of this class. However, as reported in literature for numerous occurrences, this general trend does not exclude relevant variations and sequence inversions (e.g., diarsenides following triarsenides etc.). To interpret these different paths, the plot still offers useful keys, explaining these variations in terms of variability of As/S ratios. In fact, if reduction of arsenic immediately triggers precipitation of Ni-Co-Fe arsenides (Markl et al., 2016), their composition must also record the rapid evolution of physicochemical parameters of fluids during ore precipitation, especially their "reduced" As/S ratio and relative sulfur content. Arsenides precipitation may start everywhere in the curve and can move along the curve itself in directions that depend on fluctuations of As/S ratio and sulfur activity in the hydrothermal fluids. The result is a graphical visualization of the observed wide variations in arsenide mineral assemblages inside the same vein. Overall, these evidences may suggest a source from a rapidly evolving mineral system affected by local geological conditions, rather than derivation from separate pulses of compositionally different fluids.

Keywords: mining exploration, mineral assemblages, metallogeny.

Sardinia was the most flourishing mining region of Italy with over 600 mining concessions and about 70 Mm^3 of mining dumps. The Fluminèse and Arburèse districts (SW Sardinia) are currently considered a target for Strategic and Critical Raw Materials (S-CRMs) due to the occurrence of F-Ba, Ni-Co-Bi, and LREE in mining dumps and underexplored hydrothermal vein systems and skarns.

One of the most relevant mine sites in the Fluminèse district is the Santa Lucia historical mine, exploited from 1868 to the 1980s. The mineralisation consists of a system of NW-SE, N-S and E-W veins (Filone Palazzo and Sa Mena E S'Oreri), hosted in Cambrian metalimestones and Ordovician metasiliciclastics. The ores include fluorite, baryte, base-metal sulfides, Pb-Zn sulfates and oxides in a quartz-calcite gangue.

The Santa Lucia veins occur in the vicinity of other unrelated and km-scale systems such as the five-element (Ni-Co-As-Bi-Ag±REE) veins and, at 15 km NW in the Arburèse district, the Montevecchio polymetallic vein deposit. The nearest is the Pala Su Sciusciu vein running E-W from the easternmost part of the Santa Lucia vein system. It consists of a quartz vein and hosts fluorite, baryte and, most notably, Sb-Ni-Co e LREE phases. Its geometry and mineral assemblage suggest a genetic link with the five-element system hosted in Ordovician-Silurian metasiliciclastics and black shales of the Arburèse district.

Here we report the first identification and preliminary SEM-EDS characterization of Santa Lucia primary LREE fluorocarbonates, such as euhedral hexagonal synchysite/bastnaesite associated with calcite, subhedral rutile and coronadite in quartz, and secondary anhedral Ni-oxides and phosphide associated with quartz.

The LREE and Ni-Ti assemblages suggest an affinity between the F-Ba-Zn-Pb Santa Lucia veins and the nearby Ni-Co-Sb-bearing Pala Su Sciusciu vein and Ni-Co-As-Bi-Ag±REE five-element veins. Ni-Co(-Sb)-arsenides, -sulfoarsenides and -sulfides are a trademark of the five-element veins (Scano, 2023) and have been reported to occur also in the surrounding Montevecchio veins. Moreover, REE-bearing mineral phases have been recently identified in the quartz-siderite gangue of both five-element and Montevecchio veins (Moroni et al., 2019; Deidda et al., 2021; Scano, 2023; Sedda et al., 2024). The variety of mineral assemblages (e.g. the relative abundance of fluorite and Ni-Co-Sb) may reflect factors such as the composition of host rocks, the extent of fluid circulation and processes of remobilization of elements from the surrounding F-rich Variscan granite-related ores (e.g. skarns and greisen).

In conclusion, this new set of results may serve as a hint for future investigations regarding CRM occurrences in the *Santa Lucia* area, and for a better understanding of the potential metallogenic relationships between apparently unrelated systems in the *Fluminèse* and *Arburèse* districts.

Keywords: hyperspectral remote sensing, Zn mineralization, alteration mineral mapping.

Non-sulfide Zn mineralization has gained growing economic importance in recent years, becoming an attractive target for mineral exploration. Despite the occurrences of large alteration footprints associated with these deposit types, they remain underexplored through hyperspectral imaging methods. In this study, we investigate the alteration footprints of two distinct deposits comprising the supergene non-sulfide mineralization at Skorpion (Namibia) and the hypogene willemite-rich deposit at Beltana (Australia). The Skorpion mineralization occurs within a Neoproterozoic volcano-sedimentary succession, in the Gariep Belt, resulting from the oxidation of the massive sulfide by wall-rock replacement and in-situ oxidation (Arfe et al., 2017). The Beltana high-grade hypogene willemite mineralization is hosted in Lower Cambrian carbonate rocks, in the Arrowie basin. It is structurally controlled and associated with extensive hematite-rich hydrothermal zincian dolomitization (Groves et al., 2003).

This study aims to identify and characterize the district-scale hydrothermal and supergene surface alteration for both study areas by using hyperspectral imagery of EnMAP satellite instrument. The 30 m resolution EnMAP data are collected in the Visible Near-Infrared (VNIR) and Shortwave Infrared (SWIR) range, between 420 and 2450 nm in 224 contiguous bands, at a spectral resolution of 6.5 nm and 10 nm with a signal-to-noise ratio of ≥ 400:1 and ≥ 170:1 in the VNIR and SWIR, respectively (Kaufmann et al., 2006). A large suite of spectrally active minerals was detected over these deposits, including Fe oxy-hydroxides (hematite-goethite), carbonates (dolomite-calcite), and di- and tri-octahedral phyllosilicates (micas-kaolinite-smectite-chlorite). The spectral mineral maps representative of the abundance, composition, and crystallinity of these mineral phases were obtained by applying a multiple-feature extraction workflow based on polynomial fitting (Rodger et al., 2012). The results were validated using laboratory spectroscopy, analytical geochemistry (i.e., XRPD and FESEM-EDS) using thirty rock samples collected from both study areas.

This work demonstrates EnMAP capability in identifying distinct alteration footprints of various non-sulfide Zn deposits, supporting mineral exploration by providing district-scale vectors toward the mineralized centres, facilitating follow-up field works and drilling programs.

Circular economy in the dimension stone industry: problems and challenges related to fine fractions generated during marble exploitation

Tazzini A.*, Gambino F., Mancini S. & Dino G.A.

Dipartimento di Scienze della Terra, Università di Torino.

Corresponding author email: antonio.tazzini@unito.it

Keywords: marble sludge, sustainable mining, circular economy.

Marble and carbonate stones account for 58 percent of the world's dimension stone production and have been used as primary materials for construction and ornamental purposes since ancient times. However, according to recent studies (e.g., Mehta et al., 2020), the waste generation in the marble industry is estimated to be very high, with about 30-40% of production of fresh and high-quality blocks, while about 70% of the extracted material in the quarry is lost as waste. The fine fractions generated during marble exploitation and processing activities, which include microfine marble dust and sludge, represent a particularly difficult fraction to manage due to high cost for disposal and the lack of adequate protocols for recovery, other than landfills (Careddu & Dino, 2016).

According to data from recent studies (e.g. Tazzini et al., 2024), the fine particles generated from the exploitation of marble in the Carrara Marble Basin ("marmettola") have very promising characteristics, such as very fine and homogeneous grain sizes (silt), pure calcium carbonate composition (> 90%), and no relevant pollutants. This could indicate a potential for reuse in various industrial sectors that require high quality micronized $CaCO_3$ products (e.g. filler in paper production, paints, or chemical applications such as cosmetics and pharmaceuticals). Furthermore, it has potential applications in the construction industry as a mineral filler, substituting original materials like sand or aggregates in concrete or mortars (e.g. Marras et al., 2022).

Despite promising data, the marble industry, especially in the CMB, faces persistent issues and challenges. In quarry areas, there is often an accumulation of waste, especially the fine fractions ("marmettola"), which are often improperly stored and dumped in quarry yards. This not only causes economic losses for the companies, but also violates EU waste recycling principles and creates environmental problems (e.g. on rivers and springs).

This issue is exacerbated in quarries that use chemicals (like epoxy resins) to strengthen marble benches and blocks before transport, methods that are growing fast to optimize quarry production and reduce waste. However, in case of cutting of a fully resin-impregnated marble bench or block could result in a mixture of dust, water, and resin residues, demanding additional attention compared to the other (and more pure) fine particles. Targeted research, using further mineralogical and chemical analysis (e.g., XRF, ICP-MS, FTIR), is underway, with the aim of investigating both the potential environmental impacts of this materials and the possibility of its recycling, in a circular economy and sustainable mining perspective.

Positively reshaping the perception of these materials, particularly in the CMB, one of the world's most renowned marble districts, could turn them from being perceived negative into a valuable resource, generating a positive impact on both the environment and society.

Age and evolution of the Raibl carbonate-hosted Zn-Pb deposit (NE Italy)

Velicogna M.[1], Beltrame M.[1], Barago N.[1], De Min A.[1], Lenaz D.[1], Nimis P.*[2], Chiaradia M.[3], Venier M.[1], Chelle-Michou C.[4] & Tavazzani L.[4]

Corresponding author email: paolo.nimis@unipd.it

Keywords: lead, zinc, carbonate-hosted deposits.

The Bleiberg-Kreuth, Mežica, Raibl and Salafossa ore deposits are the most representative Pb-Zn ore deposits in the eastern Southern Alps, and have produced more than 75% of the total Pb and Zn extracted from the Alps (Brigo et al., 1977). These four deposits, as well as most other Pb-Zn deposits that are hosted in Alpine Triassic sedimentary sequences, are located near the Periadriatic Line, an E-W striking fault of regional importance that divides the Austroalpine nappes in the north from the Southern Alps and Dinarides to the south.

The Raibl mine is located in the Julian Alps near the village of Cave del Predil (Friuli Venezia Giulia, Italy), close to the borders with Slovenia and Austria. The deposit is hosted by the Carnian Schlern Dolomite (locally also known as Dolomia Metallifera), which is locally interlayered with a basinal unit formed by carbonatic-tuffaceous sediments ('pseudo-Buchenstein' or Acquatona Formation; Brigo & Cerrato, 1994; Jadoul et al., 2002). The Raibl ore bodies are composed by different amounts of sphalerite, galena and iron sulphides, forming columns and veins and, rarely, stratiform bodies. Occasionally, mineralized breccias filling fissures and erosion cavities also occur. Colloform sphalerite (i.e. schalenblende) is the most common ore type, which is represented by yellow or red sphalerite bands hosting dendritic or crystallized galena. Depending on the sector of the deposit, pyrite and/or marcasite may also be present. Gangue minerals are dolomite, calcite and rarely barite.

Previous workers subdivided the Raibl deposit into three sectors based on the chemical features of sphalerite and geometry of the ore bodies, and suggested a relation between mineralization style, paleogeography and tectonic evolution (Omenetto et al., 1979; Brigo & Cerrato, 1994). In particular, the episodic (re)activation of Triassic syngenetic faults is considered to be one of the main driver of the mineralization processes, promoting the circulation of metallogenic fluids and a prolonged polyphase remobilization and re-concentration of original sulphide ores. However, the actual timing and duration of the main mineralization stage(s) has largely remained unconstrained.

We present a large set of new in situ U-Pb ages of petrographically well-characterized hydrothermal carbonates found in spatial association with the sulphides. The combination of petrographic observations with U-Pb geochronological data allow to distinguish several generations of carbonates (pre-, syn- and post-ore) crystallized between 234.3±5.7 Ma and 92±10 Ma. By combining the radiometric ages of the sulphide-associated hydrothermal carbonates with the chemical and isotopic composition of the ore minerals, it is possible to link the mineralizing events with the activation (or re-activation) of the Triassic faults during the Mesozoic. A comparative analysis with similar Alpine Zn-Pb ore districts will be crucial to build a comprehensive metallogenic model that encompasses all the coeval ore deposits occurring in the Alps.

Keywords: red muds, compositional data analysis, critical metals.

Bauxite residues (RM), the byproduct of the Bayer process for aluminium extraction from bauxite ore, pose significant environmental challenges, while containing valuable critical metals (CMs). A preliminary analysis of red mud (RM) samples from the disposal sites in Portovesme, Sardinia, Italy was conducted to understand the geochemical and mineralogical features influencing the accumulation of CM in these matrices. The major elements-CM relationships were assessed by Compositional Data Analysis (CoDa).

The analytical characterization was performed through a combination of X-ray powder diffraction (XRPD) and Inductively Coupled Plasma Mass Spectrometry (ICP-MS). XRPD reveals that the main minerals are hematite, gibbsite, boehmite, anatase, cancrinite, sodalite, and quartz, consistent with what depicted in previous studies for RM from the same site (Castaldi et al., 2008; Mombelli et al., 2019). ICP-MS assessment includes the following major oxides composition (wt.%): SiO_2 (11.9-22.6), Al_2O_3 (17.4-24.9), Fe_2O_3 (22.2-30.3), MgO (0.7-4.7), CaO (2.6-5.9), Na_2O (3.5-11.5), K_2O (0.2-0.7). The average iron percentage is 25.8 wt.%, underscoring the considerable presence of iron in bauxite residues, whereas the average alumina percentage is 20.75 wt.%, consistent with the large amount of Al-hydroxides detected by XRPD. Among the LREE, the Ce is the most abundant (93-258 ppm).

CoDa was performed through Principal Component Analysis after a transformation of raw data into centred log ratio. Significant variability pertains to SiO_2, Al_2O_3, Fe_2O_3, followed by TiO_2 and MgO. Similarly, elements like Sc, V, As, Ni, Ga, Hf, and Sr exhibit variable concentration ranges, whereas Co, LREE, HREE, Ta, and W have substantially constant low concentrations within this dataset. The PC1 and PC2 association reveals that TiO_2 and Na_2O have a significant impact on the distribution of HREE, LREE, Sc, Nb, and Co, likely through mineral interactions and complex formation. MgO and Al_2O_3 play a role in controlling V, As, Ni, and Ga distribution.

This preliminary study highlights the potential of red muds as a geo-material for the recovery of critical metals, providing an environmentally friendly solution to the challenges posed by their disposal. Further research could facilitate the efficient utilization of this secondary byproduct, aligning with sustainability goals (Liu & Naidu, 2014).

Keywords: red mud, magnetic zeolite, arsenic removal.

Red mud (RM) is a waste material resulting from alumina production when bauxite ores are subjected to caustic leaching processes. Its mineralogical composition is characterized by the presence of hematite and goethite with minor amount of boehmite and, subordinately, calcium oxides, katoite, sodalite. RM has been used as alumina and iron source for the synthesis of zeolites thus promoting one useful method to reduce the amount of this waste to be deposed of in landfill. In detail, in our previous papers, this alkaline waste was used for the synthesis of LTA and X-type zeolite in combination with fly ash (Belviso et al., 2015), as alternative aluminium source for FAU and GIS types zeolite (Belviso et al., 2018) or as non-conventional Fe source for the synthesis of zeolite A with magnetic properties Belviso et al. (2020a). Red mud treated by sonication was also used to form zeolite-layered double hydroxide composite (LTA-LDH) (Belviso et al., 2020b). In all these experiments, the waste material was alkaline activated by sodium hydroxide. To the best our knowledge, zeolite synthesis from red mud by KOH alkaline activation has not been yet performed.

In this new work, the solid waste resulting from bauxite ore (red mud) was converted into useful products consisting in hydrogarnet together with zeolite. RM transformation from disposal material into new source was carried out using potassium hydroxide as activator and hydrothermal process (HY) or vapor phase crystallization (VPC) approach. The results indicate the formation of katoite and zeolite L (LTL topology) with both approaches. All the synthetic products display magnetic properties. In addition, a preliminary investigation on arsenic removal from drinking water (from 68 to 87%), makes the synthetic materials appealing for environmental applications. Finally, the synthesis of large amount of very useful newly-formed phases using vapour molecules confirms the efficiency of the innovative and green VPC process.

Keywords: hydrodispersed asbestos, fibers, groundwaters.

Recently, there has been a growing recognition of asbestos fibers in groundwaters, highlighting these as an unconventional source of exposure. Utilizing contaminated water for domestic, agricultural, and industrial purposes poses the risk of fibers migration from water to air, impacting residential, public, and occupational settings. Research suggests that polluted water sources can lead to airborne fiber concentrations exceeding regulatory limits due to processes like evaporation or mobilization (Avataneo et al., 2022). Water serves as a conduit for fibers, facilitating their dispersal and accumulation in distant locations. Consequently, hydrodispersed asbestos emerges as a novel environmental pollutant, with systematic assessment of its presence still lacking. Moreover, the risk of ingesting asbestos fibers via drinking water remains inadequately addressed, with conclusive evidence yet to be established. This study investigates asbestos pollution in groundwaters in ophiolite area of Calabria Region (Southern Italy). In detail, 22 water samples (including springs and river waters) were collected in the central part of Calabria region and thoroughly characterized. Tremolite emerges as the predominant asbestos mineral, followed by chrysotile, actinolite, and anthophyllite. Additionally, non-asbestos minerals such as Mg-hornblende, gedrite, edenite, and rutile were also detected. Geochemical analyses identified two main hydrochemical facies, Ca-HCO3 and Mg-HCO3, with variable heavy metal concentrations ranging from 0.23-17.13 ppb for Cr, 4.72-49.12 ppb for Fe, 1.12-30.36 ppb for Ni, and 5.37-30.24 ppb for Zn, respectively.

The analyses revealed the ubiquitous presence of asbestos fibers in investigated waters, with concentrations up to 330000 fibers/Liter. Morpho-dimensional examination indicated variability in fiber dimensions, with a significant proportion falling within pathogenic criteria. The highest concentration was observed in a Mg-HCO3 river water sample highlighting the issue of fiber transportation and accumulation in areas distant from the source. Consequently, distribution maps of fiber levels were generated. These findings show that groundwaters can be considered a potential pathway for asbestos contamination, emphasizing the necessity for comprehensive assessments and further research to mitigate health risks associated with asbestos exposure via water sources.

Mineralogical and petrographic assessment of asbestiform minerals in the Timpone Seluci metabasites (Pollino Massif, Southern Italy)

Caggiano J., Cisullo C.*, Buccione R., Rizzo G. & Mongelli G.

Dipartimento di Scienze, Università della Basilicata, Potenza.

Corresponding author email: carmine.cisullo@gmail.com

Keywords: mineralogy, asbestiform minerals, Pollino Massif.

There is a wide interest about the toxicity and carcinogenicity of asbestos minerals occurring innatural rocks since the inhalation of asbestos could cause health problems such as malignant mesothelioma and lung cancers. In the Timpone Seluci metabasites the main constituent of the asbestos minerals is actinolite with the presence of further minerals such as glaucophane. In this work we performed a petrographic and mineralogical characterization of Timpone Seluci (PZ) metabasites which belong to the Frido Unit of the Liguride complex in the southern Apennines. The studied metabasites show a massive structure and with colours ranging from dark green to blue. Petrographic characterization was performed by using optical microscopy (OM) and scanning electron microscope (SEM) while bulk mineralogical composition was assessed by using X-ray powder diffraction analysis (XRPD). The main minerals found in the studied rocks are plagioclase, quartz, clinopyroxene, blue amphibole, green amphibole, lawsonite, epidote, pumpellyite while accessory and secondary minerals are apatite, opaque minerals, chlorite and sericite. Actinolite exhibits acicular and fibrous habitus. Mineralogy and petrographic features reveal that metabasites have undergone a metamorphic event with high-pressure conditions, as evidenced by the finding ofglaucophane and lawsonite, attributed to Alpine metamorphism. Subsequently, the metabasites were affected by a retrograde event under greenschist facies, testified by the presence of albite, chlorite and actinolite. The presence of some of the main mineralogical phases observed in the petrographic study was confirmed by X-ray powder diffraction and scanning electron microscope analysis.

Recycling detoxified asbestos cement in several commodities

Keywords: asbestos, inertization, recycling.

The large amount of asbestos containing materials (ACM) still present in the built environment represents an environmental concern. The application of a sustainable detoxification process followed by recycling is recommended by the EU. With the A-FIRE project (Asbestos Fast Inertization & Recycling), we thermally treated asbestos-cement (Eternit®-like) slates commonly used for roofing at 1100-1150°C, obtaining the transformation of asbestos into non-toxic minerals, cement-like phases and glass (Vergani et al., 2022). We used this product as secondary raw material (SRM) for the production of sanitary ware (Bernasconi et al., 2022), as filler in epoxy resin for flooring applications (Campanale et al., 2023), in mortar for plaster applications (Capitani et al., 2024), in rock-wool production, as partial substitution of cement, in biopolymers and geopolymers. The recycling in sanitary ware is possible up to 5 wt.% of detoxified asbestos cement (DAC), provided that sulphates that adversely affect the workability of the slurry could be washed out and if the whiteness is not a prerequisite. Recycling DAC as filler in epoxy is possible up to 30 wt.%, where it can substitute for common inorganic filler such as barite and wollastonite, reducing the cost of the composite and increasing the durability of the flooring. Recycling DAC in mortar for plaster application as inert up to 7 wt.% does not alter the water demand and workability of the mixture and slightly increases the flexural and compressive strengths. Recycling DAC in the production of rock-wool mixed with diabase in the proportion 70:30 by weight is possible and leads to fibres with morphology, composition and biosolubility similar to those of commercial rock-wool. Tests as substitute of cement, as filler in biopolymers (polylactic acid) and as SRM in geopolymers are in progress; preliminary results are very promising. Finally, Life Cycle and Cost Benefit Analyses suggest that asbestos inertization and recycling represents a sustainable alternative to deep landfilling.

Advancements in zeolite-based recovery of Rare Earth Elements: a step towards resource security and sustainability

Colombo F.*[1], Fantini R.[1], Di Renzo F.[2], Malavasi G.[1], Malferrari D.[1] & Arletti R.[1]

Keywords: zeolite, ree, circular economy.

Rare Earth Elements (REEs) represent a group of seventeen elements, including the Lanthanides along with scandium and yttrium, playing a pivotal role in modern technology. Their demand has been escalating due to their extensive use in various applications such as computer memory, DVDs, rechargeable batteries, catalytic converters, magnets, mobile phones, LED lighting, superconductors, glass additives, and medical imaging agents. An European study on Critical Raw Materials (Bobba et al., 2020) highlights REEs as crucial for the energy transition, projecting a significant surge in their utilization by 2050. However, the supply risk is heightened as China currently dominates the market, supplying 98% of the EU's REEs. Diversifying the supply sources is imperative to enhance resource security and reduce dependency on a single country. Various waste materials have been identified as potential sources of REEs, including phosphogypsum, red muds, mine tailings, and electronic wastes. Effective recovery methods such as selective precipitation, solvent extraction, adsorption, and ion exchange are exploited for REEs recycling. Among these methods, the use of zeolites, known for their cation exchange properties, hold promise for REE recovery (Confalonieri et al., 2022). However, their stability in acidic solutions and selectivity towards different REEs require further exploration. In this work (Colombo et al., 2024) the cation exchange capacity of a synthetic 13X zeolite, FAU type, against four REEs with concentrations mimicking those obtained from the leaching of spent fluorescent lamps (Eduafo et al., 2015) was evaluated. The aim was to assess the efficiency of zeolites in REE recovery and develop a methodology for selective separation. Despite acidic conditions during testing, zeolite cation exchange properties remained largely unaffected. NH4-13X zeolite exhibited good affinity for REEs, with Ce, La, and Y reaching maximum exchanged values of 23, 22, and 16 atoms per unit cell (p.u.c.), respectively. Eu concentrations were too low to saturate the zeolite across all liquid-to-solid ratios, hindering the evaluation. The optimal liquid-to-solid ratio for Ce and La was found to be 50/1, while Y saturated the zeolite even at a 10/1 ratio. Ce and La exhibited a higher affinity for the zeolite than NH4 and Na, while Y showed intermediate affinity. This selectivity may stem from Y's smaller ionic radius compared to Ce, La, and Na. REE recovery from exchanged zeolites showed minimal Ce and Eu recovery but nearly half of La and Y were recovered. Studies involving selectively releasing La over Ce and Y over Eu using NH4-13X zeolite in a multi-elemental solutions system are ongoing, as well as a deep structural characterization of the exchanged zeolites via high resolution XRPD and XAS.

Keywords: nanotubes, hydrothermal synthesis, surface functionalization.

Hydrated magnesium silicate $[Mg_3(Si_2O_5)(OH)_4]$ nanotubes (NTs), in their highly biocompatible stoichiometric form, are synthesized in aqueous solution with Mg and Si precursors, under hydrothermal conditions, and used as nanoscintillators.

The brucitic $[Mg(OH)_2]$ outer layer of NTs confers a basic behaviour to the surface which, in a mild acidic environment, tends to concentrate Mg^{2+} ions, promoting positive Z-potential and surface functionalization with anionic species. This property is exploited to give therapeutic effects to NTs by surface anchoring of Chlorin e6 (Ce6) and cyclic D,L-α-peptides (CP-2).

Ce6 is a water-soluble organic dye able to produce reactive oxygen species under visible light excitation in physiological environment, and CP-2 represent an alternative for the selective target of early toxic amyloid-β (Aβ) aggregates, the main responsible of the progression of the Alzheimer's Disease.

We propose the inhibition of Aβ oligomers formation by an X-ray activated photo-dynamic approach: biocompatible and blood-brain barrier-permeable NTs are injected into blood and selectively attached to Aβ aggregates. Irradiation by low doses of highly penetrating X-ray promotes scintillation and then visible light excitation of Ce6, generating singlet oxygen, which selectively destroy Aβ oligomers (Secchi et al., 2022; 2023).

Synthesized NTs, bare and functionalized with Ce6 and CP-2, are characterized with a multi-analytical approach to assess the performance of each step of photo-activation process.

Keywords: fibrous antigorite, toxicity, asbestos.

Antigorite, a serpentine polymorph, can occur in an asbestos-like morphology and may pose risks to human health. For example, in New Caledonia, exposure to fibrous antigorite has been identified as one of the contributing causes to the mesothelioma epidemic that affected its population (Baumann et al., 2011). However, the toxicity of antigorite has yet to be fully defined.

In the perspective of assessing the hazard of this mineral, a crucial step is to investigate its key toxicologically relevant physico-chemical properties and compare them with those of asbestos minerals. This work aimed to model biodurability, fibre surface modification, and chemical reactivity following interaction with an artificial lysosomal fluid (ALF) simulating the intracellular environment of phagocytic cells (Marques et al., 2011). Two antigorite samples from Calabria and Liguria (Italy) were investigated, along with three asbestos samples: UICC chrysotile, UICC crocidolite, and fibrous tremolite (Basilicata, Italy).

Biodurability was assessed by incubating the samples in the ALF at pH 4.5 for up to 28 days at T = 37±1°C. The leached cations were quantified by inductively coupled plasma optical emission spectrometry (ICP-OES). Surface modifications following dissolution were monitored by X-ray photoelectron spectroscopy (XPS). The focus of these analyses is on the chemical speciation of surface Fe, since Fe can catalyse, through the Fenton reaction, the generation of highly reactive hydroxyl radicals (•OH) (Andreozzi et al., 2017) capable of inducing lipid peroxidation and oxidative damage to DNA (Mossman, 2018). Chemical reactivity was evaluated by testing the release of •OH radicals in the presence of H_2O_2 for up to 15 days, on both pristine and incubated fibres, using the spin trapping technique coupled with electron paramagnetic resonance (EPR) spectroscopy.

Results show that the biodurability of the two antigorite samples is higher than that of UICC chrysotile but significantly lower than that of UICC crocidolite and fibrous tremolite. Dissolution causes changes in Fe speciation on the surface of the fibres, and the surface alteration, in turn, leads to changes in reactivity. The observed behaviour of fibrous antigorite seems to support the hypothesis of its potential toxicity, with consequent risk to human health.

Keywords: asbestos amphiboles, Mt. Etna, Sicily.

Naturally occurring asbestos (NOA) refers to the natural presence of asbestos minerals within geological formations such as rocks, sediments, or soils. Fibrous minerals, although not classified as asbestos, can also be hazardous to human health and have been reported in various rock formations. Human activities (e.g. quarrying, excavation for services, infrastructure, or agriculture) as well as natural phenomena (e.g. weathering, earthquakes and hurricanes), can disturb or expose these asbestos-containing fibres, releasing them into the environment and posing potential hazard to human health. In southern Italy, the volcanic products of Biancavilla (Etna, Sicily) mark the first known occurrence of amphibole asbestos in a volcanic environment (Burragato et al., 2005). Furthermore, mineralogical analysis of these minerals led to the identification of a new end-member of the calcic amphibole group of the edenite series, which was identified and approved as a fluoro-edenite by the CNMMN (IMA, code 2000-049) (Pinizzotto et al., 2018 and references therein). The site of Monte Calvario (Biancavilla, CT) was therefore declared a Geosite of Global Interest in 2015 due to its degree of scientific interest. The fluoro-edenite fibrous amphibole was reported to cause mesothelioma in the regional population of Biancavilla and its carcinogenic hazard to humans was definitively established by the International Agency for Research on Cancer Working Group (IARC, 2017) by means of well documented epidemiological, chemical, in vitro and in vivo studies.

The fluoroedenite crystals found in the altered benmoreal lavas of the Biancavilla area (Pinizzotto et al., 2018) are commonly associated with feldspars, quartz, clino- and orthopyroxene, F-Cl-apatite, ilmenite and hematite, and probably crystallised from high-temperature volcanic fluids (Burragato et al. 2005). These crystals can exhibit prismatic or acicular or fibrous habit (Burragato et al., 2005; Pinizzotto et al., 2018) and their mineralogical and crystallographic investigations show a general depletion of Ca and Mg content in the fibres compared to prismatic ones, and a similar F content in both occurrences, with high F and Na contents compared to those of tremolite and actinolite fibres (Burragato et al. 2005).

Therefore, a comprehensive petrographic, mineralogical, petrophysical, and geochemical characterisation of such minerals is essential not only to assess the environmental risks to the population living near the Biancavilla asbestos sites but also to establish the knowledge base for further research into the human health impacts of these minerals as well as for the development and implementation of remediation techniques.

With this aim, this contribution will report on a review of the state of the art of naturally occurring asbestos in the volcanic geological contexts of Etna and provide new insights into the fluoro-edenite of Biancavilla, showing the preliminary results of an extensive PhD research work.

Keywords: GO, PFOA, PFOS.

Perfluorinated substances (PFAS) are environmental contaminants that are difficult to break down chemically, thermally, and biologically. Adsorption is the most effective and affordable way to remove PFAS from aquatic environments. Graphene oxide (GO) has gained popularity in water filtration because of its aqueous dispersibility, reactivity, high stability, flexibility, and low cost. Adsorption experiments, high performance liquid chromatography, in situ powder diffraction data, and thermal analysis were used in this study to evaluate PFAS removal and study the real-time evolution of graphene oxide (GO) before and after Ag functionalization, perfluorooctanoic acid (PFOA), and perfluorooctane sulfonate (PFOS) loading. Diffraction data revealed structural changes, and the interaction of PFOA and PFOS with GO interlayers caused a (001) peak shift to higher 2θ values, indicating their presence in the structure. At 150°C, functional groups were ejected, structural defects occurred, and the GO characteristic peak (001) shifted. At 350°C, the (001) reflection disappeared and the (002) peak intensity increased, suggesting that GO was converted to reduced graphene oxide (rGO). Silver loading in GO (AgGO) was confirmed by new reflections attributed to Ag nanoparticles and a decrease in d*hkl* values. The degradation of PFOA and PFOS molecules occurred between 375 and 400°C.

Thermogravimetric and High-Temperature X-ray Diffraction study on the desorption of humic monomers from Y zeolites

Keywords: zeolite, HBA, HT-XRD.

The study examined the thermal behavior of p-hydroxybenzaldehyde (HBA) desorption from Y zeolites using both isothermal and non-isothermal methods, in order to obtain a detailed structural and kinetic interpretation of the process. Rietveld refinement of in situ powder XRD data and thermal analysis revealed that HBA thermal degradation occurred in the temperature range of about 250-480 °C. This process has a considerable impact on the framework's geometry, resulting in cooperative tilting of the tetrahedra and deformation of both the 6MRs and 12MR rings. For comparison, the HBA desorption experiment was also repeated in isothermal conditions at four different temperatures (200, 250, 350, and 400°C). There were no significant differences between isothermal and non-isothermal kinetic data. Overall, the results of both experimental conditions suggest that the cooperative tilting of tetrahedra and the deformation of rings play a crucial role in HBA desorption. The similar activation energies obtained from isothermal and non-isothermal kinetics further validate the accuracy of the experimental methods employed in this study. These findings provide valuable insights into the mechanisms involved in the desorption process of HBA.

Mobility of hazardous elements in ceramic bodies

Keywords: porcelain stoneware, element mobility, immobilisation efficiency.

Waste recycling can potentially become a common practice for improving the environmental sustainability of the ceramic manufacturing process. However, the introduction of waste can considerably expand the compositional spectrum of raw materials with possible inclusion of hazardous components. Therefore, prior to the resorting of any secondary raw material, it is fundamental to assess the degree of inertization of hazardous elements (HEs) through the ceramization process. The aim of the present work is to quantitatively assess the mobility of various HEs (Ba, Co, Cr, Cu, Mo, Pb, Sb, Sn, Sr, V, Zn) introduced in silicate ceramics. For this purpose, four batches were formulated following the typical recipes to obtain: three largely vitrified ceramic products (i.e., two different porcelain stoneware bodies and a red stoneware) and a largely unreacted body (low fired brick). An artificial waste, with an aluminosilicate matrix containing all the HEs cited above, was added to all the batches in the amount of 10 wt.%. The eight batches were experimented at the laboratory scale, simulating the industrial tile-making process. After the characterization of the main technological properties of the fired products (water absorption and bulk density), they were subjected to leaching test (EN 12457-2:2002, to evaluate the HEs mobility), XRPD-Rietveld analyses for the quantitative phase composition, and SEM-EDS observation to determine the microstructure and the HEs diffusion. Obtained data indicated a different mobilization mechanism depending on both specific hazardous element and ceramic typology, with significant criticisms related to Mo, Cr and Sr, mostly in the largely unreacted body.

Mercury (Hg) pollution in riparian vegetation along the Paglia River in the Monte Amiata Hg mining district (Italy): implications for a sustainable environmental management and risks

Morelli G.[1], Ciani F.*[2], Costagliola P.[2], Fagotti C.[3], Lattanzi P.[1], Manca R.[2-4], Monnanni A.[2], Nannoni A.[2] & Rimondi V.[2-4]

Keywords: mercury, riparian trees, biomass.

Riparian vegetation plays an important role in fluvial ecosystems. Catchment runoff in abandoned mine sites is often source of heavy metals in the environment through long distance transport of contaminated sediments, which are deposited in riverbanks. In those areas riparian vegetation limits the dispersion of sediments and associated contaminants through the stabilization of the riverbanks, and takes up contaminants from the soil, acting as a temporary storage of the metals.

In this study, the potential mercury (Hg) uptake from plants growing on soil anomalous in Hg was quantified to understand the risks associated to the use of riparian trees as biofuels or in case of fire. Riparian trees were sampled from the riverbanks along a section of the Paglia River (Tuscany, Italy), that drains the abandoned Monte Amiata Hg mining district, characterized by anomalous content of Hg (>1 mg/kg). The riparian vegetation is here occasionally cut during bank maintenance, and the resulting wood may end up into wood chips for solid biofuel.

Three cores of trunks were collected from each tree sampled in five sites along the Paglia River. Poplars (*Populus* spp.) are the most abundant specie naturally widespread along the Paglia riverbanks, together with *Robinia* spp. and *Quercus* spp. At each site, a soil sample was also collected.

In soils, Hg ranged from 3.5 to 52.8 mg/kg, above the limit for Italian soils (1 mg/kg; D. Lgs. 152/2006), consistent with previous studies defining the sampling area as a "Hg impacted corridor" (Fornasaro et al., 2022).

In trees, Hg ranged between 0.5 and 93 ng/g. Anomalous Hg concentrations (195-353 ng/g) in a few trees are probably associated to soil particles trapped in the tree barks. Most of trees presented Hg concentrations below 100 ng/g, which represent a recommended Hg limit for the quality of solid biofuels, according to the European EN ISO 17225 (2021). From a commercial point of view, Hg contents in trees should have little to moderate impact on the value of the locally harvested wood chips. On the other hand, in case of wildfires, Hg emission from burning trees in the studied area was estimated at about $1.4*10^{-3}$ kg Hg/ha, whereas from soils the emission reached 27 kg/ha, posing a risk to the surrounding environment (biota, human health and animals) and acting as a potential secondary source of Hg0 to the atmosphere.

Understanding the Hg content of the riparian vegetation allows to correctly evaluate its storage effectiveness, the mechanisms governing the Hg uptake by arboreal plants, as well as their potential as a secondary source of Hg to the atmosphere in case of fire, or upon anthropic utilization as biomass. In similar contaminated areas, investigation of metals fate and transport between soil and plants is important to assess the actual risks of emissions in case of fire or for providing remediation strategies for contaminated soils through phytoremediation strategies.

Keywords: red muds, XRD, TEM.

Red mud (RM) residues produced by Bayer process for alumina refining is a hazardous material which may be valorized as a source of secondary raw material with a potential for REE extraction (Pietrantonio et al., 2021). The mineralogic composition of RM depends on the mineral composition of the source material, i.e. bauxite and on the specific processing parameters of the Bayer cycle. In turn, bauxite is a complex ore that can contain up to one hundred mineral phases (Ostojić et al., 2014). In this study, ten RM samples supplied by the Eurallumina company (Portovesme, Sardinia, Italy) and randomly collected from three storage basins were investigated combining X-ray powder diffraction (XRPD), Inductively Coupled Plasma Mass Spectrometry (ICP-MS) and Transmission Electron Microscopy (TEM).

XRPD results evidence that the common phases to all samples are hematite, gibbsite and boehmite, anatase, cancrinite, sodalite and quartz as also found in previous investigations (e.g. Snars & Gilkes, 2009; Castaldi et al., 2011 and references therein).

Oxide composition (wt.%) from ICP-MS analysis indicates significant amounts of Al_2O_3 (20.8) and Fe_2O_3 (25.8) as major components. Elements like Sc, V, As, Ni, Ga, Hf and Sr exhibit high variability whereas Co, light rare elements (LREE), heavy rare elements (HREE), Ta and W have low variability. Abundance of Ce (93 ÷ 258 ppm) is a notable feature of the analysed samples.

TEM investigation was carried out on the sample with the highest concentration of Ce. From a morphological viewpoint, the selected sample shows particles with variable morphology, with occurrence of lamellar or acicular crystals, mostly forming globular nano-aggregates. SAED patterns show peaks, corresponding to the main phases detected by XRD. Chemical mapping reveals an elemental distribution consistent with the main phases detected by XRD and SAED and suggests the occurrence of a second Ti-bearing (titanite) and a Ca-phosphate phase (apatite). At the present stage of investigation, there is no clear evidence of a Ce-bearing phase (i.e. Ce may be dispersed in small amount in several different minerals).

Petrography, geochemistry and mineralogy of serpentinite rocks in the ophiolite units at the Calabria and Basilicata regions, Southern Apennine (Italy): state of the art and ongoing research

Punturo R.*[1-2], Rizzo G.[3], Buccione R.[3], Visalli R.[1], Indelicato V.[1-4] & Cirrincione R.[1]

[1] Dipartimento di Scienze Biologiche, Geologiche e Ambientali, Università di Catania. [2] Istituto di Geologia Ambientali e Geoingegneria, CNR, Roma. [3] Dipartimento di Scienze, Università della Basilicata, Potenza.

Corresponding author email: rosalda.punturo@unict.it

Keywords: serpentinite, ophiolite, Southern Apennines.

This contribution summarizes results carried out over the last decade deriving from a multi-analytical and multidisciplinary study on serpentinites in the ophiolite units of Basilicata and Calabria regions, southern Italy, depicting the "state of the art" .

Indeed, due to their multifaceted importance, that spans from tectonic and petrological to economic and in terms sustainable development, there has been increasing interest in these serpentinites.

From the tectonic and petrological viewpoint, since serpentinite rocks testify the ocean-floor metamorphism that took place and transformed the original mineralogy and fabric of previous ultramafic rocks, their knowledge is a critical key-point for understanding the complex microplate tectonics of the central Mediterranean area.

From the economic point of view, it is worth noting that, due to their beauty and attractiveness, serpentinite rocks from southern Apennines have been exploited and marketed as heritage stones since prehistorical times worldwide. Therefore, their detailed knowledge may provide a useful tool to understand their behavior when they are employed as building materials, to predict their performances upon emplacement in monuments, and to plan correct restoration by considering the provenance of the lithotypes employed. Another important topic deals with environmental issues since it has been reported that serpentinites from Calabria and Basilicata may contain asbestiform and other fibrous minerals, as testified by the occurrence of chrysotile, tremolite, and actinolite asbestos located within the veins, which could lead to health problems due to asbestos fiber exposure. Finally, the contribution presents and discusses recent preliminary studies which highlighted as serpentinite may be considered as an important potential CO_2 sequestration sink and may thus influence global climate.

Sustainable development in traditional ceramic glazes: harnessing MMVF waste for environmental innovation

Keywords: ceramic glaze, thermal inertization product of fibres, secondary raw material.

We have developed a ceramic glaze by utilizing the thermal inertization product of Man-Made Vitreous Fibres (MMVF) as a secondary raw material. The MMVF used in this project are derived from rock wool, primarily composed of silicon with varying amounts of alkalis, aluminum, and iron. Despite their widespread use in sectors such as construction due to their exceptional properties like high chemical and physical stability, MMVFs, being fibrous materials, pose potential carcinogenic risks.

Zetadi S.r.l. has patented a thermal inertization process for these fibres, subjecting them to a prolonged thermal cycle with a maximum temperature of 1350°C, resulting in the transformation of MMVFs into an inert product termed "ReWo" (Recycled Wool).

In recent years, the ceramic industry has increasingly emphasized resource optimization and waste recycling, aligning with the principles of a circular economy. Utilizing "extramuros" waste like "ReWo" has become essential. This waste, entirely amorphous, exhibits excellent fusibility at high temperatures, making it an ideal melting component in ceramic products.

We conducted experiments with various ceramic glaze formulations, incorporating 40% to 50% "ReWo" along with other secondary raw materials, such as boric glass from laboratory glassware. The most promising formulation comprises 44% "ReWo" and 10% hematite, resulting in a lustrous, burgundy ceramic glaze. Additionally, the glaze exhibits high resistance to acid/base attacks, and leaching tests indicate negligible release of hazardous elements. These findings underscore the suitability of "ReWo" as a valuable secondary raw material for traditional ceramic glaze manufacturing.

Corresponding author email: giovanna.agrosi@uniba.it

Keywords: volumetric information, spatial distribution, genetic implications.

In recent years, the investigation of minerals by imaging methods provides an accurate and high-resolution textural representations and distributions of chemical elements (chemical zoning), presence and distribution of point defects as impurities and OH and extended defects as domains, twins, inclusions etc…. These methods often can be used in non-destructive way on samples, offering a possibility to map minerals with no loss of precious material and its valuable information and guaranteeing the reproducibility of analyses.

Comparisons among maps obtained with different techniques can be particularly valuable to fully characterize rare and precious minerals, very important to obtain important genetic implications. As an example, information about the ambient mantle have been acquired applying different imaging techniques to diamonds and their inclusions. X-ray topographic images, obtained by a diffractometric technique sensitive of deformation field associated to extended structural defects, were combined with μ-FTIR maps and optical images to study plastic deformation on super deep diamonds from Juina (Brazil) (Agrosì et al., 2017). The combined use of these methods shows a good fit between the mapping of spatial distribution of extended defects observed on the topographic images and the μ-FTIR maps corresponding to the concentration of N and H point defects. A further example of the validity of this methodological approach regards a study of multiphase inclusions entrapped within a diamond from Juina (Brazil), using a combination of imaging non-destructive methods: μ-CT was used to investigate the size, shape, distribution and X-ray absorption of inclusions, mapping by μ-XRF, μ-Raman Spectroscopy and μ-FTIR were used to determine the chemical and mineralogical composition of the inclusions. This study allowed the first finding of maohokite and huntite in diamond and provided evidence of formation of ferropericlase–magnesiowüstite and diamond in a carbonate-rich environment at depths corresponding to the Mantle Transition Zone (Agrosì et al., 2019).

The powerful role of imaging techniques has been also successively applied to the study of meteorites. Investigations carried out using a 3D reconstruction obtained by μ-CT supported by chemo-mineralogical characterization obtained by SEM-EDS, allowed to obtain volumetric information about spatial distribution of different mineralogical phases, internal structures, grain features, volume percentage and shape of voids, adding new elements about the origin of porosity in Al Haggounia 001 meteorite (Manzari et al., 2023). Lastly, preliminary non-destructive analyses by μ-CT and SEM-EDS of micro-spherule FB-A1 from Monte Gariglione (Italy), revealed the presence and volumetric distribution of exotic Al-Cu alloys disseminated in a porous matrix of silicate glass containing olivine, Fe-Ni droplets and oxides, allowing the second finding of natural quasicrystals (Agrosì et al., 2024).

Keywords: diamond, FTIR, nitrogen.

Mineral inclusions in natural diamonds represent entrapped portions of the Earth's mantle acting as witness of its composition and geochemistry. This makes diamonds a unique window on the processes in the Earth's mantle through time. It is well known that N represents the most common impurity in diamonds and its distribution into crystal defects is strongly controlled by temperature conditions (Taylor et al., 1990; Speich & Kohn, 2020). Upon increasing temperature, single nitrogen (C centers) progressively tends to aggregate into clusters of atoms and vacancies (A and B centers) (Goss et al., 2004). Fourier Transform InfraRed (FTIR) spectroscopy is the most valuable method to estimate the aggregation state of N and retrieve the temperature conditions in which the diamonds grew. This study aims to assess the possible involvement of diamonds mineral inclusions in the growth of the defects due to the N incorporation. For this purpose, four lithospheric octahedrally-shaped diamonds from the Siberian craton having silicate and sulfide inclusions of eclogitic origin have been investigated. The diamonds have been studied through high resolution FTIR mapping (2-4 cm^{-1}) at Diamond Light Source-Beamline B22 (UK). Preliminary analyses show the predominance of B centers as the main N defect, which leads to classify diamonds as 'Iab' type. Maps collected at the diamond-inclusions interface reveal a preferential N concentration near the inclusion with a marked abundance of A centers close to the interface. This scenario opens the possibility of a determining role by silicate and sulfide inclusions during the diamond growth stage because of their direct involvement in the distribution of N defects inside the crystal structure. Further single-crystal X-ray diffraction analysis together with Raman spectroscopy, could help to better determine the nature of inclusion (syngenetic-protogenetic-epigenetic) and contextualize the N defect distribution found around our suite of inclusions.

Micro-Raman mapping of the oxidation state of Mn in deep-ocean polymetallic deposits

Bernardini S.*[1], Della Ventura G.[1], Sodo A.[1] & Jovane L.[2]

[1] Dipartimento di Scienze, Università di Roma Tre. [2] Instituto Oceanográfico da Universidade de São Paulo, Brazil.

Corresponding author email: simone.bernardini@uniroma3.it

Keywords: Raman Spectroscopy, manganese, marine polymetallic deposits.

Marine ferromanganese deposits (crusts and nodules) are important strategic reservoirs for rare and critical elements (e.g., Co, Mn, Li, Pt, Zr, Nb, Te, Ni, V, Bi, Mo, W, and REY) that are essential to high-technology and green-energy applications (Hein et al., 2013). Their occurrence, mineralogy, and chemical composition reflect the processes of formation and the genetic depositional environment (e.g., water redox chemistry and biological activity). In these deposits, Mn may occur under different oxidation states (Mn^{2+}, Mn^{3+}, and Mn^{4+}) depending on the (bio)geochemical conditions existing during mineral growth. Marine ferromanganese crusts and nodules are thus precious archives of regional and global oceanic and climatic conditions. However, these deposits occur typically as cryptocrystalline and fine–grained mixtures of different Fe-Mn oxides and their characterization is extremely challenging by standard X-ray diffraction.

Raman spectroscopy provides a valuable tool for characterizing Fe-Mn oxide mixtures (Bernardini et al., 2019), being sensitive to short-range cation-anion arrangements. Moreover, the laser spot on the sample can be reduced to ~1 μm^2 allowing for high spatial resolution chemical analysis (Bernardini et al., 2021; 2023). Beside the identification of the mineral, Raman spectroscopy provides a quick and reliable determination of the oxidation state of Mn down to the microscale (Bernardini et al., 2021), which is unachievable in a fine scale by other techniques (e.g., XANES and XPS).

Here we show that the intensity ratio between some peculiar bands in the Raman spectrum can be used to map the microscale spatial distribution of the oxidation state of Mn in deep-ocean ferromanganese deposits. Thanks to its imaging capabilities, Raman spectroscopy may be used as an innovative tool opening a new way for the use of these widespread geomaterials for environmental (redox) reconstructions of past marine environments.

Transmission electron microscopy in Earth Sciences: conventional and advanced applications

Capitani G.*

Dipartimento di Scienze dell'Ambiente e della Terra, Università di Milano-Bicocca.

Corresponding author email: giancarlo.capitani@unimib.it

Keywords: Conventional TEM, high resolution TEM, time-resolved TEM.

Transmission electron microscopy (TEM) is the reference technique for investigations of solid materials below the micrometre scale. It is widely used in Material Sciences, Life Sciences and Earth Sciences. The success of TEM relay on the fact that with a single instrument, during the same session, one can get information of the morphology, crystallography end chemical composition of the sample with a nanometre resolution. With modern, properly equipped instruments, a sub-angstrom resolution can be achieved, crystal structures can be determined, and temporary state of the matter photographed. In this presentation, common TEM operation modes, such as diffraction contrast imaging (bright field and dark field), high resolution imaging (HREM), selected area diffraction (SAED) and will be briefly describes, as well as recently developed techniques, such as electron diffraction tomography (EDT) and time-resolved TEM (Fast-TEM).

2D image analysis of mortars: amount of cement paste and texture of the aggregates

Keywords: texture, image analysis, mortar.

The texture of phases in rocks has been quantified by image analysis on polished mesoscopic slabs and/or thin sections to visualise phases, voids and particles. 2D sections are digitalised at variable magnifications using a high-resolution scanner (HRS), transmission optical microscopy (TOM) and scanning electron microscopy (SEM) (Higgins, 2006). However, similar investigations are rare for construction materials (Abbas et al., 2009; Han et al., 2016). In fact, measurements of the abundance of different fractions (cementitious paste vs. aggregates or pores) and the types and textures of the aggregate clasts are lacking. Here, the authors explore the quantification of textural attributes on 16×4×4 cm^3 standard mortars, prepared with 1:2:4 weight fractions of water:cement:aggregate, respectively. As determined by XRPD (X-ray powder diffraction), these aggregates are mainly composed of quartz (qz), plus minor amounts of alkali-feldspar (af) and sheet silicates (ss); their sieved grain-size distribution (ϕ vs. wt.%) is 0.2, 10, 33.3, 29.5, 19 and 8 wt.% for ≤ 0.125, 0.125-0.25, 0.25-0.5, 0.5-1, 1-2 and 2-4 mm (Fuller curve), respectively (Galderisi et al., 2023). A 4×4 cm^2 polished thin section was prepared and imaged with three methods at variable magnifications: i) 1:1 by HRS, ii) 25:1 by TOM (plane polarised light) and iii) 100:1 by SEM (back-scattered mode). The unique HRS image of 14 cm^2 was directly analysed, whereas 18 for TOM and 208 for SEM adjacent (partly overlapped) microphotographs were used to prepare two stitched images. Qz is 32.6 area%, manually separated pores are 0.2 area% and cement+af+ss is 67.3 area% via HRS; instead, cement, pores (manually separated) and qz+af+ss (aggregate) are 54.3, 1.0 and 44.7 area% via TOM. The SEM image quantifies cement, pores, qz and af+ss as 41.8, 1.7, 45.1 and 11.4 area%, respectively. The SEM outcomes corroborate the XRPD measurements, while the HRS result is unable to, and the TOM outcome only roughly evaluates the actual cement and aggregate fractions. The 2D measurements of aggregate clasts by TOM and SEM were used to construct 2D Fuller curves using the sieving thresholds (Fuller curve). Several 2D size distributions were built considering the long, mean and short dimensions of the axis of equal-area ellipse, object diameters, bounding box sides, object sizes, Feret diameters and diameter of equal-area circle per aggregate clast. Several of these 2D curves for TOM and SEM will approximate the 3D Fuller curve obtained by sieving. Overall, HRS is rapid, but its measurements are mainly qualitative and only for particular transparent objects (here for qz and voids). Compared to SEM, TOM overestimates cement (41.8 vs. 54.3 area%) and underestimates aggregates (45.1+11.4 vs. 44.7 area%), but pores are similar (1.7 vs. 1.0 area%). Hence, SEM shows the best discrimination capacity of the types and textures of aggregates, besides the cement: aggregate ratio, but it is time-consuming.

Keywords: transmission electron microscopy, scanning electron microscopy, energy dispersive spectrometry.

In recent years advancements in imaging and analytical techniques have enabled the acquisition of chemical and structural information from geo-relevant materials with an extraordinary space resolution. This has facilitated new interpretation and the gathering of information that, just a few decades ago, would have been unattainable. In this work we demonstrate the application of chemical and imaging techniques, utilizing scanning (SEM) and transmission (TEM) electron microscopy coupled with energy dispersive spectrometry (EDS), for the characterization of various minerals and their associated geological processes. Specifically, we investigate peridotite and its alteration, as well as polysomatic and polytypic disorder in CaREE-fluorcarbonates.

A serpentinized peridotite from the Monteferrato ophiolitic body has been studied using SEM- and TEM-EDS. Chemical analysis, conducted with the Aztec AutoPhaseMap and QuantMap software (Oxford Instruments), revealed that the serpentinization was a complex hydration process that converted the original mantle peridotite into a polyphase serpentinite. Indeed, geometric relationships among different serpentine domains indicate at least eight serpentinization events, each characterized by lizardites with varying Al and Fe contents. These different generations of lizardite are likely correlated with tectonic events, particularly in the more massive portions of the serpentinized ultramafics where brittle rheological behavior facilitated the ingress of aqueous fluids through fractures, subsequently filled and healed by new generations of lizardite.

The characterization of species and crystal-structural modularity in mixed-layer minerals, such as CaREE-fluorcarbonates, and the significance of short-range stacking disorder and long-range polysomes, offer valuable insights for interpreting the genesis of these minerals. High-resolution electron microscopy (HRTEM) is essential for elucidating the polysomatic and polytypic disorder comprehensively, since the contrast is sensitive to the different stacking of CO_3 layers that appears with different slants in HR, revealing the actual crystal system symmetry and any polytypic disorder (Capitani, 2019). Understanding polysomatism and polytypism is critical, as intergrowths of different polysomes may indicate changes in crystallization conditions or fluid composition (Gysi & Williams-Jones, 2015), and chemical transport involved in polysomatic reactions may govern reaction kinetics (Veblen, 1991). This becomes particularly important when the investigated minerals are primary ores for critical elements such as CaREE-fluorcarbonates.

Keywords: imaging techniques, spectroscopy, microscopy.

Improving the visualization of objects and their characteristics has always been a topic of interest in all scientific disciplines, particularly in Geology where the description of morphological, as well as chemical, mineralogical and physical features of samples is mandatory. For this reason, the study of minerals and rocks as a Science probably starts with the advent of the polarizing microscope (attributed to David Brewster in 1815), while a second major step coincides with the development of scanning electron microscopy (SEM, a technique fully developed in the second half of the XX century) and later of transmission electron microscopy (TEM). It is during the last 15-20 years, however, that imaging tools, mostly based on spectroscopic techniques have significantly accelerated our possibility to access with an unprecedented resolution and completeness of information all types of (solid) geological samples: rocks, minerals and fossils. The availability of fast computational procedures nowadays allows creating any kind of 2D and 3D images from arrays of analytical points thus providing in short time accurate and high-resolution distributions of chemical elements spanning the whole periodic table (including light elements), trace to ultra-trace constituents, isotopes, oxidation states, porosities etc. Very recently, the laboratory availability of 3D techniques like X-ray tomography, traditionally restricted to large-scale facilities (synchrotrons) has provided a significant impetus to the spatial analysis of rocks for applications ranging from structural Geology to ore Mineralogy, Cultural Heritage, Biomineralogy, etc..

In this opening short communication for this session we will discuss the evolution of the imaging methods, particularly during the last century, from the development of methods based on optics, to those based on the use of X-rays to those based on spectroscopies using lower-energy beams. The different talks presented during this session will show how these techniques may help in solving issues at different scale in Earth Sciences.

Color changes in topaz treated via irradiation and heat

Elettivo G.S.[1], Tempesta G.*[1], Bernardini S.[2], Vadrucci M.[3] & Agrosì G.[1]

[1] Dipartimento di Scienza della Terra e Geoambientali, Università di Bari "A. Moro". [2] Dipartimento di Scienze, Università di Roma Tre. [3] Centro di Ricerche ENEA, Laboratorio di sviluppo di acceleratori di particelle per applicazioni medicali, Frascati (RM).

Corresponding author email: giuseppe.elettivo@uniba.it

Keywords: gems, topaz Irradiation, treatment.

Natural topaz is commonly colorless, therefore various treatments (via irradiation and/or heat) are used to enhance its hue and/or clarity, from colorless to blue, the latter being the much-appreciated in jewelry. In this research we carried out a complete spectroscopic characterization of the effects induced by irradiation and subsequent heat treatment on a series of topaz crystals. The studied samples come from primary deposits of Hematita and Ouro Preto (Brazil), from the pegmatites of Alto Ligonha (Mozambique) and from secondary deposits of Tunduru (Tanzania) and Ilakaka (Madagascar). The original color of the crystals was different: some of them were colorless, some showed a natural blue color and one a brownish orange coloration.

The crystals were treated by using two different techniques: accelerated electrons and an innovative X-ray irradiation technique. All samples were characterized before and after the treatments by using spectroscopic techniques including UV-VIS, μ-RAMAN, EPR and FTIR. The samples were also chemically analyzed by SEM-EDS and μLIBS spectroscopy to evaluate the contribution of possible chemical variations to the color changes while modification in the OH vs O2- contents were studied via IR and Raman spectroscopies. In particular, the UV-VIS techniques were used to monitor the changes occurred during the treatment and address the mechanisms that trigger the new color in the crystals. All treated samples displayed a similar broad absorption centered at 620 nm, indicating the onset of the blue color during treatment. Another extremely interesting feature is the red-shift of the UV absorption thresholds in the treated samples that can be related to the changes from OH to O-; this feature was detected via analysis of UV-VIS spectra through variations of the FWHM of peaks in the UV range, by comparing the spectra collected on natural blue and treated blue samples. UV-VIS spectroscopy thus proved to be an extremely useful technique to ascertain whether samples have undergone irradiation treatment. The other spectroscopic techniques used, RAMAN, FTIR and EPR were found to be useful for establishing which defects are caused by the irradiation treatment and which trigger the blue color in topaz samples. The results of our work finally provide the minimum dose (3.6x107 Gy) to use by a LINAC (5 MeV) and the minimum temperature (230°C for 30 min) to induce the color changes in topaz.

SPM of layer silicates and interaction with single biomolecules at the nano-atomic scale

Moro D.*, Ulian G. & Valdrè G.

Corresponding author email: daniele.moro@unibo.it

Keywords: layer silicates, mineral - single biomolecule interaction, scanning probe microscopy.

Physical and chemical properties of minerals and materials surfaces can be effectively studied and even modified at the nano-atomic scale by using Scanning Probe Microscopy (SPM) methodologies. In fact, nowadays, advancements of SPM have made available a wide range of surface investigations at the nanoscale, such as for instance Atomic Force, Electric Force Microscopy, Kelvin Probe Force Microscopy, Magnetic Force Microscopy and very recently nanospectroscopic methodologies (Kurouski et al., 2020). SPM surface investigations include morphological, rheological, mechanical, electrical and magnetic properties of the surface, and the interaction with biomolecules at the single - molecule level (Moro et al., 2016). In the present work, we employed SPM to simultaneously investigate both the surface nanotopography and surface potential of important layer silicates, and in particular cleaved clinochlore samples. The same surfaces where also studied after interaction with fundamental biomolecules, such as nucleotides, DNA, RNA, amino acids, oligopeptides, red blood cells. The findings of this research allowed us to design and create mineral surfaces with specific physico-chemical properties controlled at the nanoscale, that were also used to drive the condensation, deposition and alignment of biomolecules, and stretching of DNA chains. The SPM observations were conducted at RT (~20°C), atmospheric pressure and relative humidity of about 40%. Clinochlore surface presents atomic flat terraces (~0.2 Å rms), extended from several micrometers to few nanometers, with a typical in-depth separation of ~4 Å (the thickness of the brucite-like interlayer sheet). The electrostatic surface potential difference varies between 100 mV and 500 mV, depending on the local crystal chemistry and environmental conditions. The surface is able to condense, organize, and agglomerate biomolecules at the nanoscale onto specific regions, with possible important catalytic repercussion mediated by surface charge and crystal-chemistry. The mineral - amino acids interaction process was also investigated by quantum mechanics simulations at the DFT/B3LYP level of theory, providing the conformation of the molecule on the surface, the intermolecular bonding scheme and the Brønsted-Lowry basic/acid strength related to Al^{3+}/Mg^{2+} substitutions in the brucite-like sheet and to Al^{3+}/Si^{4+} in the TOT (Moro et al., 2019; 2020). These methodological approaches and results give a contribute to the advancement of knowledge on layer silicates surface properties at the nano - atomic scale, and biomolecules - minerals interaction at a single - molecule level. They are of interest in a wide variety of basic and applied research fields, including mineralogy, environment, biology, medicine and nanotechnology.

Keywords: clinochlore, AFM, KPFM.

Spatially resolved techniques are of paramount importance to characterize the local topographical, chemical and physical properties of mineral surfaces, which in turn can determine their overall reactivity to the surrounding environment. In this regard, scanning probe microscopy (SPM) comprises a family of advanced techniques that allows the 3D measurements of surface topography and properties at the nano-atomic scale, such as electrical, magnetic, rheological, thermal and electrochemical ones. Furthermore, SPM-based nanolithography employs SPM tip-to-sample interactions for nano-atomic scale surface modifications (Bian et al., 2021).

In this work, we present atomic force, Kelvin probe, electric force microscopy and nanolithography of clinochlore surface. Kelvin probe force microscopy and electric force microscopy (EFM) techniques have been used for detailed 3D surface nano-characterization of the electrical properties. Furthermore, natural and synthetic 3D meso-nanostructures of clinochlore were investigated and produced by scanning probe microscopy related nanolithography methods (Moro et al., 2016; 2019).

The measurement were conducted at RT (~22°C), atmospheric pressure and relative humidity of about 40%. A Nanonis (SPECS Zurich, Switzerland) SPM Controller with two oscillators connected to a MultiMode head (Digital Instruments, Santa Barbara, California) was used. In static-mode EFM, specifically FIB-machined Si3N4 gold-coated tips (k ~0.06 N/m) were used and the probe-deflection vs. tip-surface voltage difference was calibrated by using a cleaved graphite standard. In dynamic-mode, NCHPt NanoWorId (Switzerland) Pt/Ir-coated silicon tips (k ~2.8 N/m, working frequency ~70 kHz) were employed. After cleavage, SPM revealed a meso-nanostructured heterogeneous clinochlore surface in terms of morphology, hydrophilic/phobic character and surface potential, related to the mixed sub-nm thick layer stacking structure of the mineral. Successful removal of sub-nm thick structural layers at the nanometric scale was also achieved.

Keywords: biomineralogy, imaging techniques, fish otolith.

Biomineralization serves as a crucial link between soft organic tissues, reflective of atmospheric and oceanic compositions, and the solid materials of the Earth, highlighting the intricate interplay between biology and the environment (Palazzo, 2022). In this framework, fish otolith structures, acting as invaluable repositories of information, offer insights into fish adaptation, behaviour, and relationship to environmental conditions (Popper et al., 2019; Hüssy et al., 2021).

The present multidisciplinary and multiscale approach deepens the previous research on *Merluccius merluccius* otolith structures as "information recorders". By employing scanning electron microscopy and high-resolution micro-CT techniques, we delve into the 3D morphology and ultra-morphology of otoliths, elucidating their differences during ontogenesis and between genders (Palazzo et al., 2022). Specifically, we characterize the "sulcus acusticus" and its sub-regions in undifferentiated, female, and male *Merluccius merluccius* otoliths, uncovering new and characteristic features with potential adaptive and functional roles in sound perception.

Our research aims to explore the acoustical implications of otolith variability and establish shape-structure-function relationships during fish ontogenesis and between genders. The present research contributes to the understanding of the otolith features related to fish hearing capabilities and behaviour, improving the state-of-the-art knowledge in this field.

Keywords: mineral pigments, micro mapping and imaging analyses, macro mapping and imaging analyses.

The study of the materials used in paintings requires micro-invasive or non-invasive approaches to reduce the damage and to conserve the integrity of the artwork. Since the mineralogical composition of pigments used in paintings are complex and not homogeneous, mapping and imaging techniques are preferred for their capability to map the elemental and molecular distributions.

One of the most useful micro-invasive approaches involves the study of stratigraphic sections using micro-Fourier-Transform InfrarRed (FTIR) spectroscopic imaging and mapping combined with scanning electron microscopy (SEM) and energy-dispersive X-ray (EDX) mapping. These two techniques can identify the molecular and elemental compositions of materials, respectively, including mineral pigments (Pronti et al., 2020), and well recognize the structure and mixtures of pictorial layers but small fragments (less than 1 mm) must be taken from the artworks.

The development of portable devices has allowed us to analyze paintings directly in situ, in a non-invasive way, with the advantage of not moving the artworks and avoiding any sampling.

A macro-FTIR scanner, in reflection mode (MA-rFTIR), permits to acquire distribution maps of minerals obtaining the chemical images of the investigated surfaces (Legrand et al., 2014; Pronti et al., 2024), particularly on wall paintings and not-varnished paintings. Through the combination with macro-X-ray fluorescence (MA-XRF), elemental maps are integrated into the molecular ones enabling a more comprehensive identification of the mineralogical composition of paintings.

In this presentation, the analyses of the mineral pigments used in Roman wall paintings and in ancient and modern easel paintings will be discussed using both micro and macro mapping and imaging approaches.

Theoretical and experimental study of structural, vibrational, and electronic properties of dolomite

Ranellucci F.*, Ulian G., Moro D. & Valdrè G.

Dipartimento di Scienze Biologiche, Geologiche e Ambientali, Università di Bologna.

Corresponding author email: francesca.ranellucci@unibo.it

Keywords: dolomite, crystal chemistry and physics, DFT.

Dolomite $CaMg(CO_3)_2$ is an important mineral in a geological and environmental perspective. It has been thoroughly studying for its ubiquitous presence in sedimentary rocks as being part of the Earth's carbon cycle therefore, making it an important object of study to understand climate change (Liu et al., 2024). In this work we used novel multimethodology approaches, mainly theoretical, but also some experimental, to strengthen the knowledge of the minero-physical properties of dolomite. As mentioned, the study aims mainly to theoretically simulate the structural, vibrational and electronic properties of dolomite, and compare them to experimental data. The experimental knowledge was obtained from both existing updated literature and instrumental measurements performed in our laboratory on natural samples of dolomite taken from Traversella, Turin (Italy). The identification of dolomite in the samples and assessment of possible contaminations or presence of other minerals was performed by X-ray diffraction analysis (XRD), Environmental scanning electron microscopy coupled with energy dispersive spectroscopy (ESEM-EDS) at low vacuum, without requiring sample metallization, and vibrational analysis through FTIR (Fourier transformed infrared) and Raman spectroscopies. Ab initio simulations within the density functional theory (DFT) framework were performed with the CRYSTAL17 code. The effect of the Hamiltonian, chosen among 11 different functionals of the Jacob's ladder (Local density approximation - LDA, generalized gradient approximation - GGA, meta-GGA, global and range-separated hybrids) was assessed. In addition, D3 dispersive correction factor was applied when conceivable. Structure, vibrational and electronic properties of dolomite were investigated at 0K, typical settings of ab initio simulations (Valenzano et al., 2007). Vibrational frequencies were computed at the Γ point in the first Brillouin zone, and the LO-TO splitting was calculated. Overall, the cross-correlation between the experimental and theoretical data showed consistent results from the micro- and nano-scale down to atomic scale. The crystal structure of the mineral calculated using the different DFT functionals was in line with that obtained by XRD analysis. All the simulated IR and Raman spectra exhibited blue shifted bands, with the tendency of more blue-shifted bands in LDA whereas red-shifted in GGA. Finally, the calculated electronic properties, i.e. band structures and density of states (DOS), showed a band gap of ~5.0 eV, in good agreement with previously reported data (Hossain et al., 2011; Wang et al., 2021).

Study of color zoning in tourmalines from different localities before and after treatments using chemical analysis and high-resolution images

Rizzo F.*

Dipartimento di Scienze della Terra e Geoambientali, Università di Bari "Aldo Moro".

Corresponding author email: floriana.rizzo@uniba.it

Keywords: tourmaline, chemical zoning, treatments.

Tourmalines are complex borosilicate belonging to the cyclosilicates class characterized by high chemical and structural complexity that making them a fascinating subject for mineralogical and petrogenetic studies. Tourmalines complexity contributes to its diverse physical properties and remarkable chromatic diversity, ranging from colorless to various shades of red, pink, blue, black, yellow, and green or multicolored zonation (Pezzotta & Laurs, 2011; Rizzo et al., 2023). Thermal treatment and irradiation are frequently applied in the market to improve their optical clarity and/or intensify the original color. This study examines five tourmaline samples from different pegmatite provinces, employing a comprehensive analytical method to investigate the causes of color change before and after electron beam irradiation and consequently thermal treatment. The preliminary chemical composition of tourmalines for the identification of main chromophores was obtained performing analysis point using scanning electron microscopy (SEM-EDS) and after detailed traverses across the samples with electron microprobe analysis (EMPA). These data were integrated also processing high-resolution images using SEM- back scattered electron (SEM-BSE) and variable pressure scanning electron microscopy (VPSEM) to obtain cathodoluminescence effects to study in detail the zoned samples. The samples were subsequently irradiated with doses equivalent to $5.1x10^4$ Gray and heated with values ranging from 450°C to 600°C producing a significant color change, respectively an intensification of color following irradiation and brighter colors after thermal treatment. Post treatments SEM-BSE and VPSEM images acquired on the zoned areas previously analyzed, showing no differences comparing to the image of the pristine samples. This indicated that no solid-state diffusion occurred as a result of the treatments.

SINBAD-IR beamline at DAFNE-Light: application and developments of FT-IR spectroscopy in the field of Earth Sciences

Romani M.*, Pronti L. & Cestelli Guidi M.

Istituto Nazionale di Fisica Nucleare, Laboratori Nazionali di Frascati.

Corresponding author email: martina.romani@lnf.infn.it

Keywords: FT-IR spectroscopy, chemical imaging, material science.

The SINBAD-IR is the Synchrotron Radiation beamline based on Fourier transform infrared spectroscopy at DAFNE-Light laboratory of INFN-National Laboratories of Frascati (Balerna, 2021). The beamline is specialized into micro imaging and spectroscopy in different research fields, including material science, earth science, biology/radiobiology, cultural heritage, and geophysics. In the field of geology, mineralogy and astrophysics, FT-IR spectroscopy is a widely used technique providing detailed information on the chemical composition and crystalline structure of the materials constituting rocks, minerals, crystal, and planetary bodies. Both inorganic and organic compounds, along with fluid/volatile substances contained within the crystalline lattice, can be detected (Conte et al., 2022; Della Ventura et al., 2024). By using an IR microscope coupled with an imaging detector it is possible to obtain 2D and 3D high-resolution chemical images delineating the presence and the distribution of crystalline phases and inclusions. Moreover, the possibility of using synchrotron radiation allows the analysis of grains sized between 5^{-10} microns, allowing the acquisition of spectra with a high lateral spatial resolution and a high and signal-to-noise ratio. The fusion of FT-IR analyses with other complementary ones such as SEM-EDX, micro-Raman, and micro-UV analyses enables a comprehensive characterization of analyzed samples by correlating morphological, molecular, and elemental data. In this work, some of the applications on geological, mineralogical and astrophysics materials, carried out at the Synchrotron Radiation laboratory, are presented, highlighting the advantages of the technique and future developments.

Keywords: quantitative petrology, Calabria-Peloritani Orogen, image analysis.

Understanding the metamorphic journey of a rock becomes accessible through meticulous examination of its microstructures. These microstructures, which are the final product of the metamorphic evolution experienced by crystalline basements, can be the result of complex chemical reactions and often also deformation events, providing insights into the pressure-temperature trajectory followed by the rocks. Symplectites represent one of the most peculiar microstructures that can be observed in metamorphic rocks, displaying worm-like structures constituted by mineral intergrowths that develop simultaneously in a solid-state reaction (Vernon, 2004).

Optical and electron microscopy are commonly employed to quickly obtain qualitative insights into rock microstructures and identify their constituents, while image analysis techniques can be used to extrapolate more quantitative data. The increasing use of image processing methods in geological and petrological studies has proven to be a valuable tool across various fields of geosciences (Lanari et al., 2019; Ortolano et al., 2018; Visalli et al., 2021). Primarily, these methods rely on multivariate statistical analysis of EDS/WDS X-ray multispectral images that record the elemental distribution within rocks and minerals (e.g., Lanari et al., 2019 and reference therein). The large use of this technique has also prompted the development of innovative GIS-based semi-automatized tools facilitating the identification and classification of mineral phases, as well as the quantification of modal parameters from selected thin section micro-domains (Ortolano et al., 2018; Visalli et al., 2021).

In this study, high-resolution thin-section scans and X-ray elemental maps were processed by using the GIS-based Micro-Fabric Analyzer (Visalli et al., 2021) and Quantitative X-ray Map Analyzer software (Ortolano et al., 2018), obtaining grain-size distribution, mineral modal abundancies, and chemical compositions.

This is to define the effective equilibrium reactant volumes useful to compute reliable isochemical sections unraveling the P-T conditions that triggered the development of the symplectitic microstructures, occurring as Pl-Hbl-Cpx coronitic intergrowths around relict eo- or pre-Variscan garnets in a late Variscan amphibolite sample from the Aspromonte Unit (NE Sicily).

Keywords: meteoritics, refractory inclusions, petrology.

Carbonaceous chondrites offer a glimpse into the early solar system's birth and evolution. These types of rocks represent the best specimens for studying refractory inclusions, the very first minerals forming in the solar system (Connelly et al., 2012). We have conducted initial studies on the carbonaceous chondrite NWA 128000. In particular, we focus our study on some of these mineral aggregates, known as Ca-Al-rich inclusions (CAIs). We aim to delve into the events that occurred within the protoplanetary disk. Analyses were performed by backscattered electron (BSE) imaging, X-ray elemental mapping and electron microprobe analysis with a Zeiss Sigma 300 Field-emission scanning electron microscope (FE-SEM) equipped with a high-resolution backscattered electron detector and a QUANTAX 60x60 mm^2 detector for energy dispersive X-ray spectrometry (EDS). One of the studied irregular shape CAIs show a core-mantle structure that may represent a sequence of two distinct nebular condensations caused by transport in a different protoplanetary disk environment. A second CAI type shows multiple sets of mono-mineralic rims interpreted as a record of recurring partial melting episodes during high-temperature events. These high-temperature events in the solar nebula, have probably been generated by "flash heating" (Wark & Boynton, 2001). Finally, the rounded CAI texture testifies to a complete melting event. The coexistence of various CAIs within a single thin section hints at a dynamic protoplanetary disk environment. Targeted investigations will aim to refine our petrological understanding of their formation scenarios.

A preliminary petrological study of chondrules in NWA12800 meteorite

Vitrano A.*[1], Viti C.[1], Della Ventura G.[2], Lucci F.[3] & Vetere F.[1]

[1] Dipartimento di Scienze Fisiche, della Terra e dell'Ambiente, Università di Siena. [2] Dipartimento di Scienze, Università Roma Tre. [3] Dipartimento di Scienze della Terra e Geoambientali, Università di Bari "Aldo Moro".

Corresponding author email: a.vitrano@student.unisi.it

Keywords: meteoritics, chondrules, petrology.

Chondrules, abundant in chondrite meteorites, are small, rounded silicate grains whose formation mechanisms still elude us (Russell et al., 2018). Describing their various textures proves invaluable in unravelling the crystallization history of these miniature worlds. This study aims to characterise chondrules founded in NWA12800, in order to produce datasets useful for upcoming petrological experiments. Analyses were performed by backscattered electron (BSE) imaging, X-ray elemental mapping and electron microprobe analysis with a Zeiss Sigma 300 Field-emission scanning electron microscope (FE-SEM) equipped with a high-resolution backscattered electron detector and a QUANTAX 60x60 mm^2 detector for energy dispersive X-ray spectrometry (EDS). Chondrules display diverse textural types, including barred olivine, porphyritic olivine pyroxene, and radial pyroxene (RP). These textures reflect variations in their crystallization conditions within the protoplanetary disk. Angular fragments of chondrules suggest impact processes, indicating episodes of fragmentation under sub-solidus conditions. Chondrules often exhibit dust-accretionary rims, composed of compacted material from the surrounding matrix, suggesting a history of free-floating in space and subsequent accretion of fine-grained material onto their surfaces. The presence of igneous rims on certain chondrules points to heating events that partially melt pre-existing dust-accretionary rims, highlighting episodes of thermal alteration and metamorphism in the early solar system. The acquired data are useful for design experiments aimed at understanding the petrological history of chondrules and improving existing models.

Keywords: apatite supergroup, crystal structure, "carbonato-apatite".

The existence of a "carbonato-apatite" has been hypothesized since the 19th Century (e.g., Henry, 1850). The name carbonato-apatite itself points to something in which $(CO_3)^{2-}$ ions play a significant role. Actually, in the literature the name carbonato-apatite often refers to minerals in which the wt.% CO_2 is very low. And when the crystal-chemical role of $(CO_3)^{2-}$ ions is considered, odd and unlikely proofs are sometimes produced, e.g., carbon is supposed to substitute for Ca in large, nine-coordinated sites, or $[CO_3]$ planar triangles are supposed to substitute for $[PO_4]$ tetrahedra.

At the best of our knowledge no reliable crystallographic data which demonstrate how $(CO_3)^{2-}$ can be accommodated within the apatite framework have been published so far.

Recently an apatite-like mineral has been sampled at Kobylianka ore occurrence near Hýľov, Košice Region, Slovakia. Symmetry and unit-cell parameters match those of apatites; preliminary EPMA data gave, in wt.%, SO_3 0.27, As_2O_5 22.76, PbO 74.94, Cl 0.20. Those data, in the lack of direct determination of wt.% H_2O, could lead to the empirical formula $Pb_{4.99}(As_{2.94}S_{0.05})O_{12.01}[(OH)_{0.92}Cl_{0.08}]$, with (OH) calculated assuming 12 O + 1 [(OH),Cl] per formula unit. The resulting ideal formula, $Pb_5(AsO_4)_3(OH)$, would correspond to "hydroxylmimetite", a potential new mineral species.

A single-crystal X-ray diffraction study was carried out on that sample. Quite unexpectedly, some maxima were found along the channels of the structure which were interpreted as due to carbonate ions, based on both the electron densities and the geometry of bond distances and angles which match those of a $[CO_3]$ planar triangle. Moreover the three oxygens of the carbonate ion form reliable bond distances with the Pb2 atoms. Preliminary Raman spectra confirmed the occurrence of carbonate groups in that sample. Therefore the low amount of monovalent anions – $(OH)^-$, F^-, Cl^- – is balanced by a significant amount of $(CO_3)^{2-}$.

Based on the SCXRD information it may be argued that the apatite-like mineral from Kobylianka is an intermediate member between the two compositions $Pb_5(AsO_4)_3(OH,Cl)$ and $Pb_5(AsO_4)_3(CO_3)_{0.5}$. The empirical formula resulting from the structural refinement is $Pb_5(As_{2.93}S_{0.07})_{\Sigma=3}O_{12}[(OH)_{0.35}Cl_{0.10}]_{\Sigma=0.45}(CO_3)_{0.31}$; it is close to the 50% boundary, however it lies on the carbonate-dominant side. Accordingly it could represent a potential new mineral species, not "hydroxylmimetite", yet the first example of an apatite supergroup mineral having (CO_3) as a species-forming constituent.

Additional data must to be collected on that sample before it can be submitted for its official recognition as a new mineral, in particular quantitative data on the wt.% H_2O and CO_2 – both key constituents – are mandatory. However, the crystallographic data already represent a strong and unequivocal proof that $(CO_3)^{2-}$ ions can be incorporated within the apatite framework.

The strange case of a mineral with pyroxene chemistry and HP-olivine structure

Bindi L.*

Keywords: Earh's mantle, new mineral, Mg-silicates, shocked meteorites.

High-pressure minerals found in shocked meteorites can provide valuable insights into the deep interior of our planet Earth. They can give clues about the extreme pressure and temperature conditions that exist deep within the Earth's mantle, and, by studying their stability fields, we can infer the physical and chemical environments at great depths. Most of the models for our deep Earth are based on well-known and common minerals. We here demonstrate that the scenario could be much more complex than thought. During a mineralogical investigation of the Suizhou meteorite, a L6 shocked chondrite having shock melt veins less than three hundred micrometers in thickness, we discovered a new mineral that seems identical to wadsleyite (M^{2+}:Si = 2:1) when looked at the scanning electron microscope or with an electron microprobe (same albedo), but it has the pyroxene stoichiometry (M^{2+}:Si = 1:1) and retains the wadsleyite structure. In detail, electron microprobe analyses pointed to the following empirical formula (based on 8 oxygen atoms pfu) $[(Mg_{2.73}Fe^{2+}_{0.14}Na_{0.03}Al_{0.03}Ca_{0.02}Si_{0.05})\Sigma_{3.00}(Si_{0.49}[]_{0.51})\Sigma_{1.00}]Si_2O_8$, ideally $Mg_3(Si_{0.5}[]_{0.5})Si_2O_8$ (the symbol [] stands for structural vacancy). Single-crystal X-ray studies showed the mineral to be orthorhombic, space group *Imma*, with the following unit-cell parameters: $a = 5.5820(10)$, $b = 11.418(3)$, $c = 7.708(2)$ Å, $V = 491.3(2)$ Å^3 and $Z = 4$.

This new mineral could be very common. Indeed, by means of routinely identification methods (e.g. EBSD), it can be misidentified as wadsleyite and, if one uses only the chemical composition it can be misidentified as one of the $MgSiO_3$ polymorphs (enstatite, akimotoite, majorite or bridgmanite). The present discovery underlines how complex can be the family of Mg(Fe)-silicates and how many secrets are still to be discovered.

Atomic dynamics of chalcedony under non ambient conditions: a Raman spectroscopy study

Keywords: chalcedony, moganite, Raman spectroscopy.

Chalcedony (an ensemble of quartz crystals with a size < 1 micron) is widespread in near-surface rocks, and it has proved to be an important marker in many geological environments (Heany, 1993 and reference therein). Chalcedony also represents one of the main natural hosts containing the silica polymorph moganite. The moganite structure consists of alternative stacking slabs of left-handed and right-handed a-quartz, forming a framework containing 4-membered rings of corner-sharing SiO_4 tetrahedra, in contrast to the other low-pressure silica polymorphs whose structure is built up of 6-membered SiO_4-rings (e.g. Kingma & Hemley, 1994). Moganite is the second most widespread SiO_2 polymorph in nature after quartz (Heany & Post, 1992). However, it has been recognized as a mineral species only in 1999 (The New IMA List of Minerals) because it commonly intergrows with granular and or fibrous micro-crystalline quartz varieties. Consequently, moganite is not as well characterized as quartz, neither the effect of moganite presence on the high-pressure/temperature behaviour of microcrystalline quartz varieties has been thoroughly studied. In this work we analysed samples of moganite-bearing chalcedony using in situ Raman spectroscopy up to 7 GPa at ambient temperature as well as up to 1200K at ambient pressure. Our results provide insights on the effect of pressure and temperature applied on multiphase micro-crystalline material affected by metastability and or phase transition. We finally test the possibility of using hard-mode Raman spectroscopy (Bismayer, 2000) as a tool to characterize the character of phase transitions (e.g. first vs. second order transitions) and how it is affected by coexistence of different phases.

New thermo-elastic and crystal-chemical insights on 11.5 Å phase: a major water carrier to the mantle transition zone

Chrappan Soldavini B.*[1], Merlini M.[1], Gemmi M.[2], Fumagalli P.[1], Joseph B.[3], Bais G.[3] & Polentarutti M.[3]

[1] Dipartimento di Scienze della Terra "A. Desio", Università di Milano. [2] Istituto Italiano di Tecnologia, Pontedera (PI). [3] Elettra-Sincrotrone Trieste S.C.p.A., Basovizza (TS).

Keywords: DHMS, 11.5Å phase, Earth's mantle.

In the past three decades, experimental studies have demonstrated the stability of new hydrous silicates in the MgO-Al_2O_3-SiO_2-H_2O (MASH) system, known as "Dense Hydrous Magnesium Silicates" (DHMS). These phases, like the DHMS in the simpler MgO-SiO_2-H_2O (MSH) system (e.g., phase A), can form after the destabilization of layer hydrous minerals (serpentine, chlorite). Recent research has studied their stability under mantle pressures and temperatures, highlighting their role in the deep-water cycle and their impact on the mantle's water budget (Hermann & Lakey, 2021).

Among these phases, the 11.5 Å phase, with chemical formula $Mg_6Al(SiO_4)_2(OH)_7$, has been identified as stable in the region between 7-11 GPa and 500-1000°C, and plays a potential role in storing and transporting water to the mantle transition zone (Cai & Inoue, 2019; Hermann & Lakey, 2021). In subduction contexts, the 11.5 Å phase has been associated with the destabilization of chlorite in Al-rich systems and can store up to 13 wt.% of water, a notably high content compared to other DHMS under similar conditions. Its crystal structure was determined by Gemmi et al. (2016) using standard precession-assisted electron diffraction tomography (PEDT), revealing a layered structure consisting of TOT groups and double di-octahedral layers of face-sharing octahedra (O-O), with unit cell parameters a = 9.012(1) Å, b = 5.201(1) Å, c = 23.202(5) Å, β = 97.8(1)° and space group $C2/c$.

We performed multi-anvil syntheses under different mantle P-T conditions (6-10 GPa and 700-900°C) to assess the effect of iron and chromium on the crystal-chemistry and stability of the 11.5 Å phase, starting from natural Fe-bearing chlorite sample and synthetic Cr-bearing systems. The results reveal that solid solutions from pure Mg-Al term can form with Fe-Al and Mg-Cr end-members.

The synthesis performed at the highest pressures crystallized single crystals up to 50x50x50 μm^3. Single crystal diffraction allowed ab-initio structure determinations and refinements, confirming the structural description reported by Gemmi et al. (2016).

In addition, we report the determination of PV and VT equations of state, which allow the density estimation for the 11.5 Å phase at mantle conditions. We observed also an interesting single crystal to single crystal phase transition at high temperature, at 400°C, upon partial dehydration, with noticeable 5% volume expansion and a partial unpacking of the double Mg-octahedral layers.

Micro- and nano-scale investigation of (Ca-REE) fluorcarbonates: clues for REE partitioning and mobility

Conconi R.*[1], Fumagalli P.[2] & Capitani G.[1]

[1] Dipartimento di Scienze dell'Ambiente e della Terra, Università di Milano-Bicocca.
[2] Dipartimento di Scienze della Terra "A. Desio", Università di Milano.

Keywords: Rare Earth Elements, REE-fluorcarbonates, Transmission Electron Microscopy.

Micro- and nano-scale studies of ore minerals holds significant potential to enhance prospecting methods, metallurgical processes, and recycling strategies. Indeed, nanoscale processes revealed to be key factors for the control of large-scale ore deposits, since nanoparticles and nanominerals, apparently, play a significant role as agents of elemental transport, including heavy metals and radionuclides, particularly within hydrothermal systems (Reich et al., 2011). In this context, CaREE-fluorcarbonates, which are primary ore for Rare Earth Elements (REE), are the perfect example of how the micro- and nano-studies on geo-relevant minerals holds potentialities for understanding the crystallization pathway and elements partitioning in hydrothermal systems. Indeed, recent mineralogical and crystallographic studies on this class of minerals shed light on their nature and genesis. Particularly, the study of polysomatism may reveal important for the understanding of the crystallization conditions and fluid composition (Gysi & Williams-Jones, 2015; Conconi et al., 2023).

The CaREE-fluorcarbonates studied were found within the miarolitic cavities of a granophyre in the Western Southern Alps (Italy). Different mineral species with different morphologies and compositions were observed: (i) synchysite-(Ce) forming hexagonal prisms and rosette-like aggregates, (ii) bastnäsite-(Ce) forming blocky aggregates and (iii) bastnäsite-(Nd) forming more complex micro and nanostructures. Regarding the latter, transmission electron microscopy studies revealed a nanostructure consisting of an intergrowth of bastnäsite-(Nd) nanocrystals with hematite nanocrystals and phyllosilicates. A potential scenario regarding their formation has been proposed, suggesting that different CaREE-fluorcarbonates followed a crystallization sequence influenced by temperature and fluid fractionation. Initially, synchysite-(Ce) was formed, succeeded by bastnäsite-(Ce), and finally bastnäsite-(Nd). The varied morphologies observed were not only attributed to the prevalent REE in the fluid but also to fluctuating temperatures and cooling rates. Our research underscores nature's ability to effectively segregate REE from each other, such as Y from La, Ce, and Nd; Ce from Nd and La; additionally, Th, a radioactive and toxic element, appears to incorporate into the structure of CaREE-fluorcarbonates during the concluding stages of crystallization.

A new synthetic strategy to produce hollandite-type nanocrystals, useful for environmental application

D'Angeli I.M.*[1], Rilievo G.[2], Magro M.[2], Molinari S.[1], Favero M.[1], Barbaro A.[3], Brenker F.[3], Singerling S.A.[3], Vianello F.[2] & Salviulo G.[1]

Keywords: nanomaterials, tetragonal symmetry, temperature treatment.

Hollandite-type crystals attract attention thanks to their unique and interesting chemical-physical features. Herein, an innovative synthetic strategy was developed for the production of novel nano-sized hollandite-type single-crystalline potassium ferrotitanate (KFTO). The synthesis consists of a simple hydrothermal method using as a starting material an electrostatically stabilized nano-assembly of TiO_2 nanotubes (TiNTs) (Zennaro et al., 2013) and Surface active maghemite nanoparticle (SAMNs) as starting materials (Magro et al., 2020). The evolution of the TiNTs-SAMNs conjugate, took place at the unprecedented temperature of 800°C, which is remarkably low in comparison to other hydrothermally generated KFTO materials (Gorshkov et al., 2021). The as-obtained nanomaterial was extensively characterized through X-ray powder diffraction, transmission electron microscope, scanning electron microscope, Fourier transform infrared spectroscopy, dynamic light scattering, and Raman spectroscopy. The refinement performed using the Rietveld data analysis reveals that the synthetized hollandite belongs to the hollandite supergroup, which is characterized by tetragonal symmetry with lattice parameters $a = b = 10.1502$ Å, $c = 2.9716$ Å, similar to the natural priderite (Post et al., 1982).

In particular, the nano-particulate gives rise to stable colloidal suspensions, displaying a zeta potential of -40 mV, that is a suitable feature for environmental applications. Besides enriching the chemistry TiO_2 derived nanomaterials, can stimulate further research on alternative synthetic strategies based on nano-sized reagents and environmental applications.

Sphalerite from Longobucco and Fonte Argentila mineralization (Sila Massif, Calabria, southern Italy): crystal chemistry and genetic implications

Fregola R.A.*[1], Ciccolella A.[1], Ruggieri G.[2], Ventruti G.[1] & Schingaro E.[1]

[1] Dipartimento di Scienze della Terra e Geoambientali, Università di Bari "Aldo Moro".
[2] Istituto di Geoscienze e Georisorse, CNR, Firenze.

Keywords: sphalerite, crystal chemistry, Longobucco and Fonte Argentila mineralization.

Sphalerite is the main ore-mineral of the vein-type mineralization of Longobucco (LGB) and Fonte Argentila (FAR), outcropping within granodiorite of the Sila Batholith (Calabria, southern Italy). Such mineralization are of historical importance, but not deeply investigated yet (Fregola et al., 2023). We have examined the crystal chemistry of sphalerite through a combination of optical microscopy (OM), scanning electron microscopy (SEM), electron probe microanalyses (EPMA), μ-Raman spectroscopy (μ-RS), single crystal X-ray diffraction (SCXRD), and X-ray powder diffraction (XRPD).

Textural and paragenetic observations using optical microscopy allowed us to discriminate three distinct generations of sphalerite from LGB and FAR, corresponding to different mineralization episodes of the ore deposit. Sp-1 is light coloured (from light-yellow to brown), Sp-2 is dark coloured (from reddish-brown to dark brown), whilst Sp-3 is colourless. Colour variation is mainly due to different Fe-content, with the darker Sp-2 being the Fe-richest one (up to 11.3 wt.%; 0.21 mol% FeS). Sphalerite contains also minor amounts of Cd (up to 0.7 wt.%).

The phase composition of sphalerite samples has been confirmed by XRPD.

Data from μ-Raman spectroscopy, collected from sphalerite Sp-1, Sp-2 and Sp-3, have been correlated to the corresponding Fe concentrations. The colourless Fe-poorest Sp-3 shows the typical spectrum of almost pure ZnS sphalerite, with the main band at about 350 cm^{-1} (h3, A3; Raman band due to Zn-S bond vibrations). Raman spectra of Sp-1 and Sp-2 show a further band at about 300 cm^{-1} (h1, A1; Raman band due to Fe-S bond vibrations) becoming gradually dominant with increasing Fe-content, with respect to the Zn-S band. By plotting the obtained ratios of band intensities (h1/h3) and areas (A1/A3) against the corresponding FeS mole fractions, our results are in good agreement with the calibrated curves reported by the literature (e.g., Osadchii & Gorbaty, 2010).

The refined unit cell parameters, measured by SCXRD on Sp-1 and Sp-2 sphalerite of different colours (from pale yellow to reddish-brown), range between 5.4158 Å and 5.4230 Å. Using these cell parameters and the corresponding mol% FeS values in the equation by Chareev et al. (2017), we have estimated sphalerite formation temperatures in the range 117-141°C for the light Sp-1, and up to 192°C for the dark Sp-2. Such values are in good agreement with those obtained from our preliminary fluid inclusion analyses performed on quartz, as well as from our geochemical analyses of sphalerite trace element composition (Ciccolella et al., 2024).

Corresponding author email: sabrina.nazzareni@unipr.it

Keywords: impact crater, pyroxene, water content.

The Dellen impact structure is located in a ca. 20 km wide basin filled by two lakes in the east central Sweden. This complex structure is covered by a thick moraine deposit, and most impact melted material can be found as loose blocks and boulders scattered throughout the moraine. Geophysical measurements show the presence of a coherent impact melt body about 9 km in diameter and 200 to 500 m thick for which impact ages range between 90, 110, to 140 Ma.

Here we describe the petrography and mineral chemistry of an impact melt glass (commonly referred to as dellenite) consisting of phenocrysts of subhedral orthopyroxene (average $Wo_4En_{63}Fs_{33}$), skeletal plagioclase (average $An_{59}Ab_{38}Or_3$), and euhedral magnetite within a glassy matrix of rhyolitic composition. Moreover we aimed to use the pyroxene crystals as a petrological tool to define the host rock cooling rate and the water content dissolved in their parental melt during pyroxene growth.

MicroFTIR measurements performed both in the glass matrix and in the euhedral glass blebs within the skeletal plagioclase show the presence of 1.4 wt.% H_2O in the rhyolitic glass. Comparing the water content of the glass with the water solubility of a silicate melt with the same composition as determined by the model by Papale (1999) suggests that the studied sample vitrified at a pressure of about 200-300 bar.

Dellenite orthopyroxene, studied by polarized FTIR spectroscopy, Mössbauer spectroscopy, single crystal X-ray diffraction and EMPA, are iron rich enstatite (Wo_4 En_{63} Fs_{33}) with a Fe^{3+}/Fe_{tot} ratio of 1.6%. Opx have very weak to absent OH vibrational IR bands, corresponding to H_2O contents ranging from 0 to 39 ppm H_2O. The variable contents seem to indicate H loss during post-formation processes, which may occur via $Fe^{2+} + OH^- = Fe^{3+} + O^{2-} + ½H_2$ redox reaction. In volcanic pyroxenes H loss may be a common process, however since H incorporation is associated to point defects with slow diffusion rates, by reversing the redox reaction the original H content of pyroxene can thus be recovered by thermal annealing experiments under reducing conditions (Weis et al., 2016; Nazzareni et al., 2020).

In order to restore H that was possibly lost, dellenite pyroxenes were thermally annealed under hydrogen atmosphere (at 1 Atm) in a horizontal glass-tube furnace. FTIR spectra were recorded after each heating step showing an increase in H content to a final average water content of 45 ppm.

Cations partition as derived by the SC-XRD and EMPA were used to calculate the orthopyroxene closure temperature (Tc) point to a Tc value of 833°C due to a quite fast host-rock cooling rate.

A tentative model for the evolution of the rhyolitic portion of the Dellen impact melt is under development merging geophysical data with our experimental data on water content of pyroxene and glass, and pyroxene geospeedometry.

Keywords: spectroscopy, heavy metals, montmorillonite.

Clays and organo-clays are largely proposed in the literature to reduce heavy metals (HMs) contamination in wastewater, via solid/liquid adsorption from many productive sectors (Mao & Gao, 2021). HMs, if spread in the environment, can have harmful effects to humans and to natural organisms. Among others, animal breeding represents one of the sources of HMs, being HMs, namely zinc oxide and copper salts, added to feed to improve animal health (Hejna et al., 2019). In this respect, the knowledge of the interactions HMs-sorbents is fundamental to understand sorbents behaviour in order to develop them for use in the field. In this work, both pristine STx-1b, a Ca-montmorillonite (STx, hereafter) and STx-modified with collagen hydrolysate (supplied by Ilsa group), are studied as sorbent for Cu^{2+} and Zn^{2+}. The capture of Cu^{2+} and Zn^{2+} has been performed with solid/liquid adsorption process, and inductively coupled plasma-optical emission spectroscopy (ICP-OES) has been applied to determine captured Cu^{2+} and Zn^{2+}. Specific Cu^{2+} and Zn^{2+} contents have experienced, namely 2 mmolCu/gcarrier and 1.04 mmolZn/gcarrier. Pristine STx is able to capture up to 0.55 mmolCu/gcarrier of Cu^{2+} and up to 0.45 mmolZn/gcarrier, of Zn^{2+}; while organoclay 0.47 mmolZn/gcarrier and 0.52 mmolcu/gcarrier, when applying an initial content of 2 mmolCu/gcarrier and 1.04 mmolZn/gcarrier for copper and zinc respectively. To gain insight into the different sorbent solids capability they have been fully characterized by XRPD, SEM-EDX, EPR, XPS and FT-IR, before and after metal capture. The results are discussed in terms of the nature and strength of the bonds.

Corresponding author email: giovanniorazio.lepore@unifi.it

Keywords: janchevite, oxychloride, crystal-structure.

Janchevite, the V-dominant analogue of parkinsonite, is a rare mineral belonging to the layered lead oxychlorides group. As in the case of parkinsonite, janchevite has been previously described (Chukanov et al., 2018) in the *I*4/*mmm* substructure but a full structural determination has not been reported to date. Here we present the results of an investigation on a sample of janchevite from the type locality (Kombat mine, Namibia), which was studied through single crystal X-ray diffraction, electron probe micro-analysis and X-ray absorption spectroscopy.

The superstructure of janchevite (R = 5.2%) was determined using intensity data gathered from a two-domains non-merohedral twinned crystal. Despite the pronounced tetragonal subcell reflections, the structure exhibits triclinic symmetry (space group *P*-1), with lattice parameters $a = 8.8382(7)$, $b = 8.8567(7)$, $c = 11.7103(17)$ Å, $\alpha = 103.385(10)$, $\beta = 94.192(10)$, $\gamma = 90.294(6)°$, $V = 889.13(16)$ Å^3 and $Z = 2$. Chemical analyses revealed the presence of Mo, As, Si, in addition to Pb, Cl, O, and V. The structural framework comprises alternating layers of PbO litharge and Cl- anions in a 2:1 ratio. High-charge cations (V^{5+}, Mo^{6+}, As^{5+}, Si^{4+}) are incorporated into the litharge sheet, creating square cavities hosting MoO_5 square pyramids and $(Si,As,V)O_4$ tetrahedra.

Through chemical, structural, and spectroscopic investigations, the crystal chemical formula was revised to $Pb_9VO_{10.25}\square_{0.75}Cl_{2.5}$ ($Z = 2$), analogously to what previously suggested for parkinsonite (Welch et al., 1996; Lepore & Welch, 2010). This implies the presence of additional apical oxygen atoms between adjacent Pb layers, which influence the interlayer thickness. In particular, a linear correlation between the interlayer oxygen content and the nature of structural defects has been observed.

Keywords: in-situ synchrotron X-ray powder diffraction, thermal stability, ZSM-5 zeolite.

Organic species such as tetra-n-propylammonium (TPA) and Na cations have been found to be effective in directing the structure of ZSM-5 zeolite. The optimization of synthesis conditions is crucial to producing highly crystalline ZSM-5 zeolite and, consequently, to controlling the properties of the resulting material for specific applications. ZSM-5 actual symmetry (orthorhombic Pnma, with 12 crystallographically independent tetrahedral sites in the unit cell) depends on the synthesis and post-synthesis treatment, SiO_2/Al_2O_3 ratio, structural defects, temperature, and amount of sorbate organic molecules.

Through in situ synchrotron powder diffraction of four TPA-ZSM-5 samples with varying Si/Al ratios (15, 25, 50, and 100), this work examines the thermal stability and high temperature structure development. By performing Rietveld refinements on the room temperature data, it was discovered that the TPA^+ ions are situated at the junction of the sinusoidal and straight channels in every ZSM-5 sample. The refined TPA^+ content increases with the increasing Si/Al ratio of the zeolite. All four ZSM-5 samples have good thermal stability, as demonstrated by the high temperature refinements; they stay crystalline until the thermal treatment reaches its conclusion (800°C). The great degree of flexibility of the MFI framework is confirmed by the fact that burning the template does not result in any discernible changes to the channel form or framework geometry. Furthermore, thermal studies provided valuable insights into how aluminum presence affects the way TPA and zeolite structures interact.

Second world occurrence of badalovite, $Na_2Mg_2Fe(AsO_4)_3$, from the Etna volcanic complex, Sicily

Keywords: badalovite, Etna volcanic complex, crystal structure.

Badalovite, $Na_2Mg_2Fe(AsO_4)_3$, is a member of the alluaudite supergroup (Hatert, 2019), discovered in the Arsenatnaya fumarole of the Tolbachik volcano, Kamchatka, Russia (Pekov et al., 2020). Following the examination of a suite of mineral specimens from Eastern Sicily, a new occurrence of badalovite was identified on a sample collected by the mineral amateur Gaetano Sicurella. This sample was from the Monte Calvario quarry, Biancavilla, Etna volcanic complex, Sicily, well-known for being the type locality of two F-bearing phases, i.e., fluorophlogopite and fluoro-edenite (Sicurella et al., 2010, and references therein).

Badalovite occurs as vitreous to resinous orange prismatic crystals, in some cases forming sheave-like aggregates, up to 0.5 mm in length, associated with equant to tabular crystals of hematite. This mineral was previously described as UM2 (Unnamed Mineral) by Sicurella et al. (2010), who reported the occurrence of major Na and As as main chemical constituents, with minor Fe, P, and Ca.

Badalovite from Biancavilla has unit-cell parameters a = 11.9970(4), b = 12.7731(4), c = 6.6349(2) Å, β = 112.7170(10)°, V = 937.85(5) Å^3, space group $C2/c$. These values can be compared with those given by Pekov et al. (2020), i.e., a = 11.9034(3), b = 12.7832(2), c = 6.66340(16) Å, β = 112.523(3)°, V = 936.59(4) Å^3. Electron microprobe analysis (National Museum, Prague) gave (average of 10 spot analyses): SO_3 0.05(4), P_2O_5 2.72(66), As_2O_5 54.97(56), Al_2O_3 0.12(8), Fe_2O_3 10.67(2.58), MgO 13.16(2.40), CaO 4.56(1.30), MnO 3.39(20), ZnO 0.32(14), Na_2O 9.18(79), K_2O 0.06(2), sum 99.20(70). The empirical formula, based on 12 O atoms per formula unit, is $Na_{1.68}K_{0.01}Ca_{0.46}Mg_{1.85}Al_{0.01}Mn_{0.27}Zn_{0.02}Fe^{3+}_{0.77}(As_{2.84}P_{0.11}S_{0.01})\Sigma_{2.96}O_{12}$ (Z = 4). The crystal structure was refined to $R1$ = 0.0504 for 1612 unique reflections with $Fo > 4\sigma(Fo)$ and 101 refined parameters. Its crystal structure is isotypic with other alluaudite-supergroup minerals and agrees with the structural features described by Pekov et al. (2020).

The genesis of Sicilian badalovite is probably related to the interaction between fumarolic and volcanic rocks, possibly at temperature not lower than 450°C, in accordance with the occurrence of the Russian badalovite. Moreover, badalovite is another, previously undetected, host for the high As contents identified in the Biancavilla area by previous authors (e.g., Mazziotti-Tagliani et al., 2012), who explained such high contents (up to 1000 mg/kg) as due to the As-enrichment in fluorapatite only. Actually, the finding of badalovite suggests that further mineral species hosting As may be hidden among fumarolic assemblages occurring in the Biancavilla area.

Keywords: fluorcarletonite, HT-SCXRD and HT-FTIR, ab initio calculations.

Fluorcarletonite, $KNa_4Ca_4Si_8O_{18}(CO_3)_4(F,OH) \cdot H_2O$, from Malyy Murun syenite massif (Aldan Shield, Siberia, Russia) was recently recognized as a new mineral species by the Commission on New Minerals and Mineral Names of the International Mineralogical Association (IMA no. 2019-038). It is described as double-layer sheet silicates with 1:2.25 T:O ratio (Hawthorne et al., 2019). Two adjacent single layers are interconnected by sharing a common oxygen of downward-pointing tetrahedra. The $[Si_8O_{18}]^{4-}$ sheets are linked with sheets consisting of $NaO_4^{2-}F^-(H_2O)$ and $NaO_5^{2-}(H_2O)$ octahedra, NaO_8^{2-}, $CaO_7^{2-}F^-$ or CaO_8^{2-} and KO_{10}^{2-} polyhedra. Finally, two independent CO_3-groups are linked to Na- and Ca-polyhedra (Kaneva, et al. 2020).

In the present study the high temperature behavior of fluorcarletonite has been investigated by combining in situ high temperature single crystal X-ray diffraction (T range 25-550°C), ex situ high temperature Fourier transform infrared spectroscopy (25-700°C) and ab initio calculations. The lattice parameters and cell volume increase in the 150-550°C temperature range while the mineral undergoes a progressive dehydration process. At 550°C about 40% water loss was observed. When compared with the fluorcarletonite structure at room temperature, the partially dehydrated fluorcarletonite shows: the same space group (*P*4/*mbm*); increased distances between the oxygens of the H_2O molecules (O11w and O12w) and their Na-centered octahedral cations (Na1 and Na2, respectively); distortion of the four- and six-member tetrahedral rings of the double silicate layer. The dehydration process mainly involves the water oxygen at the O11w site, having a different local environment with respect to the oxygen at the O12w site. At T > 600°C, the complete dehydration is accompanied by deprotonation of the OH groups substituting for the F atoms and by the collapse of the structure when the CO_2 is released. The adopted approach allowed the determination of the temperature thresholds at which modifications occur in the fluorcarletonite crystal structure under controlled heating conditions. The findings contribute to provide insights into the thermal behavior of sheet silicates with fluorcarletonite-like topology.

Keywords: magnesiocarpholite, crystal chemistry, HP-LT metamorphism.

HP metamorphism has been documented in the siliciclastic successions exposed in the inner Northern Apennines, a fold-and-thrust belt belonging to the Alpine-Himalayan belt system, formed since the Late Cretaceous by the convergence and collision of the Adriatic and European plates. In the metapelitic rocks exposed in the Middle Tuscan Ridge, HP metamorphism (P = 1.2-0.8 Gpa; T = 350-420°C) gave rise to typical mineralogical assemblages composed of quartz-phengite-chloritoid-pyrophylite-rutile-hematite±chlorite±pa ragonite±kyanite±Ti oxides and developed along a syn-kinematic composite foliation. (Mg, Fe)-carpholite quartz veins, transposed along the main schistosity, have also been documented.

The carpholite group encompasses hydrated inosilicates and a recent review of chemical variation of carpholite, specifically (Fe, Mg)-carpholite, []$(Fe,Mg)\ Al_2Si_2O_6(OH)_4$, is reported in Mesto et al. (2021). In the present work preliminary data about the crystal chemical characterization of magnesiocarpholite from the northern Apennines are reported. The investigated samples, that underwent single crystal X-ray diffraction (SCXRD) analysis, are from two localities: Torrente Gonna, where carpholite occurrence was reported by Brogi & Giorgetti (2012) and from Poggio delle Vipere, where carpholite occurrence was reported by Giorgetti et al. (1998). The relevant carpholite samples are labelled G1 and PVi, respectively.

Structure refinements from SCXRD data, in the *Ccce* space group, converged at R(%) = 3.82 and 2.64 for sample G1 and PVi, respectively, with unit cell parameters a = 13.728 Å, b = 20.113 Å and c = 5.107 Å and V = 1410 Å^3 for G1 sample, and a = 13.731 Å, b = 20.114 Å and c = 5.115 Å and V = 1413 Å^3 for PVi Mg-carpholite.

In the crystal structure, there are one symmetry independent tetrahedron, three symmetry independent octahedra (M1, M2, and M3), and two hydrogen positions (H1 and H2). The M1 octahedron is Mg,Fe-centered, whereas the M2 and M3 octahedra are Al-centered. Hints of the presence of Na in sample PVi are found, coherently with the chemical composition in Brogi & Giorgetti (2012).

XMg (i.e. molar $Mg/(Mg+Fe^{2+}+Mn)$) is 0.68 and 0.61 for the G1 and PVi crystals respectively, as derived from the refined occupancy at the M1 site. This parameter is correlated to the lattice variation mainly along the a and b axes and to geometrical distortions of the M1, M2 and M3 octahedra (Mesto et al., 2021).

Partially crystalline silica varieties in gemmology: the case study of the blue Andean opal

Monico S.*[1], Marinoni N.[1], Gatta G.D.[1], Adamo I.[2], Prosperi L.[2], Mácová P.[3] & Ševčík R.[3]

Keywords: blue Andean opal, microstructure, chemical composition.

Opal is an amorphous or poorly crystalline hydrated form of silica (usually given as $SiO_2 \cdot nH_2O$) occurring in veins and nodules of various colours. The term *opal* defines several sub-categories of aggregates with varying structural orders, from a glass-like structure to packed silica nano-spheres or nanograins (Gliozzo, 2019). Opal's intrinsic and peculiar complexities enhance its desirable aesthetic aspect, appreciated in gemmology and jewellery. A well valued and popular opal variety is the blue Andean opal, from the Acari Mine (Arequipa Department, Peru). The distinctive blue hue of this variety is commonly ascribed to the presence of copper-rich mineral inclusions (Gaillou et al., 2008; Caucia et al., 2015).

In this study, a multi-methodological approach has been used to investigate the features of the blue Andean opal. X-ray diffraction methods have been used for the characterization of the mineralogical assemblage, along with the quantification of the amorphous fraction, showing the challenge in distinguishing among opal subcategories due to their blurred boundaries. Raman mapping highlighted different silica phases and the distribution of impurities within the matrix. The microstructure of the blue Andean opal resulted emblematic of the precipitation processes of the silica aggregate. The analysis of trace elements concentration provided information about the potential composition of the original fluids, from which the Andean opal precipitated. Notably, this research highlighted that the blue colouration of the Andean opal is ascribable to the presence of a mineralogical inclusion, but it is also influenced by the combined effect of factors closely dependent on the geological processes and environment of formation.

Interpreting mineral transformations

Pavese A.*

Dipartimento di Scienze della Terra, Università di Torino.

Corresponding author email: alessandro.pavese@unito.it

Keywords: reactions, thermodynamics, stability.

Interpreting mineral transformations is a key to get insights into processes taking place in natural and anthropic environments. In such a respect, different strategies have been developed to provide a frame in which the driving forces that trigger, on the one hand, and govern, on the other hand, transformations of mineral phases can be properly set. The extraordinary experimental potentialities which are nowadays accessible through laboratory and large scale facilities provide unprecedented possibilities of novel explorations, along with progressive improvements and consolidation of theoretical/computing tools that interplay with observations a crucial role in allowing scientists to develop coherent unitary vision of complex phenomenologies. In this light, the mechanisms of thermodynamic stability of minerals can be framed in the context of general theories, like, for instance, the catastrophe theory (Poston & Stewart, 1996), Bader bonding theory (Bader, 1994) and Landau theory (Tolédano & Tolédano, 1987). The many-phase and one-phase approaches exploiting different strategies are valuable instruments for a general interpretation of the occurrence of instability in mineral systems, and can in such a light be employed for predictions. In particular, microscopic features associated with electron density and macroscopic observables related to thermal-elastic properties provide “token” signals that, linking irreversible processes thermodynamics and catastrophe theory in a unitary vision, herald the loss of stability and announce transformation of the original mineral phase in a more stable system. Changes of state and phase transitions provide examples of application of the notions abovementioned.

Keywords: tourmaline, crystal structure refinement, electron microprobe analysis.

The tourmaline supergroup minerals are complex borosilicate belonging to the cyclosilicate class.

These minerals can be considered not only precious multicolored gemstones, but also an important minerals for geological and petrogenetic research (Dutrow & Henry, 2011). Usually, tourmalines are treated with various methods to enhance their appearance and to make them more marketable. However, the processes involved in enhancing the aspect of these minerals are still widely debated. To investigate in detail these processes, five samples from five different pegmatite provinces were analyzed through a multi-analytical approach to identify the causes of color changes after two types of treatments: e-beam irradiation and thermal treatments. The selected samples exhibited pink and blue hues and one sample highly zoned colors. Oriented sections were prepared from each crystal and used for microchemical, structural, and spectroscopic analyses. The compositional variations were investigated by scanning electron microscopy (EDS SEM), electron microprobe analysis (EMPA) and micro laser induced breakdown spectroscopy (μ-LIBS). Structural information has been obtained through single crystal X-ray diffraction (SC XRD) and structure refinement (SREF). Their electronic and vibrational spectra were collected by UV-Vis, μ-Raman, and optical absorption spectroscopy (OAS). The data show that the different colors can be attributed to the presence of multiple chromophores, such as Mn and Fe and negligible quantities of Ti and Cu. The samples were subsequently irradiated with doses equivalent to 5.1x104 Gray and heated at T ranging from 450 to 600°C. Post-treatment characterization was performed exclusively using spectroscopic techniques that are sensitive to chromophores variations. Changes in Mn and Fe valence states in the UV-Vis and OAS spectra were observed after the different treatments: irradiation induces the oxidation of $Mn^{2+} \rightarrow Mn^{3+}$ and $Fe^{2+} \rightarrow Fe^{3+}$, resulting in darker colors in tourmaline, whereas the thermal treatments induced reduction of $Mn^{3+} \rightarrow Mn^{2+}$ and $Fe^{3+} \rightarrow Fe^{2+}$, producing brightening or even loss of color. Some exceptions were observed for certain zoned samples or those containing rare elements like lutetium and ytterbium. UV-Vis and OAS spectroscopy proved to be useful techniques for characterizing color changes.

Crystal chemistry of clinopyroxenes and spinels enclosed in mantle xenoliths (Mandakh-Mandal-Gobi area, Mongolia)

Sist E.*, Parisi F. & Princivalle F.

Dipartimento di Matematica, Informatica e Geoscienze, Università di Trieste.

Corresponding author email: efremsist@gmail.com

Keywords: mantle xenoliths, pyroxenes and spinels, petrological implications.

The Mandalovo volcano is one of many relict volcanoes located in the Mandakh-Mandal-Gobi zone (MMG), a region of alkali-basalt magmatism which extends entirely in the East Mongolian Volcanic Area (EMVA), the largest Late Mesozoic intracontinental volcanic domain in East Asia (Yarmolyuk et al., 2020). The origin of the EMVA is still debated (Yarmolyuk et al., 2020; Sheldrick et al., 2018), but two are the most accredited hypothesis. Sheldrick et al. (2018) claim that alkali-basalt magmatism could have been associated with the closure of the Mongol-Okhotsk Ocean and the following development of a subduction zone and lithospheric delamination processes between Late Jurassic and Early Cretaceous. By contrast, Yarmolyuk et al. (2020) argue that it could be related to a convergent boundary initiated along the eastern Asian margin. This resulted in the formation of parallel marginal volcanic belts and further into a composite large igneous province. Numerous lithologies related to those magmatic events are now forming the MMG zone, mostly basanites, hawaiites and trachybasalts, usually containing lherzolite xenoliths (Yarmolyuk et al., 2020). Composition and site-occupancy data of certain minerals contained within mantle xenoliths can give us important constraints on the geodynamical context in which they formed and on the cooling history of the rock (Dal Negro et al., 1982; Princivalle et al., 1999). In clinopyroxenes and spinels, for instance, the abundance and distribution of Fe and Mg in M1 and M2 sites and of Al and Mg in T and M sites can provide the intra-crystalline closure temperature of the system and hints on the depth from which the xenolith could have derived (Dal Negro et al., 1982; Princivalle et al., 1999). In this study we analyzed two mantle xenolith samples from the Mandalovo volcano to determine their modal mineralogy, mineral chemistry and structure of several spinels and clinopyroxenes. To determine the modal mineralogy, we performed PXRD analysis using a Siemens D-500 powder diffractometer at the University of Trieste. Data refinement was then accomplished using the Rietveld refinement method. To determine the crystal lattice features, cell and sites volumes and sites occupancy, we carried out SC-XRD using a KUMA KM4 at the University of Trieste and, to determine chemical composition of the minerals we performed EMPA analysis using JEOL-8200 Super Probe at the University of Milano Statale. Both samples were classified as spinel lherzolites (51.3-52.3% olivine, 35.6-37.6% orthopyroxene, 9.8-11.6% clinopyroxene and 0.3-1.5% spinel, error ±5%). Intra-crystalline closure temperature of the system was calculated at 797°C and 821°C from clinopyroxenes and 784°C and 767°C from spinels for the first and second sample respectively (error ±50°C). Those data are compatible with a slow cooling rate and an alkali-basalt emplacement-related origin. Pressure conditions from which mantle xenoliths could have been taken over by the basaltic magma have been estimated between 20 and 22 kbar, compatible with a 60 km-depth origin and concordant with chemical and structural information reported above.

Graphene-brucite 2D heterojunctions: an ab initio crystal-chemical investigation

Ulian G.* & Valdrè G.

Dipartimento di Scienze Biologiche, Geologiche e Ambientali, Università di Bologna.

Corresponding author email: gianfranco.ulian2@unibo.it

Keywords: graphene, 2D brucite, optoelectronics.

The null band gap of graphene is a well-known issue that limits some specific applications of graphene in opto- and microelectronics. This led to several research studies in the so–called van der Waals composites field (known as heterostructures, or heterojunctions), where two monolayers of different materials are stacked and held together by dispersive interactions. The properties of these composite materials can be tuned by different parameters, for example, the type of 2D materials employed, the number and the stacking order of the layers (e.g. AB-AB, AAB-AAB), and their spatial orientation relative to each other (Novoselov et al., 2016). Hence, using the words of Kroemer (2001), the heterostructures presenting specific interfaces between different materials become the device.

The idea here reported is to use brucite $Mg(OH)_2$ as a bidimensional material to modulate the optoelectronic properties of graphene. In fact, brucite presents both high surface flatness and hydrophobicity, it is a dielectric with large band gap and, differently from the silanol groups of the (001) quartz surface, the hydroxyl ions in brucite are regularly aligned along the [001] direction, forming an atomic-flat surface. Furthermore, brucite is widely available, both isolated and within the structure of chlorites, low cost, non-toxic, and easily cleavable. In addition, Kelvin probe force microscopy studies revealed that the brucite-like layer of clinochlore presents a hydrophobic behaviour, despite the presence of a high number of OH groups (Valdrè et al., 2011).

In the present work, the crystallographic relationships between a single (001) brucite layer and graphene were considered by realizing several heterojunctions with different sizes to properly account for inequivalent stacking and to investigate how the crystal-chemistry and point defects/substitutions could affect the position of the electronic bands, their occupation, and the emergence of possible band gaps.

Density Functional Theory simulations carried out at the PBE-D2 and HSE06 levels of theory demonstrated that the (001) brucite substrate can deeply alter the band structure of graphene, resulting in a heterojunction with either a more conductive behaviour or a small band gap. It is worth noting that the band gap opening in the Al-bearing brucite-graphene interfaces was about 30-45 meV, which is one order of magnitude greater than the values calculated for other important heterojunctions, such as the MoS_2-1H/graphene one. The graphene-brucite composite is held together by weak van der Waals interactions, with a binding energy that increases by including gibbsite-like Al^{3+}/Mg^{2+} point defects in the (001) brucite surface.

All these observations could open to further fundamental research of the physical properties of this kind of natural materials, useful for the design and implementation of innovative heterojunctions with tailored properties and improved features (Ulian & Valdrè, 2023).

Keywords: X-ray diffraction, clay minerals, landslide.

The evolution of earthflows is understood to be polyphasic, characterized by periods of slow movement interrupted by dormancy. In some cases, earthflows can undergo sudden accelerations and increased mobility, known as surges, under specific conditions. These surges are often associated with a shift in the earthflow mechanism, transitioning from sliding dominance to flow dominance, due to material fluidization. This study focuses on understanding surge development and the solid-to-fluid transition of clayey earthflow materials by means of geotechnical and geomorphological approaches combined with mineralogical characterization of 14 selected earthflows in the southern Apennines of Italy. The geomorphological analysis revealed a variety of kinematic behaviours among the events with some displayed prolonged periods of dormancy, while other ones showed alternating phases of activity and inactivity. Earthflows materials here analysed are characterized by a relatively wide grain size distribution with a consistent presence of clay and silt contents that in most of these cases exceed 70%. These finer fractions ($d < 75$ μm) were mixed to corundum (20 wt.%) and then micronized (grain size < 10 μm). The resulting powders have been characterized from a mineralogical point of view by means of X-ray powder diffraction analyses (XRPD) using a Bruker D2 Phaser 2nd gen diffractometer and combined Rietveld and reference intensity ratio methods (RIR) with TOPAS 5 software (BRUKER AXS Company) (Cesarano et al., 2018). XRPD analyses were conducted to identify the dominant mineralogical phases in fine-grained sediment samples. Within the phyllosilicate phases, variations in proportions of chlorite (Chl) and kaolinite (Kln) were observed. The percentage of low-order and amorphous phases (LO-AP) encompasses remaining components, including mixed-layers, as well as potential thixotropic minerals. Among non-phyllosilicate and accessory minerals, quartz (Qz), feldspars (Fsp), carbonate phases (Cal), and occasional oxides (Opq) are ubiquitous. Carbonates primarily consist of calcite, with lesser proportions of dolomite, while being entirely absent in some samples. This absence is particularly significant, as carbonate dissolution can serve as a proxy for the weathering state of investigated materials. The findings could provide valuable insights into the mineralogical composition and weathering state of the sediment samples, contributing to a better understanding of their role in solid-to-fluid transition processes.

Keywords: ammonium adsorption, natural zeolite tuff, cattle livestock effluents.

Treatment method for recovery of NH^{4+} from livestock effluents based on the adsorption process with zeolite-rich tuff is highly promising due to its effectiveness, lack of chemicals or toxic substances and social acceptance. The adsorption process is heavily influenced by numerous factors, whose combination determines the efficiency of NH^{4+} removal, for this reason the main focus of this study is to evaluate the interaction among several variables with the aim of finding the optimal operative conditions for a wide range of possible real scenarios. Since numerous studies have been conducted on synthetic solutions and few zeolites as adsorbents, this work has investigated the NH4+ adsorption process considering the interaction between authentic cattle livestock effluents as i) separated manure (SM), ii) separated digestate (SD) and iii) microfiltrated digestate (MD) and different types of zeolite-rich tuffs as i) chabasite (CHA), ii) clinoptilolite (CLP) and iii) phillipsite (PHI). All the materials tested in this study were supplied by WAM GROUP S.p.A. The initial [NH^{4+}] are respectively 729.91±57.00, 711.25±21.62 and 861.99±13.62 mg L^{-1} for SM, SD and MD. For each zeolite two different particle sizes were tested, fine and granular. Moreover, two operating temperatures (25 and 40°C) were tested for the digestates, while the experiments on SM are only referred at 25°C. The effects of stirring speed have also been investigated in kinetic studies. The [NH^{4+}] content was measured with the Kjeldahl method and further elaborations were conducted with R, while isotherm model fitting was performed with package PUPAIM.

The non Linear Langmuir Model has been considered the most representative for the treated materials, in line with existing literature. The experimental equilibrium data reveals that higher ion exchange capacities are associated with solid-liquid ratios ranging between 3 and 5%, so subsequent kinetic studies were conducted at 3%.

All kinetic curves have similar trends, characterized by an exponential increase in adsorption capacity followed by a plateau phase. The optimal agitation time for cost-effectiveness is 120 minutes for all the conditions. Higher temperatures and fine particle are associated with increased adsorption capacities; however, the temperature effect is significantly more pronounced than the size effect. The interaction between zeolite and MD shows better performance compared to SD and SM, likely due to greater homogeneity and slightly higher initial [NH^{4+}], which is also a crucial factor in the adsorption process. CHA and CLP show the most favorable response to treatment compared to PHI. Agitation speed is a parameter with negligible impact as long as solid-liquid contact is ensured.

This research emphasizes the importance of considering the specificity of all factors involved in NH^{4+} removal utilizing zeolites in order to identify the optimal operational conditions for the treatment process.

Exploring pressure-induced crystal structure and fluid interactions in ABC-6 zeolite group

Battiston T., Comboni D.*, Lotti P. & Gatta G.D.

Keywords: zeolites, adsorption processes, X-ray crystallography.

The infiltration of molecules (or solvated ions) into the nano-cavities of microporous materials opens new routes for enhancing mass transfer from fluids to molecules incorporated in the structure. Thoroughly exploring this phenomenon, in both synthetic and natural zeolites, could expand their industrial applications, such as the development of new functional materials and enhancement of catalytic performance (Gatta et al., 2018; Comboni et al., 2020). From a geological standpoint, understanding this phenomenon can unveil the role played by zeolites as fluid carriers during the early stages of subduction of oceanic sediments and altered basalts.

In this research, we examined the interaction between crystals and fluids, driven by pressure, in three distinct natural zeolites belonging to the ABC-6 group: erionite (ERI framework type, 6-membered ring sequence: ABBACC), offretite (OFF, with AAB seq.), and bellbergite (EAB, with AABCCB seq.). The objectives of the experiments were: 1) to understand the potential role of erionite as a fluid carrier during subduction, given its presence, as a secondary mineral, in altered oceanic basalts (Vitali et al., 1995); and 2) to compare the mechanisms employed by structurally similar frameworks (characterized by the presence of 6-membered rings) in accommodating bulk compression and adsorbing new molecules.

The results revealed that erionite, a common zeolite, exhibits the highest magnitude of adsorption among the studied species. Additionally, the occurrence and magnitude of the phenomena were found to be governed by the H_2O content of the hydrous P-transmitting fluids. Offretite framework allowed Ne atoms to penetrate into the 12mRs channel in response to applied pressure, exhibiting weak Van der Waals interactions with the extra-framework population.

Keywords: magnetic properties, LTA zeolite, bauxite.

Bauxites are natural deposits resulting from weathering of aluminosilicates rocks under warm and humid conditions. They are mineralogically characterized by main the presence of boehmite [AlO(OH)], gibbsite [$Al(OH)_3$], and kaolinite [$Al_2Si_2O_5(OH)_4$], beside Fe oxides/hydroxides such as hematite [Fe_2O_3] and goethite [FeO(OH)]. This typical composition makes bauxite deposits as primary source for aluminum extraction and, subordinately, iron production. Moreover, the presence of iron in the typical chemical composition of bauxites can take a discriminating role in their exploitation.

However, mineralogical composition also makes bauxite as inexpensive source of silica and alumina for the zeolite synthesis and Fe oxides/hydroxides can provide important additional magnetic properties to this final product. Zeolites are crystalline hydrated aluminosilicates belong to the group of tectosilicates. Beside the excellent ion exchange and sorption capacity, zeolite can be characterized by other important properties such as magnetic features making them easily removable after using an external magnetic field (Belviso et al., 2015; 2020) and thus applicable in different fields, sometimes even very innovative ones.

In this work, three bauxite samples collected from Upper Cretaceous deposits of southern Italy were characterized for their magnetic parameters and used for the synthesis of zeolite with LTA topology (zeolite A). The results indicate differences in antiferromagnetic behaviour among the three raw materials. All the synthetic products, instead, display the same antiferromagnetic behaviour thus suggesting that the method used for the zeolite crystallization neutralizes the parameters responsible for raw bauxite magnetic differences.

Keywords: Vajont landslide, illite/smectite mixed layer, tephra.

The Vajont landslide that occurred on 9 October 1963 caused about 2,000 deaths when 300 Mm^3 of rocks slid from the Mt. Toc slope into the newly created reservoir, displacing some huge water waves that flooded the nearby villages. Basal sliding occurred within a lithostratigraphic sequence of cherty-marly limestones and clay interbeds belonging to the Fonzaso Formation of Upper Jurassic age. We investigated the mineralogical (X-ray powder diffraction), geochemical (X-ray fluorescence) and geotechnical properties of the Vajont clays, which were collected from the landslide failure surface and the surrounding area. The clayey materials contained variable amounts of clay minerals (32-93%), calcite (5-66%) and quartz (2-20%). The dominant clay minerals were illite/smectite (I/S) mixed layers with a high illite content (85-50%), which was consistent with the high percentage of K_2O of the bulk (1.17-5.77%). Clay interbeds with a prevalence of clay minerals (CM > 71%) were characterised by low values of the residual friction angle (φres = 6.7-14.9°), whereas clayey materials with a large content of granular minerals had greater values of φres (19.5-26.7°). The Vajont clays included in the Fonzaso Fm. can be referred to as K-bentonites and can be interpreted as distinct deposits of volcanoclastic materials (tephra), representing the sedimentary inputs of volcanic ashes that interrupted the "normal" calcareous sedimentation during the late Oxfordian-upper Tithonian (158-145 Ma). The clay interbeds are the result of a temporal sequence of complex geological phenomena, including: (1) initial eruption and injection into the atmosphere of volcanic ash from a distance source; (2) transport by wind and subsequent sedimentation in the Jurassic Vajont Basin; and (3) weathering and/or alteration of the original volcanoclastic material caused by diagenesis and burial-related phenomena. Clay-rich interbeds within sedimentary sequences, especially those including smectite and/or mixed layers clays with low shear strength, represent a typical example in which a relatively minor geological feature has a major impact on the behaviour of the rock mass and the related slope stability condition. The Vajont clays played a different mechanical role in the occurrence of the prehistoric rockslide and the 1963 en-block remobilisation. When referring to the ancient slope failures, distinct clay-rich layers that were concentrated within some specific lithostratigraphic intervals of the limestone sequence caused a localised decrease in the available shear strength, allowing for relative shear displacements along the dip-slope bedding planes. This caused the formation of a stepped basal failure surface. During the 1963 remobilisation, the clay layers contributed to the average shear strength decrease of the debris material forming the basal shear zone of the slide, but the main triggering factor was the increase in pore pressures caused by the reservoir-induced groundwater inflow.

Analysis of practices with the potential to create sustainable value for the natural zeolite sector

Borsatto F.*[1-2] & Jabbour C.[1]

[1] Fundação Instituto de Administração FIA, São Paulo, Brazil. [2] ZeoGroup, Brazil.

Corresponding author email: fernandoborsatto@celtabrasil.com.br

Keywords: natural zeolites, sustainable value, sustainable development.

The main objective of this research is to identify practices in the mining sector of natural zeolites with the potential to create sustainable value according to the dimensions of the framework developed by Hart & Milstein (2003). To this end, a theoretical foundation was made on the definitions of sustainable value and its implications for business models, especially those related to the mining sector, in which the natural zeolite industry is inserted. Following, the dimensions of the Hart and Milstein framework was characterized, namely pollution prevention, product stewardship, clean technologies, and vision of sustainability, with the aim of raising elements that could support the identification of practices with potential of sustainable value as the premises of each dimension. Supported by the theoretical foundation, an applied research was carried out, with a qualitative and exploratory approach, using semi-structured interviews with specialists, five of them professionals in the mining sector of natural zeolites and four stakeholders from the scientific community. As results, it was identified 41 practices which were analyzed, first, considering the conceptual foundations of this research and then, were associated with 18 different potentials ways of creating sustainable value. Finally, these practices were classified according to the concepts of the four dimensions of the framework proposed by Hart and Milstein. In the dimension of pollution prevention, techniques for collecting dust generated in the process to be sold as value-added products were mentioned. Regarding the dimension of product stewardship, it was discussed, among other practices, the challenges in reducing emissions in the distribution chain and which may present opportunities for partnership between companies in the sector. From the perspective of the clean technologies, the practices relate to the ability of natural zeolites to reduce the environmental footprint through technologies of the future were the main point of discussion. Finally, in the dimension vision of sustainability, practices related to the development of products that meet the needs of less favored countries were highlighted.

Corresponding author email: s.boscia@studenti.unisannio.it

Keywords: clay minerals, metakaolin, environmental sustainability.

Thanks to physical and chemical peculiarities, kaolin is an important resource both for environmental protection and for the prominent role it can play in sustainable technological development. After suitable heat treatment, it provides metakaolin (MK), a raw material that finds large implementation in industries field. The calcination of kaolin produces an amorphous phase with high pozzolanic hydraulic reactivity suitable for the manufacturing of ceramic-like materials after alkaline activation by means of Na or K silicate and Na or K hydroxide. The good physical-mechanical properties of these alkali-activated materials (AAM), combined with the low CO_2 emission in production processes, make them a viable sustainable alternative to traditional cementitious binders.

The present research stems from the collaboration among DST (UniSannio), DISTAR (UniNa) and BI-QEM SPECIALTIES SpA enterprise, to formulate and test new mix design of ceramic-like materials based on MK activated by alkaline solutions, as well as to test in the mixtures the superplasticizers produced by BI-QEM SPECIALTIES SpA, generally used for traditional cements.

This contribution reports preliminary data on the mineralogical characterization of two commercial MKs produced by IMERYS SpA (ARGICAL M1000S and M1200S) and the mixtures obtained to verify their alkaline activating capacity. The preliminary characterization was performed by using Fourier transform infrared spectroscopy with attenuated total reflectance module (ATR-FTIR), thermogravimetry and differential scanning calorimetry (TG-DSC) and X-ray diffractometry on powders (XRPD).

Typical absorption bands referable to the presence of kaolinite and quartz were observed in the ATR-FTIR spectra of both MKs. XRPD analyses confirm the presence of these phases along with anatase and illite/mica and, only for M1000S, of halloysite and chlorite. Thermal analyses confirm such mineralogical differences as well as a different total weight loss (LOI) (3.23 wt.% for M1000S and 1.58 wt.% for M1200S).

The heat treatments did not bring about a complete transformation of kaolinite in MK, particularly for M1000S which shows higher residual amounts of kaolinite, likely due to quite short calcination time or low temperatures. It is worth to note that the above reported mineralogical composition likely affects also physical properties such as Pozzolanic Index and Activity Index, which are 1100 mg $Ca(OH)_2$/g and 1.03 for M1000S and 1400 mg $Ca(OH)_2$/g and 1.10 for M1200S, respectively.

An ongoing phase of the present research is the evaluation of the geopolymerization reaction of commercial MKs with Na-AAM (in different proportions) and their compatibility with superplasticizers through comprehensive mineralogical, chemical and physical-mechanical tests.

Detailed characterization of mixed-layer illite/smectite provide new constraints for the geodynamic reconstruction of the Southern Apennines

Cavalcante F.[1], Belviso C.[1] & Prosser G.*[2]

[1] Istituto di Metodologie per l'Analisi Ambientale, CNR, Tito Scalo (PZ).
[2] Dipartimento di Scienze, Università della Basilicata, Potenza.

Corresponding author email: giacomo.prosser@unibas.it

Keywords: mixed-layer illite/smectite, geodynamic evolution, southern Apennines.

Reconstructing the thermal history in thrust and fold belts is crucial to define the pattern of tectonic loading in thrust sheets that underwent exhumation during the subsequent evolution of the orogen, providing fundamental information for the geodynamic reconstructions.

In this study, differences in thermal maturity, indicating the original extent of regional thrust sheets in the axial sector of southern Apennines, were ascertained by using data on clay mineralogy. The area is characterized by the presence of clayey sequences that underwent tectonic loads of a few kilometres during their evolution. In particular, to deduce thermal maturity, we analysed illite-smectite (I-S) mixed layers by X-ray powder diffraction in 56 samples collected in the Lower Cretaceus Galestri Formation, which is characterized by a monotonous lithologies consisting of beds of micritic limestones intercalated in prevailing shale. This formation was originally deposited within the Mesozoic Lagonegro basin, representing a wide deep-sea domain located between the Apennine and the Apulia carbonate platforms. During the Miocene orogenic evolution, the Lagonegro Units were incorporated in the Apennine fold and thrust belt, and were in turn overthrusted by the Apennine Platform and by internal units derived from the Ligurian Tethys Ocean, such as the Sicilide and the Liguride Units. Finally, the Calabria Basement was tectonically superposed on the Liguride Units, as shown in northern Calabria. The Lagonegro Units presently make up two major thrust sheets (Patacca & Scandone, 2007). The upper thrust sheet (Lagonegro Unit II) consists of middle Triassic to lower Cretaceous proximal deposits, with abundant carbonate debris, whereas the lower thrust sheet (Lagonegro Unit I) is composed of upper Triassic-lower Cretaceous deep-sea deposits displaying distal facies.

The data show a strong variation in terms of thermal maturity between the two Lagonegro units. In fact, samples collected from the Lagonegro Unit II are characterized by the presence of R0 illite (25-55%)/S and R1 illite (60-70%)/S, whereas the samples from the deeper Lagonegro Unit I display R1 illite (65-85%)/S. More interestingly, mineralogical data show a general increase of thermal maturity from North to South along the axial zone of the chain, consistent with a higher tectonic loading in the southern sector of the fold and thrust belt. This is explained by a variation in the thickness of the tectonic pile originally present above the Lagonegro Units from North to South. In the northern sector, the Lagonegro Units were covered tectonically only by the Sicilide thrust sheet, whereas in the central sector the pile of tectonic units was significantly thicker since it included the Apennine platform and the Sicilide/Liguride Units. Even higher thickness is recorded in the southern sector, were the same units occurring in the central sector were possibly overthrusted by the eastern margin of the Calabria basement.

Relationships between mineralogical and microstructural features in low-T metapelites from the Pollino area

Cavalcante F.[1], Belviso C.[1], Lettino A.[1], Lando I.G.[2] & Prosser G.*[2]

[1] Istituto di Metodologie per l'Analisi Ambientale, CNR, Tito Scalo (PZ).

Keywords: P-T estimates in metapelites, microstructural analysis, southern Apennines.

Correlation between T conditions and deformation intensity in metasediments affected by low-T metamorphism in orogenic complexes can be documented by microstructural and mineralogical studies. This is because deformation significantly influences metamorphic reactions, promoting the growth of new minerals during development of cleavage planes (e.g., Knipe, 1981). The Pollino area represents an ideal area for studying these relationships since metapelitic rocks of the Liguride Complex show a nearly continuous variation from diagenetic to low-grade metamorphic conditions. Deformation and metamorphism are connected to the evolution of the Liguride accretionary prism, developed on top of the W-dipping subduction of the Ligurian Tethys oceanic crust from the Cretaceous to the Oligocene (Cello & Mazzoli, 1999).

The study has been performed by comparing mineralogical analyses of phyllosilicates obtained by XRD (Cavalcante et al., 2012) with microstructures observed by FE-SEM in rock fragments. Samples have been collected along a transect oriented about NE-SW which crosses metapelites characterized by different T overprint. In the northeastern sector, samples have been collected in the non-metamorphic North Calabrian Unit, where the presence of mixed I/S layers R1 and R3 indicate T varying from 110-140°C in the Saraceno Formation to 130-150°C in the Crete Nere Formation. Microstructures are mainly characterized by a S1 foliation, nearly parallel to the S0 bedding planes. Only in the Crete Nere Formation, microfolds are connected with the development of an incipient axial plane cleavage (S2).

The Southwestern sector is characterized by the low-grade metamorphic Frido Unit, characterized by strongly variable overprint from north to south, documented by variations in the Kübler Index (KI) of potassic white mica. Minimum T, corresponding to the transition from diagenesis to anchimetamorphism, can be estimated in the northern sector of the Frido Unit, while the highest T (300-350°C) can be determined in the southern sector. In the central sector estimated T ranges between 230 and 290°C. According with T estimates, a dominant S1 schistosity, overprinted by an S2 cleavage that develops along the axial plane of incipient crenulations, is observed in the northern sector. The situation changes markedly in the central sector, where the S1 appears intensely deformed by evident crenulations leading to the development of a marked axial plane schistosity (S2). In the central-southern sector, the Frido unit shows a dominant S2 schistosity, with relicts of the former S1 that can be observed in microlithons. The most intense deformation is observed in the southernmost sector, as indicated by an almost total disappearance of the S1 foliation, outlined by relicts of phyllosilicates orthogonal the main S2 schistosity. Results of the study indicate a marked relationship between T conditions and microstructural features in the metapelites of the Liguride Units.

A sustainable use of carbonates-rich clays for alkali activated materials manufacturing

Clausi M.*[1], Fernández-Jiménez A.[2] & Pinto D.[1]

[1] Dipartimento di Scienze della Terra e Geoambientali, Università di Bari "Aldo Moro".
[2] Instituto de Ciencias de la Construcción Eduardo Torroja (IETcc), CSIC, Madrid.

Corresponding author email: marina.clausi@uniba.it

Keywords: carbonates-rich clay, mechanical pre-treatment, alkali activated materials.

Kaolinite clay represents the main natural aluminosilicate precursor used as for manufacturing geopolymers and alkali activated materials (AAMs) owing to its high reactivity in alkaline environments. However, this natural source is no widespread on the Earth and suffers of competitive markets, so large-scale use of this type of clay cannot be considered. The use of polymineral clay sediments, on the contrary, could represent an viable alternative solution in the view of valorizing local resources. However, the chemical and mineralogical variability of polymineral clays can influence their potential suitability as AAMs precursors.

Among polymineral clays, carbonates-rich clay from Apulian region (Italy) was successfully tested in the formulation of AAMs alone and in combination with several industrial by-products (Clausi et al., 2023; D'Elia et al., 2023; 2020). Furthermore, it been noted that the performance of this clay during alkaline activation can be improved significantly after a combined mechanical-thermal pre-treatment (D'Elia et al., 2018). However, in a perspective of reducing the environmental impacts related to the thermal activation, more sustainable activation methods need to be evaluated.

This contribute is aimed at studying alkali activated materials obtained from carbonates-rich clay subjects to the sole mechanical pre-treatment as activation method to increase the clay reactivity. Mineralogical and textural changes occurred in the clay after the use of two different milling equipments (high energy vibro-miller and conventional ball miller) were prior investigated and showed a variable delamination of clay minerals and reduction of calcite grain size.

Different AAMs were prepared modifying both the alkaline activator used (NaOH 8M or a sodium silicate solution) and the curing temperature. The obtained samples were characterized by XRPD, FTIR, OM, SEM/EDX and mechanical tests.

Results showed as mechanical activation method strongly influences the microstructures of pastes. Compacted pastes with mechanical strengths up to 10 MPa and 17 MPa were obtained using sodium silicate as alkaline activator and a curing temperature of 85°C, from clay activated by conventional ball miller and vibro-miller, respectively.

Although further studies are needed to optimize compositional and technological parameters, the obtained findings are encouraging, enough to aiming further studies towards applications in construction industry and soils stabilization.

Keywords: red clays, porcelain stoneware, iron effect.

The ceramic tile industry requires annually a huge amount of raw materials. Clays represent the 40% of them, while feldspars and quartz sand represent the remaining 60%. It is thus straightforward how the supply chain of these materials, mainly imported from outside the European Union, strongly affect the economy of the European ceramic districts. In Italy, before 2022, most of ball clays was imported from Donetsk basin, in Ukraine. The recent geopolitical upheaval poses serious questions on the supply chains. Moreover, there is recently a growing pressure for greater resource efficiency and the transition to a circular economy. From a technological viewpoint, it would be desirable to find other raw materials with suitable properties, such as appropriate plasticity, easy sinterability, and light color. Actually, porcelain stoneware classically consists of a batch with low iron content, typically below 1% by weight, which imparts light coloration. However, the new body formulations designed under the needs of higher sustainability entail a significantly higher iron content than the typical values. The understanding of the iron effect on the firing behaviour and performance of finished products has long been very little or at most limited to the colouring of the fired material. In this work, we present the characterization of two red clays deriving from quarries located near the Sassuolo ceramic district iron-rich (~7% Fe_2O_3). The features of these samples were compared with those of a German ball clay containing lower levels of iron (~3% Fe_2O_3). Moreover, we tested the effects of a partial substitution of Ukrainian ball clay body (used as benchmark) with the most suitable Italian red clay and the German ball clay into a standard batch for porcelain stoneware. The obtained bodies were fully characterized from milling to firing. Results demonstrated that the effect of relatively high iron content on the firing behaviour of porcelain stoneware tiles must be assessed together with the overall variation in the mineralogical and chemical composition of the batches. The use of red clays of different mineralogical composition has a clear impact on vitrification paths and on the temperatures at which maximum densification is achieved. This in turn affects the phase composition and the chemical composition of the vitreous phase at the optimal firing temperature. The firing transformations of Fe-bearing minerals consist in the formation of hematite (at expenses of Fe-oxyhydroxides) and incorporation in the liquid phase of iron made available by the breakdown of clay minerals. The Mössbauer analyses allowed to observe that in overfiring conditions the partial reduction of Fe^{3+} to Fe^{2+}, with release of oxygen, induces a significant bloating, higher in the Italian red clay bodies than German ball clay ones.

Enhanced adsorption of mycotoxin zearalenone by clay-chitosan-surfactant composite

Keywords: clays-chitosan-surfactant composites, mycotoxin-zearalenone, adsorption.

Mycotoxins are a large group of highly health-hazardous contaminants which are frequently found in animal feeds, foods for human consumption and agricultural products. Aflatoxins, ochratoxin A, zearalenone (ZEN), fumonisins and trichothecenes are the most frequently occurring mycotoxins. Zearalenone is a common contaminant of corn and possess strong estrogenic activity causing serious reproductive problems in humans and animals. Various methods (physical, chemical and biological) have been taken to remove mycotoxins from contaminated animal feed. Among physical methods, adsorption is considered as the most efficient in treating mycotoxins contamination. Clay minerals (bentonite - BENT) as naturally abundant, green, non-toxic and low-cost are shown to be effective adsorbents for aflatoxin B1 - AFB1, but they are ineffective in binding other mycotoxins, like ZEN. In order to increase ZEN adsorption, modification of BENT with organic molecules such as surfactants is necessary (Lian et al., 2019). Recently, composites of natural biopolymers (e.g. chitosan) and clays have been studied as adsorbents for AFB1 and ZEN (Wang et al., 2020). Chitosan is a particularly interesting biomaterial due to its biocompatibility, biodegradability, antimicrobial activity and adsorption properties. In our previous work, a natural BENT from Beretnica deposit in the Republic of Serbia was modified with chitosan isolated from mushroom *Agaricus bisporus* under laboratory conditions - CM (composite BCM) (Kozarski et al., 2023) and subsequently with surfactant - hexadecyltrimethyl ammonium bromide in amount equal to 50% of the CEC of BENT (composite BCMS). Both composites were characterized by Fourier transform infrared (FTIR) spectroscopy and tested as adsorbents of ZEN. Characterization results confirmed presence of chitosan and/or surfactant in composites. The results on adsorption of ZEN showed that BCMS composite had a high adsorption of ZEN, while its adsorption by BCM and BENT was low, at pH 3 (Smiljanić et al., 2023). The aim of this research was to further investigate the adsorption of ZEN by BCM and BCMS composites. Composites were characterized by DSC/TGA analysis and by determination of zeta potential which additionally confirmed presence of chitosan and/or surfactant in composites. Adsorption of ZEN was followed at different amounts of composites in suspension at pH 7 and results were compared with toxin adsorption at pH 3. Adsorption of ZEN by BCM was also low at pH 7, while presence of surfactant in BCMS significantly increased toxin adsorption. Adsorption of ZEN by BCMS composite was followed at different initial ZEN concentrations at pH 3 and 7 and its adsorption increased with increasing of the initial toxin concentration at both pH values. Results confirmed that although surfactant ions in BCMS are responsible for adsorption of ZEN, composite also contains biocompatible chitosan isolated from mushroom with potential antimicrobial activity.

Innovative modified natural zeolites: effective strategies for hexavalent chromium removal from polluted waters

de Azevedo B.*, Panattoni F., Tardani M. & Masini C.

Zeocel Italia by DND Biotech, Pisa.

Keywords: water, zeolites, filtration, chromium.

Industrial activities produce large volumes of wastewater containing harmful chemicals such as nitrogen compounds, heavy metals, anionic species like chromium, and surfactants. Improper disposal of these substances can adversely affect the environment and human health. Among the various cost-effective technologies for removing these contaminants, adsorption stands out as particularly effective.

Zeolites are affordable, eco-friendly natural minerals known for their impressive adsorption capabilities. These crystalline aluminosilicate minerals feature a symmetrical structure that creates a porous, three-dimensional framework. This structure gives natural zeolites the ability to act as cation-exchangers and molecular sieves, making them widely used in separation and purification processes to remove cations such as ammonium and heavy metals.

This study focuses on developing modified natural zeolites designed to exchange anions, particularly targeting chromate and dichromate ions. These ions are the two main forms of toxic hexavalent chromium [Cr (VI)] in water, posing significant environmental and health risks. Two modified zeolite formulations, BIZ and TIZ, were developed using saline exchange and surface metal modification techniques, respectively, starting from a natural zeolite consisting mostly of clinoptilolite, albite, orthoclase, muscovite, and quartz, with a Si/Al ratio of 4.8-5.5. The structural and morphological characteristics of the zeolites were analyzed using powder X-ray diffractometry (XRD) and transmission electron microscopy (TEM). Their effectiveness in removing chromium was tested through adsorption experiments using both synthetic and real contaminated water samples in batch and column tests.

The results highlighted the natural zeolite's inability to remove Cr (VI) effectively. However, the chemical modifications significantly enhanced the zeolite's selectivity for Cr (VI), substantially improving retention through surface adsorption, chemical reduction, and anion exchange mechanisms. While BIZ demonstrated higher adsorption capacities, TIZ showed quicker kinetics in chromium removal from water.

Keywords: clay successions, isotope fingerprint, geological origin.

Clay sediments are a relevant part of several stratigraphic records, and the study of their composition is a valuable tool for unravelling issues related to basin sedimentation and tectono-stratigraphic evolution.

This study aims at deciphering the relationship among clay successions from the Campania sector of the southern Apennines by combining mineralogical and geochemical investigations. These include mineralogical (X-ray diffraction), bulk chemistry (XRF), and Sr-Nd-isotope analyses. The investigated clays have already been the object of an extensive programme of survey and analyses carried out to identify the potential sources of clays used as raw materials for ceramics in antiquity in the Campania region of Italy (De Bonis et al., 2013). They are mainly associated with Lower Cretaceous to the Upper Miocene preorogenic/foredeep basin sediments and more recent Neogene synorogenic foredeep and postorogenic wedge-top basin deposits (Vitale & Ciarcia, 2018). The latter are mostly associated with carbonate sedimentation, which accounts for the Ca-rich chemical character of the clay sediments and for the presence of calcite. Feldspar is detected in most clayey sediments, while quartz is ubiquitous. Clay phases are composed of different phyllosilicate minerals generally including chlorite, kaolinite, and mixed layers, mostly represented by illite-smectite.

Isotope fingerprinting provides very interesting results that were already spotted during the implementation of this approach for the provenance study of archaeological ceramics (De Bonis et al., 2018). The extreme sensitivity of the Sr and Nd isotopes pinpointed the differences of clay sediments from a genetic point of view. Actually, distinctive isotopic fingerprints characterise the clay sediments of the investigated successions according to their geological origin and age.

Corresponding author email: cir.migliaccio001@studenti.uniparthenope.it

Keywords: red mud, geopolymer, zeolite.

Red mud is the primary waste product generated through the Bayer process for alumina production from caustic digestion of bauxite. It requires a proper management due to its high alkalinity (pH between 10 and 12) and for this reason its disposal represents one of the biggest issues in the mining industry. In the past, these bauxite residues were disposed of in natural or artificial water basins, but this management led to problems with the release of pollutants resulting in the contamination of the aquifers and the basins themselves. The annual production of red mud is higher than 150 million tons per year and for this reason new technologies are being developed for its treatment and reuse, according to circular economy and environmental protection. (Khairul et al., 2019).

Red mud combined to metakaolin represents a suitable material for developing geopolymer formulations. The composition of geopolymers is similar to that of zeolites, but unlike the latter, geopolymers have an amorphous structure. In fact, similar to zeolites, geopolymers are usually obtained from aluminosilicate precursors by polycondensation in an alkaline environment using sodium or potassium silicate. During this reaction, a three-dimensional network of SiO_4^{4-} and AlO_4^{5-} tetrahedra, with bridging oxygen atoms, is formed, characterized by the presence of rings of various sizes. Na^+ or K^+ from sodium or potassium silicate are used to balance the negative charges that are formed on the Al tetrahedral site. In addition to activation in an alkaline environment, in recent years an acid-type activation has also been developed regarding the geopolymerization reaction. As for the acid activating solution, a phosphoric acid solution can be used. Acid activation allows the production of poly(silico-alumino-phosphate) characterized by the presence of $[AlO_4]^{5-}$, $[SiO_4]^{4-}$ and $[PO_4]^{3-}$ units (Occhicone et al., 2024).

In this work, starting from red mud and metakaolin, both basic- and acid- geopolymer samples with dense, foamed (with the addition of foaming agent) or hybrid structure (with the addition of polydimetilsiloxane) were synthesized and characterized form chemical and mineralogical point of views by means of X-ray diffraction, optical and scanning electron microscope, Fourier transform infrared spectroscopy, mercury intrusion porosimetry. The obtained samples show excellent chemical and physical properties and high compressive strength (up to 63 MPa), suggesting their application in the building sector. In addition, preliminary tests suggest the effective use of these materials for the adsorption of organic pollutants, heavy metals and surfactants due to the presence of active sites and mobile metal ions. A comparison with the technological performance of clay- and zeolite-rich materials is provided as well.

Mechanochemical technologies for decontamination of soils polluted by organic and inorganic xenobiotics based on the use of clay substrates and oxides/hydroxides

Di Leo P.*

Istituto di Metodologie per l'Analisi Ambientale, CNR, Tito Scalo (PZ).

Corresponding author email: paola.dileo@cnr.it

Keywords: mechanochemistry, organic and inorganic pollutants, clay minerals.

The mechanochemical method, based on grinding reactants in solid phase, has recently attracted attention for its capability to degrade both organic and inorganic pollutants. Compared with other techniques, the mechanochemical method offers advantages for simple operations on a large capacity of materials, including toxic chlorinated compounds, by eliminating the use of organic solvent and facilitating the estimation of overall kinetic and thermodynamic parameters for the degradation process. The aim of this review is to highlight the models of xenobiotics-mineral surfaces reactions in mechanochemical treatments in which direct contact, i.e. without any solvent mediation as in the case of batch-type experiments, between the mineral surface and the organic ligand is achieved. The catalytic efficiency of mineral surfaces in degrading xenobiotics was investigated and the most probable xenobiotic degradation mechanisms and the adsorption sites most suitable for their catalytic degradation were identified. The phyllomanganate was the most efficient in removing both organic molecules and the degradation was also revealed by the release of increasing amount of Cl^- (for PCP) and Mn^{2+} ions (for both PCP and CAT) during the time of milling and the subsequent incubation time (Di Leo et al., 2012; 2013). From the spectroscopic analyses it is clear that Mn^{4+} octahedra represent the preferential sites for oxidative mechanism of PCP and CAT, by means of the formation of a monodentate and bidentate inner-sphere complex, respectively. Mechanochemical interaction of PCP molecules with the trioctahedral smectite is weak and mainly occurs on the external surfaces, thus causing amorphization of the trioctahedral clay mineral by formation of a double film of PCP molecules onto the mineral surfaces. On the contrary, the dioctahedral smectite exhibits strong mechanochemical interactions with PCP molecules via the phenolic group. Mechanochemical interactions of both pollutants with kaolinite mainly occurs via adsorption on external clay mineral surfaces through the phenolic group and, in the case of PCP, do not involve the chlorine atoms of the ring (Ancona et al., 2016).

Long-time grinding of expandable clay mineral (24 h) allowed Cd sorption on two sites (Di Leo et al., 2019): Type I, exhibiting characteristic of an outer-sphere complex likely localized in the montmorillonite interlayers and coordinated by two water molecule shells, i.e. in an exchangeable position; Type II sites, where Cd was more tightly bound to the TOT layers, either onto broken edges via the new OHs formed during the mechanochemical treatments or onto montmorillonite surfaces likely bridged via a water molecule. Desorption isotherms also confirmed a two-adsorption site model. This information could be useful to understand, develop and manage new remediation technologies based on mechanochemical treatments.

Keywords: clay, clay characterization, AAMs.

In the current landscape of materials research, there is a growing interest in the development of low environmental impact binders and construction materials, such as the so-called alkali-activated materials (AAMs). Traditionally, attention has been primarily focused on the use of kaolinitic clays and waste materials as precursors for AAMs (above all fly ashes and blast furnace slags), due to their high content of silica and alumina, which constitutes a fundamental requirement for the synthesis of AAMs. However, the demand for more widespread and abundant source material has led to a shift in perspective, highlighting the importance of natural polymineralic clays as suitable alternative raw materials for AAMs owing to their high abundance throughout the world. Nevertheless, the use of polymineralic clays as viable aluminosilicate precursor for AAMs poses several problems due to their high chemical and mineralogical variability in nature, so further investigations are needed.

The present research deals with the characterization and pre-treatment of different types of clays from natural outcrops and originated as waste from anthropic processing, to evaluate their suitability as precursor for AAMs. Specifically, the investigation involves three natural clay samples, as well as several samples of clays from tunnel sludges and sediments dredged from port areas, showing significant difference in term of mineralogical and chemical composition. Samples under study were characterized based on a multi-faceted approach utilizing various analytical techniques such as X-ray fluorescence (XRF) and X-ray diffraction (XRD), scanning electron microscopy (SEM), Fourier transform infrared spectroscopy (FT-IR) and grain size distribution analysis to evaluate their chemical, mineralogical and structural composition properties. Additionally, geotechnical and geomechanical tests, including oedometer and unconfined compression tests, were conducted to assess the soil mechanical properties. Furthermore, the selected clays were subjected to either mechanical and/or thermal treatment to increase their amorphous content and then their degree of reactivity during the alkali activation. Characterization of selected natural clay samples showed a great compositional variability depending on the type of clay and the geological context to which they belong. Specifically, the three natural clays samples consist of carbonate-illite-rich clay, illite-smectite interstratified clay and illite-rich clay, respectively. Tunnel sludges and port dredging sediments consist of illite-smectite dominated and carbonate-illite-rich clays, respectively, with relevant contents of organic matter.

The preliminary data of this study are part of a PhD research project aiming to gain a holistic understanding of the properties and behaviour of studied clays, elucidating their potential as both AAMs precursors and their performance as a binder suitable for various uses, e.g. for the mechanical improvement of soils or as supplementary cementitious materials.

Characterization and valorization of dam sediments: potential use in building materials

Keywords: sediments, ceramics, clays.

In recent years the possibility of reusing large amounts of secondary raw materials has been investigated as it represents an important opportunity in terms of environmental preservation. In this respect, this study aims to explore the potential use of dam sediments as a raw material (for ceramic use such as in clay bricks, lightweight aggregates, ceramic tiles and cementitious materials). At first, the large artificial reservoirs present at a national level were identified and investigated in terms of capacity, geological characteristics, etc. Based on this information, the Mignano reservoir (Piacenza, Italy) was identified as suitable for the irrigation of approximately 14,000 hectares at a theoretical water flow rate of approximately 0.16 litres/sec per hectare. In this reservoir, sediment sampling was carried out in three different areas: upstream, central area and downstream. We subsequently carried out sample analysis in terms of physical-chemical and technological properties (chemical and mineralogical compositions, plasticity (Atterberg), thermal behaviour, optical dilatometry, plasticity, and particle size distribution). As a result, the dam sediments investigated are mainly made up of carbonates (22-25%), quartz (31-33%) and clay minerals (42-45%). Based on these findings, a feasibility study was carried out to explore the use of these sediments in the ceramic sector, particularly as partial substitutes for clay raw materials in clay brick mixtures.

Chitosan-clay composite films: investigation of functional and antibacterial properties for potential biomedical application

Keywords: bentonite-chitosan composite films, functionality, antimicrobial activity.

The preparation of polymer-clay composites is gaining increasing attention as these functionalized materials can be used in biomedical fields (Dong et al., 2021). Chitosan is the most abundant natural cationic polysaccharide polymer, frequently used because of its special properties such as non-toxicity, biocompatibility, biodegradability, antibacterial activity, and film-forming ability (Jagdale et al., 2024). In this study, chitosan-based composite films with or without natural clay were prepared, and their functional properties (mass, thickness, and swelling), as well as their antibacterial activity, were investigated. The natural bentonite from the Beretnica deposit in the Republic of Serbia (BB) (CEC = 120 meq/100 g), commercial low molecular weight chitosan (Sigma-Aldrich, USA), glycerol (as plasticizer) and a 1% acetic acid solution were used for the preparation of composite films by casting and solvent evaporation, at polymer/clay ratios: 1.5:0.0 and 1.5:1.0. The samples were designated as F0 and FBB, respectively. The average mass and thickness of the FBB composite film (24±2 mg, *i.e.*, 140±6 μm) were increased compared to the parameters of the film prepared without clay (F0) (12±1 mg, i.e., 75±8 μm). The swelling capacity of the films after 4 h (pH phosphate buffer 5.8 at 37°C) was 536±54% for F0 and 302±43% for FBB. Although the FBB sample showed slightly lower swelling, the obtained results indicated that the composite film could absorb a considerable amount of water, which is very important in the case of its application as a wound dressing (Morgado et al., 2015).

The antibacterial activity of the prepared films was tested against *Enterococcus faecalis* and *Escherichia coli* using the log-reduction method. Both F0 and FBB inhibited the growth of *E. coli,* by 0.64 log10 CFU/mL for F0 and 1.60 log10 CFU/mL for FBB, compared to the 100% cellulose film used as control, although the inhibition of F0 was not significant. On the other hand, sample F0 showed pronounced inhibitory activity (by 1.56 log10 CFU/mL) against *E. faecalis*, while the sample FBB showed bactericidal activity inhibiting the chosen Gram+ bacteria growth by 4.0 log10 CFU/mL, compared to the control sample. The results indicate that the addition of BB significantly increases the antibacterial activity of chitosan films.

Considering the wide distribution of natural bentonite (such as BB in this study), which significantly improves the properties of chitosan film in terms of antimicrobial potential, these results have a future perspective in the production of affordable and effective dressings, with still high swelling capacity, for the topical treatment of damaged and/or infected skin.

Keywords: zeolite, marine bio-waste, soil restoration.

The endemic seagrass species of the Mediterranean Sea, *Posidonia oceanica* (L.) Delile, appears to be highly effective in C storage and its decline, due to direct anthropogenic activities and indirect disturbances, unbalances C sequestration dynamics. In addition, high amounts of *P. oceanica* litter deposit along the coasts of the Mediterranean Sea every year after leaves detaching from the rhizome during Autumn. Notwithstanding the fundamental ecological role of such deposits against coastal erosion, the use of beaches for tourism purposes currently implies the removal of these deposits, which are negatively considered by stakeholders. At the same time, fishing activities, comprising industrial and small-scale fishing, are responsible for high necromass production that also turn as an undesirable bio-waste.

In the last few years, valorisation of *P. oceanica* litter throughout anaerobic digestion and aerobic stabilization processes has been proposed as a valid alternative to landfill or incineration disposal, although the presence of sea salts can negatively affect these processes (De Sanctis & Di Iaconi, 2019). Zeolite-rich rocks, working as ionic exchanger of NH_4^+ (Langella et al., 2000), can be useful to reduce its content during anaerobic digestion process and loss of ammonia, via NH_3 generation, in atmosphere during the composting process. The moderate affinity of zeolites for Na^+ would also lower the salinity of the suspension marine waste/anaerobic sludge with presumable positive effects on both anaerobic digestion process efficiency and final properties of the marine compost originated from the aerobic stabilization of the digestate. Moreover, the natural zeolites can improve the properties of compost and of receiving soils, in terms of cation exchange capacity (CEC), porosity, aeration and water holding capacity. In this general frame, EMBRACE project (PRIN 2022 PNRR) aims at reaching two major objectives, represented by i) valorisation (in terms of both energy and matter) of a marine bio-waste and of a natural zeolite-rich quarry dust; ii) use of the obtained products (quality compost with natural zeolites) in restoring degraded soils of Mediterranean coastal areas (in terms of increase of both above- and belowground biodiversity).

This contribution provides the preliminary results about the chemical and mineralogical characterization of selected zeolite-rich rocks coming from abandoned quarry of Neapolitan Yellow Tuff Formation (i.e., ex Cava Suarez, Naples, Italy). This raw material shows a total zeolite content of ca. 40 wt.% mainly consisting of phillipsite and chabazite, and sporadic analcime. The amount of low-ordered and amorphous phases, that also could contribute to ion exchange processes, is estimated up to 29 wt.% whereas non-sorbent minerals are formed by feldspars (mainly sanidine), and subordinately clinopyroxene and micas. The total CEC values is ca. 2.5 mEq/g (0.95 mEq/g for Ca^{2+}, 0.83 mEq/g for K^+, 0.60 mEq/g for Na^+ and 0.13 mEq/g for Mg^{2+}).

Acknowledgements: These results, after a comparison with the technological features of zeolitic materials already available on the market, provide valuable information for a proper setting of the pilot tests of EMBRACE project (PRIN 2022 PNRR).

Keywords: porous geopolymer, ammonium removal, agricultural sustainability.

Geopolymers have emerged as highly eco-friendly adsorbents for wastewater treatment, offering promising potential in various applications. This study focuses on the development of porous geopolymers tailored for efficient ammonium adsorption, specifically targeting agricultural use. This research aims to synthesize different porous geopolymers using varying concentrations of foaming agents (H_2O_2) and natural surfactants, aiming to enhance porosity and optimize adsorption properties. Various porous geopolymers were synthesized by incorporating different concentrations of H_2O_2 and surfactants to induce a saponification reaction and promote porosity formation (Bai et al., 2018). Geopolymers with low bulk density ($0.44 < \rho b < 0.83$), water absorption ranging from 30% to 97%, and compressive strength between 0.2 MPa and 10.80 MPa were successfully produced. Characterization techniques including FTIR, SEM, and XRD were employed to analyze the structure and properties of the geopolymers. Analysis revealed a positive correlation between foaming agent content and open porosity, water absorption, and a negative correlation with bulk density and compressive strength. Similarly, surfactant content exhibited a positive correlation with open porosity and compressive strength while negatively impacting bulk density (Vitola et al., 2020). Batch adsorption experiments with different concentrations of ammonium demonstrated that adding hydrogen peroxides enhanced removal efficiency compared to the blank condition (Samarina & Takuloma, 2019). However, higher surfactant concentrations did not necessarily improve performance. The findings underscore the potential of tailored porous geopolymers for effectively adsorbing ammonium and removing it from water, to valorize this nutrient in agricultural settings. These insights contribute to advancing the development of sustainable wastewater treatment technologies, with implications for environmental and agricultural sustainability.

Keywords: zeolitized tuff, porcelain stoneware, technological properties.

In recent times, there has been an increasing demand for white-firing clay materials in ceramic tile production, due to a progressive shift towards porcelain stoneware bodies. Furthermore, geopolitical events have challenged the ability of industries to source raw materials for porcelain stoneware production from well-established European commercial channels. In this framework, there is a need to expand the possibility to use Italian raw materials to produce porcelain stoneware. For this purpose, residues of extraction and processing of zeolitized tuff (ZT) from two active quarries in Sorano (Tuscany) have been studied. The experimental work was carried out to characterize ZT, in terms of physical and chemical properties, and test it in porcelain stoneware formulations in place of feldspar. Four residues were characterized in terms of thermal properties by hot stage microscope (HSM) and the best material was defined by the higher thermal stability (lower bloating). Two different amounts were tested (10-20 wt.%) in comparison with a reference porcelain stoneware batch. The tile-making process was replicated at the laboratory scale. Tiles of 11 x 5.5 x 0.5 cm were shaped by uniaxial pressure then dried overnight. The industrial process was simulated by fast firing in electric roller kiln at maximum temperature in the 1180-1230°C range. The microstructure of the fired specimens at maximum densification was observed by scanning electron microscopy and colourimetric parameters were measured directly on fired tiles. Waste addition led to a reduction of green and dry bulk density of about 10%, not followed by a decrease in mechanical properties. All the studied batches show a maximum in linear shrinkage and bulk density at 1200°C, reaching the standard requirement for water absorption (<0.5 wt%). For mixture with 20 wt.%, the desired values is reached already at 1180°C leading to reduce thermal energy demand. An increase in firing temperature (1210°C) led to bloating more evident for the higher waste content, followed by an increase in water absorption. For the greatest addition of ZT, a clear worsening of technological properties can be observed passing from 1200 to 1210°C. At maximum densification temperature, mechanical properties are reduced by waste addition, passing from 41 to 37 MPa (always higher than the threshold of 35 MPa till overeating conditions). Feldspar substitution, given by the increase in iron content (3.75% in place of 0.13% Fe_2O_3), is followed by a limited colour change, with a ΔE value of 3.7 and 6.8 for samples fired at 1200°C. On the base of the achieved results, in terms of technological properties and thermal stability, both the ZT concentrations can be selected as suitable for porcelain stoneware production and industrial scale up.

Secondary and authigenic phase formation in the 50-year-old tuff from Surtsey (Iceland)

Montesano G.*, Rispoli C., Petrosino P. & Cappelletti P.

Keywords: Surtsey ICDP, zeolite, hydrothermal alteration.

Subaerial and submarine lapilli tuff samples retrieved from a 152 and 192 m-deep vertical boreholes and a 283 m-deep inclined borehole drilled in 2017 in the frame of the SUSTAIN-ICDP drilling project on the island of Surtsey (SW Iceland), which is one of the Earth's best-monitored volcanic sites, were characterized throughout petrographic studies, X-ray powder diffraction analysis and systematic SEM-EDS imaging and chemical analyses. The island of Surtsey formed over a near continuous 3.5-year effusive and explosive basaltic eruptions from 1963 to 1967 (Jakobsson & Moore, 1986). Since its formation, the island was affected by authigenic alteration and secondary minerals precipitation. Surtsey volcaniclastic deposits consists in armoured lapilli tuffs in which authigenic phases, either amorphous or crystalline, formed from a fresh basaltic precursor glass (i.e., sideromelane; Peacock & Fuller, 1928). Sideromelane experienced alteration to palagonite, a metastable alteration product (Prause et al., 2020; Montesano et al., 2023) composed of a variety of amorphous/slightly-to-highly crystallized mineral products, the latter exhibiting characteristics of smectites (Montesano et al., 2023). Secondary minerals are instead considered to precipitate from interstitial fluids in pores or vesicles and primarily consist of calcium-aluminum silicate hydrate (zeolites, tobermorite and xonotlite), together with minor carbonates and sulphates.

The alteration path along the analysed subaerial and submarine sequences was identified through the integrated results, trying to develop a minerogenetic model to explain their genesis. This model would provide a reference framework for assessing the mineralogical evolution in other Surtseyan-type volcanoes.

Keywords: Vajont clays, I/S mixed layers, Rietveld.

The accurate mineralogical investigation of clays is very important for geological interpretations, as well as in applied studies. X-ray powder diffraction (XRPD) remains nowadays the most suitable and powerful technique for both clay minerals identification and quantification. However, whereas the identification of clay minerals by XRPD is today relatively feasible, their quantification remains challenging mainly in case of clays characterized by highly disordered or interstratified clay minerals. This work deals with the mineralogical quantification of the clay interbeds included in the limestone Jurassic Fonzaso Fm. outcropping in the Vajont valley, which are presently considered as a key factor in the occurrence of the famous Vajont landslide (Hendron & Patton, 1987; Bolla et al., 2020). The Vajont clays were referred to as K-bentonites and were interpreted as distinct deposits of volcanic ashes (tephra) that were included within the calcareous sedimentation during the late Oxfordian-upper Tithonian (158-145 Ma) (Paronuzzi et al., 2021). The investigated clays consist of very complex mixtures of illite/smectite (I/S) mixed-layer clay minerals, with five samples showing a prevalence of I/S mixed layers with *R0* stacking order (~50 % illite) and, subordinately, I/S *R1* type, whereas four samples are characterized by a prevalence of I/S mixed-layers with *R1* stacking order and variable illite content. Kaolinite, illite and chlorite were found in traces as further clay minerals, whereas calcite, quartz, and traces of K-feldspar were identified as non-clay minerals (Bolla et al., 2020; Paronuzzi et al., 2021). Quantitive Phase Analysis (QPA) of high disordered clays from Vajont was here performed using BGMN Rietveld software and structural models of disordered clay minerals developed by Ufer and co-authors (Ufer et al., 2012). QPA by Rietveld method showed very different mineral contents in the investigated samples, with total CM varying from 32 to 93 wt.%, calcite varying from ~5 to ~66 wt.% and amounts of quartz ranging from ~2 to ~20 wt.%. The soundness and validation of the here obtained results has been performed based on the comparison with XRF chemical data and calcite contents determined independently by calcimetry.

Ethylene capture using natural and altered zeolites during the storage period of kiwifruits

Salamè E.[1], Cinelli C.[1], Tonutti P.[1], Brizzolara S.[1], Panattoni F.[2], Tardani M.[2], Freitas Pio de Azevedo B.*[2] & Masini C.[2]

Corresponding author email: bruno@zeocelitalia.it

Keywords: zeolites, ethylene, climacteric fruits.

Fruit ripening is governed by ethylene, a plant hormone that plays a crucial role in various stages of plant life, including fruit maturation and senescence. Climacteric fruits, which continue to ripen post-detachment due to ongoing ethylene production, can have their shelf life extended by managing ethylene levels post-harvest. Ethylene can be absorbed using various methods and materials, such as potassium permanganate and zeolites. Zeolites are cost-effective, eco-friendly minerals with exceptional adsorptive abilities. Leveraging their cation-exchange capacities and molecular sieve characteristics, zeolites are predominantly employed in separation and purification tasks, particularly for extracting cations like ammonium and heavy metals. Enhancements to natural zeolites through methods like thermal treatment, acid activation, and organic or metal modification enhance their selectivity for specific targets.

This study explores the impact of natural (ZeoNat), acid-activated (ZeoH), iron-modified (ZeoFe), and copper-modified (ZeoCu) zeolites on ethylene adsorption during the postharvest ripening of kiwifruits under various storage conditions. Previous research has demonstrated these modified zeolites' capabilities in absorbing CO_2 and ethylene, with copper-modified zeolite proving most efficient. Two weeks post-incubation with these zeolites, ZeoCu significantly outperformed others in ethylene absorption, contributing to the highest firmness and lowest soluble sugar content in kiwifruits, thus indicating a delay in the ripening process. While kiwifruits with ZeoFe exhibited considerable weight loss over time, those stored with ZeoCu and ZeoH maintained substantial firmness levels even after three weeks of incubation.

Clay sediments for health in the special geological area of the Euganean Hills

Tateo F.*

Istituto di Geoscienze e Georisorse, CNR, Padova.

Corresponding author email: tateo@igg.cnr.it

Keywords: clays, mud therapy, raw materials.

The responsible use of natural resources can prove to be a formidable system for a sustainable management of our Planet. Clay minerals and zeolites are raw materials that could be widely used to support human health, and a lot of traditional and modern examples can be mentioned. Unfortunately, the cultural gap between the different disciplines makes everything complicated and the geological contribution to human health is a typical example of this problem. Today geologic materials are not considered as possible resources for health, both under routine or emergency conditions.

An example that partially bucks this trend is reported here for the Euganean Hills area. The Euganean Hills belong to a structural high, bordered by a main fault system which separates them from the Veneto-Friuli foreland. The fault system drives the strong thermal anomaly of the Euganean area, also represented by the rise of thermal water (Na-Cl type). The Hills form an isolated body within the alluvial plain, basically formed by magmatic bodies intruded at shallow depth during Eocene to Oligocene time (Pola et al., 2020). The magmatic masses intruded older marine sediments, so, it is common to observe isolated, densely forested peaks with steep slopes (magmatic lithology) and bordered by deformed sediments. Lake and marsh sedimentation occurred before reclamations, especially at the external border of the Euganean Hills (peri-Euganean depressions). Currently, two ponds are still active, they are also fed by hot springs and, being within a park area, these places are particularly picturesque. Raw materials used for therapies are traditionally taken from these small lakes, with the advantage of producing no dust, no visual impact, and no need for grinding (no additional cost, no silicosis). The lake sediments contain quartz, feldspars, carbonates and sheet silicates (low-ordered illite, mica, chlorite and kaolinite). Gypsum, pyrite and abundant organic matter are always present (Calderan et al., 2020). The particular sedimentary environment of peri-Euganean depressions possibly stimulates peculiar microbial activity, as diatoms frustules are abundant in the lake muds and non-fossilizing microorganisms occur in the same material aged at approximatively 40°C at the thermal centers (Gris et al., 2020). Selected molecules from an Euganean cyanobacteria show great therapeutic capabilities (Ulivi et al., 2011). The interaction of organic molecules and clays of the peri-Euganean depressions are poorly studied until now, possibly because only in the clay fraction minerals such as mixed layers illite-smectite are detectable. However, preliminary FT-IR data show that interactions already occur with bulk sediment.

The Euganean spas represent a worldwide benchmark for mud therapy and also thermal water is used for healing. An additional health tool is the natural landscape itself, which has a great potential for the rest and recovery of fatigued attention.

Thermal stability of some natural zeolites from Georgia, Kazakhstan, and Armenia

Tsitsishvili V.*[1], Panayotova M.[2], Mirdzveli N.[3] & Bish D.[4]

[1] Georgian National Academy of Sciences, Tbilisi, Georgia. [2] Department of Chemistry, University of Mining and Geology "St. Ivan Rilski", Sofia, Bulgaria. [3] Petre Melikishvili Institute of Physical and Organic Chemistry, I. Javakhishvili Tbilisi State University, Georgia. [4] Department of Chemistry, Indiana University, Bloomington, USA.

Corresponding author email: v.tsitsishvili@googlemail.com

Keywords: heulandite, clinoptilolite, chabazite.

The thermal stability of zeolites is a critical parameter for their catalytic applications. Structural transformations that occur upon heating in three natural zeolites (Tsitsishvili et al., 2022) were studied by thermogravimetric analysis and X-ray powder diffraction. Our results show that tuff from the Tedzami deposit (Georgia) contains ~80% heulandite and ~10% chabazite and had a bulk chemical composition described by the empirical formula $(Na_{0.25}K_{0.06}Ca_{0.19}Mg_{0.15})$ $[AlSi_{3.6}O_{9.2}]\cdot 3H_2O$. This material loses H_2O in three stages: 60% at temperatures < 250°C, another 24% in the range 250-650°C, and the remaining 16% when heated to 800°C. A sharp endotherm was recorded on the DTG curve at 780°C. The thermograms do not show a sharp endothermic peak at 430°C and the heulandite/clinoptilolite 020 reflection in the X-ray diffraction pattern of the calcined sample does not decrease, which indicates the absence of a transition to the metastable phase heulandite B, although amorphization begins. At temperatures > 700°C albite begins to form; complete amorphization of chabazite occurred above 1100°C, leaving crystalline quartz, cristobalite, albite, and impurity iron oxides magnetite and hematite. The zeolite-containing rock from the Chankanay deposit (Kazakhstan) with empirical formula $(Na_{0.115}K_{0.079}Ca_{0.228}Mg_{0.175})$ $[AlSi_{2.96}O_{7.92}]\cdot 3H_2O$ contains heulandite, chabazite and quartz in approximately equal quantities and has a high adsorption capacity for water vapor after calcination at 400 and 800°C. The DTG curve shows sharp endothermic-effects at 629, 701 and 835°C; amorphization begins at 350°C and continues until the crystalline structure of chabazite is completely destroyed at ≈ 1000°C. At higher temperatures, the XRD patters shows peaks of quartz, albite, magnetite and hematite. The tuff from the Nor Kokhb deposit (Armenia) with empirical formula $(Na_{0.05}K_{0.07}Ca_{0.36}Mg_{0.08})$ $[AlSi_{5.12}O_{12.24}]\cdot 3H_2O$ contains more than 80% of clinoptilolite, the tuff loses 70% of water when heated to 450°C, the rest up to 900°C. Upon heating, the material transforms into a heulandite-B phase at ~ 457°C, and at temperatures > 600°C, Ca-feldspar begins to crystallize. The DTG curve shows a weak endothermic effect at ~ 690°C, and the clinoptilolite 020 and 200 *d* values over the temperature range 500-700°C first increase and then decrease, indicating expansion followed by collapse along the *b*-axis by 0.13 Å and along the *a*-axis by 0.18 Å. Amorphization begins at ~ 500°C, but the broadened diffraction peaks of clinoptilolite remain in X-ray diffraction patterns up to ~ 950°C when the dehydration process is completed. The results obtained will be useful for determining the possibilities of using the studied zeolites as catalysts or supports.

An early warning system experiment for landslides in Grassano (Matera, Basilicata, Italy) with the active participation of the local population and self-made open-source instruments

Keywords: landslide, long distance monitoring, citizen science.

Can the concept of Citizen Science be applied to the field of landslide warning systems? Italy is certainly a geologically unstable country with vast areas at risk of landslides, some of which, despite having been studied at an academic level, do not have any warning system that can save the population involved at the first signs of ground movements (Budmir et al., 2022). In Grassano, a small city in the Basilicata Region, in the summer 2023, the authors started an experiment to monitor some landslide risk points together with the retrieval of historical studies on the stability of the soil and moments of dissemination for the local population. Two types of instruments were deployed: two self-made sensors, sensitive to surface ground movements, and one SAR reflector (Morigi, 2015) sensitive to micro movements of a crumbling house, covering an area of about 1 square km. The two vibration sensors were built and installed by the authors, using open source hardware and software. The ground sensor is similar to others already used in landslide risk situations with the aim of issuing alarms to the population living nearby (Biansoongnern et al., 2016), but it uses a new transmitting technology, the radio LoRa (https://www.semtech.com/lora/what-is-lora), that is a low power and autonomous radio digital transmitting system. An iron pipe about 2 m long and 4 cm in diameter is buried about half in the ground. Inside, a smaller tube, containing a shock sensor, is suspended by a thread and free to oscillate. Both the inclination of the tube, due to the slow movement of the ground measured by an accelerometer, and the impact with stones or rapid movements of the pipe, generate the emission of an alert message. It is picked up by a receiver located in a house approximately 1 km away, where it is forwarded on the Internet. Power is provided by a LiPo battery re-charged by a small solar FV panel. The receiving node selects only the messages coming from the desired TX nodes. The vibration sensors have proven to be autonomous for at least 6 months.

The people of Grassano, including some authors of this article, were fundamental to the success of this first experiment in terms of helping to install the instruments and finding information on previous studies on soil stability. Furthermore, during a day organized in the Municipal Theater, the project was presented to the local population and a debate ensued, demonstrating the interest in these topics.

The Grassano experiment has demostrated the feasibility of a sensor network system based on a new low cost transmission technology with long battery life and without the need for third-party infrastructure. More sensors, even of different variables such as precipitation, or soil moisture, can be placed in other points within the receiver's sensitivity range and using the same transmission technology. People can be involved in sharing the costs and the responsibility for decisions to be made before and during possible emergencies.

Climate change adaptation and mitigation strategies in the Kenyan Rift Valley: the case of Baringo and Bogoria lakes

Clemente E.*, Lapietra I., Colacicco R. & Rinaldi A.

Dipartimento di Economia, Università di Bari "Aldo Moro"..

Corresponding author email: emanuele.clemente@uniba.it

Keywords: adaptation and mitigation strategies, cost-effectiveness analysis, inland water management.

Over the past decade, the rising water levels of the Rift Valley lakes (Eastern Africa) have left trails of destruction, with the consequential loss of farmland and homesteads. The current study aims to identify the most affected and vulnerable areas in Baringo county, Kenya, where two lakes' - an alkaline one (Bogoria) and a freshwater one (Baringo) - have been expanding over the past fifteen years. In the present paper, a multi-disciplinary approach leveraging remote sensing and georeferenced household data is carried out to assess the socio-economic vulnerability of the affected communities. Upon the identification of the most vulnerable communities and in-field visits, a set of sustainable adaptation and mitigation interventions including sensitization workshops, plantation interventions, and naturalistic engineering works. Furthermore, such measures are evaluated via a cost-effectiveness analysis, to provide policy valuable costing insights and actionable recommendations to the local authorities.

Citizen Science for the enhancement and knowledge of the territory: the YouthMappers@Uniba experience

Colacicco R.*, Lapietra I., La Salandra M., Roseto R., Bellini F. & Capolongo D.

Dipartimento di Scienze della Terra e Geoambientali, Università di Bari "Aldo Moro".

Corresponding author email: rosa.colacicco@uniba.it

Keywords: citizen science, collaborative mapping, OSM.

Mapping practices and policies have evolved considerably over recent decades. Advances in geoinformation technologies have changed the way information is collected, analysed, stored and distributed (Olteanu–Raimond et al., 2017). In this sense, it is important to underline the emerging role of the citizen as a source of data. Due to the proliferation of location-aware devices and the opportunities of Web 2.0, it is now possible for citizens to easily acquire, share and use geographical information (See at al., 2015). One of the most famous tools, in this sense, is OpenStreetMap (OSM), a free, open geographic database updated and maintained by a community of volunteers via open collaboration. Contributors collect data from surveys, trace from aerial imagery and also import from other freely licensed geodata sources.

In recent decades, the tourism sector has represented a great resource for our country: it guarantees constant attraction and use of new resources for the valorisation and promotion of the national heritage, in line with the pursuit of Sustainable Development Goals. The Puglia region (Southern Italy) is one of the most famous regions in the world for its vast geological, natural and historical heritage. The region, in fact, is characterised by the presence of important Geosites, non-renewable geological-geomorphological assets of scientific and environmental value, and consequently great potential for the development of geotourism. However, numerous itineraries for trekking and hiking are available, these are not adequately signposted or accessible, and therefore tied to poor information.

In this perspective, the activities of the YouthMappers@Uniba (YM@Uniba), a group of young volunteer mapping students and researchers from the Department of Earth and Geoenvironmental Sciences of the University of Bari 'Aldo Moro', aim at mapping paths and amenities, within OpenStreetMap, of areas included in the National Park of Alta Murgia. This area is famous for the geological uniqueness and potential geotouristic appeal and is the first territory in Puglia aspiring to become a UNESCO Global Geopark (Tropeano et al., 2023). In addition, this part of territory is characterised by the presence of sinkholes, natural cavities produced by karst processes in soluble rocks, and man-made cavities deriving from different types of human activities in different historical ages. The related hazard is extremely high, so thematic maps (also derived from collaborative mapping) are crucial to manage and monitor sinkholes occurrence. The mappers acquired various data about (not only) paths, amenities and landscape features, through field trips, involving students from the Department's degree courses and transversal skills. This allowed the mappers to put their skills and background at the service of the large OpenStreetMap community.

The importance of such activities that include collaborative mapping lies in the possibility of continuously updating the information of the territory, a limitation that a 'traditionally' published map presents for obvious reasons.

The (un)stable stewardship: The Earth Sciences amid accrued vulnerabilities, climate disruption, and resource management

Fracassi U.*

Istituto Nazionale di Geofisica e Vulcanologia, Roma.

Corresponding author email: umberto.fracassi@ingv.it

Keywords: poly-crises, strategic interests, solutions.

Back in the XVIII century, the Earth sciences were born out of deciphering ancient life forms teeming in an aboriginal environment, unfolding on a planet that could be explained only by looking at the Solar system. In our complex and vulnerable times, modern Earth Sciences, cross-disciplinary by nature, are among the best tools to gauge location, amount, economic turnout, and societal costs of managing a delicate, densely populated landscape and the need to exploit natural resources – finite, dwindling, or more costly, not just economically.

Often depicted as the "natural aircraft carrier of the Mediterranean", Italy's landmass intrinsically holds a formidable combination of geodynamic, environmental, and strategic factors that have concocted a remarkable landscape, a host of resources, and a number of interests – some far beyond what the layperson may perceive.

Projections concerning global population rise indicate that 70% of the world's population will concentrate in urban areas (as opposed to 70% in rural areas in 1950). Such redistribution is also driven by systemic, long-term migration shifts – due to climate, resources, risks – and by unpredicted factors – from vulnerabilities to instabilities. The resulting, complex pattern is expected to pressure the environment (natural and built) at an unprecedented scale – a phenomenon already revealed by geophysical evidence in critically expanded coastal agglomerations.

More, larger cities are thus expected to draw larger amounts of energy and subsurface resources, and to compound fragile coastal environments. While such evolution may more acutely affect world regions further away, selected Italian coastal stretches are of course exposed to various natural hazards, of diverse wavelengths and spatial patterns (earthquake, tsunami, drought, sea-level rise). Some of these are in part accrued by the unique dynamics of the Mediterranean basin, while pre-existing, overlain vulnerabilities in the built environment (not merely the one belonging to our cultural and historical heritage) make for a critically delicate case of remarkable relevance throughout the Mediterranean Sea.

Since striking a balance between exploiting (ever-changing) resources and adapting to (broadening) hazards is a task that may elude any single country, the Earth Sciences should be inherent to national and international strategic choices, in the best interest of societies and governments. Such interest includes deciphering the novel challenges revealed by poly-crises and hybrid threats that mark the XXI century since its very outset.

Our collective perception about global strategies, international positioning, and existential outlook should therefore evolve, both as global societies and as a scientific community not just entitled but dearly needed to lead ways and prospect co-designed solutions, both realistic and imaginative.

Coastal and marine hazard awarness throught citizen science in School

Lisco S.*[1], Marangi M. [2], Sini V. [3] & Lapietra I.[1]

Corresponding author email: stefania.lisco@uniba.it

Keywords: citizen sciences, beach, anthropogenic pressures.

Citizen sciences activities can actively reduce the effects of natural hazards on the territory, because they spread awareness and responsiveness in individuals.

The Taranto area is infamous for the anthropogenic pressures affecting natural systems and sedimentary environments of extreme beauty and in some cases unique to the entire Mediterranean basin.

As part of this project, we chose to make a group of about 250 children attending elementary school in Taranto (Istituto Comprensivo Statale Cesare Giulio Viola) to make them active citizens of the future.

Specifically, in this project called "RicercAttori dei due Mari" the participants were shown how the beach system works, what sedimentary dynamics act on the system, and what pressures cause the greatest sediment volume losses. In addition, through experiments analogous to the real environment, participants understood how exceptional events acting in the coastal marine environment are triggered and are expected to increase in response to ongoing global climate change.

Finally, participants learned how to classify the grains that constitute beach sands in order to assess the health of beaches in a simplified manner compared to the procedure proposed by Lapietra et al. (2022) and classified sands from beach samples from Lizzano (Taranto). These sediments are particularly rich in bioclasts, so the connection between beach health and that of the shallow marine environment is particularly evident for this coastal stretch. such a data collection activity allowed participants to understand that the sandy beach environment is the result of a delicate balance between physical, biological and anthropogenic processes; that the risk of coastal erosion is linked both to land management and to our daily choices; and, finally, that active citizenship can act as a needle in the balance and direct the choices of decision makers, and act directly for a sustainable exploitation of the coast.

Corresponding author email: stefania.lisco@uniba.it

Keywords: citizen sciences, beach, monitoring.

Coastal areas are directly and indirectly affected by anthropogenic impacts. Worldwide coastal sectors are suffering from the high densities of litter items, whose sources are located both inland and offshore. To assess the beach litter (BL) distribution and to define litter composition and origin, monitoring programs are periodically carried out following standardized procedures.

In this contribution, we describe the monitoring activities carried out in the period February-March 2024 in the frame of the MAREVIVO NauticinBlu

The program has involved a total of 250 students from 3 high schools of Apulia Region, who participated in the field activities carried out along the urban beaches in Bari, Molfetta (BA) and Brindisi.

BL monitoring has been performed by analyzing the emerged beach sector, from the shoreline to its inland limit, represented by the seaward limit of the vegetation or by an anthropogenic structure (e.g. street, sidewalk). BL elements have been counted and classified according to their composition (metal, glass, plastic) and typology (e.g., bottles, cans, fragments).

Collected data have been synthesized in the form of graphs and maps, by exploiting the use of GIS software.

Active involvement of students is an appropriate way to raise their awareness toward one of the main critical issues affecting the coastal marine environment. A higher awareness is aimed at making students active citizens in prevention activities and promoting their involvement in data acquisition as part of citizen science initiatives to support scientific research activities.

Submarine fluid escapes: their role on ground instabilities. Learning examples of RETURN project

Lo Presti V., Agate M., Balsamo L., Bracci M., Cassataro R., Maiorana M.G.* & Sulli A.

Dipartimento di Scienze della Terra e del Mare, Università di Palermo.

Corresponding author email: valeria.lopresti@unipa.it

Keywords: fluid escapes, ground instabilities, submarine landslide.

The submerged structures associated with the term "Fluid escapes" are morpho-structural evidences of particular importance, linked to processes of fluid uprising, such as water or gas, from the seabed. Depending on their depth, the nature of the emitted fluid, their extent, and the area involved, both superficially and, especially, in the stratigraphy of the seabed, these effusions can play a significant role in the formation and triggering of submarine landslides. Studies conducted under the RETURN Project have allowed the analysis of these structures from geological, morphological perspectives, and to undertake an initial geo-mechanical approach. Analyzing the possible geomechanical variables associated with structures such as Pockmarks, Mounds, and Mass Transport Deposits (MTD) (Sultan et al., 2004) is indeed necessary to extract quantitative data and to study the geological evolution of these structures and the submarine landslides associated with them. The offshore of Palermo gulf and Sciacca gulf (Ag) are Sicilian marine areas where such structures are observed. In the Palermo gulf, Pockmarks are observed along the continental slope (Lo Iacono et al., 2011), and two large submarine landslides are connected to them. The formation of landslides is linked to the presence of unconsolidated sediment associated with these structures because the uprising fluids also impregnate the sediments of the flowed layers, thus causing the rupture of cohesive forces. In contrast to the pockmarks, which are depressions, the offshore area of the Sciacca Gulf (Servizio Geologico d'Italia, 2024) exhibits Mounds ([MM1] mud volcanoes). They are distributed along at least three lines of weakness, each about 2 km long and perpendicular to the coastline. The presence of these structures also indicates submarine areas with the active presence [MM2] of loose sediments susceptible to submarine landslide formation. Free gas accumulations (highlighted by enhanced seismic reflections) can be found below mass-transport deposits (MTD), whose seal capacity is attributed to its intensive consolidation in response to differences in capillary pressure and porosity. As demonstrated for the Pearl River Mouth Basin (South China), a retrogressive slope failure could be responsible for a lateral migration of free gas (Sun et al., 2017). Therefore, the identification and analysis of Pockmarks, Mounds and MTD lateral extensions comprise an important geohazard in terms of fluids escape structures prevention and control.

Probabilistic hazard maps of pyroclastic density current at Vesuvius volcano (Italy): a new strategy for risk reduction

Mele D.*, Dellino P., Dioguardi F. & Sulpizio R.

Dipartimento di Scienze della Terra e Geoambientali, Università di Bari "Aldo Moro".

Corresponding author email: daniela.mele@uniba.it

Keywords: probabilistic hazard maps, pyroclastic density current, Vesuvius.

Pyroclastic density currents are ground-hugging gas-particle flows that can originate during a volcanic explosive eruption. Dilute pyroclastic density currents are one major source of hazard at Vesuvius volcano (Italy). By combining data of deposits of the explosive eruptions of the last six thousand years and interpolating data of impact parameters (velocity, density, particle volumetric concentration, temperature, dynamic pressure), which were calculated by modeling the currents as stratified turbulent boundary layer flows, probabilistic hazard maps were obtained. They show the decay trend of the impact as a function of distance from the vent and allow depicting the expected damage. This outcome can help civil protection authorities to more precisely-implemented mitigation measures and communicate more effectively the risk to decision-makers and the population.

Zoning of territorial hazard for the evaluation and mitigation of hydrogeological risk: morphometric, meteorological, climatic, geolithological and hydrogeological - hydraulic analysis of the Rio Corr'e Pruna basin (Sardinia - Italy)

Mureddu A.*

Provincia del Sud Sardegna

Corresponding author email: mureddu.alessio@tiscali.it

Keywords: zoning, hydrogeological risk.

In October 2018, the Province of Southern Sardinia had to carry out 9 emergency interventions due to adverse meteorological phenomena that struck the Sarrabus region. In the first planning phases, historical analyzes were carried out on the extreme phenomena that affected the south-eastern areas of Sardinia (Sarrabus – Gerrei). The cyclical model detected identified frontal movements coming from the coastal plains which propagated from the sea, from the South-East quadrants ("Scirocco wind") towards the inland reliefs. The exceptional dimensions of the storm phenomena have been classified as "Mediterranean cyclones". Historically, exceptional meteoric events have hit the Sarrabus areas in the years 1900, 1907, 1910, 1940, 1951, 1953, 1971, 1986, 1993, 2013, 2018, 2021.

The particular conformation and geographical exposure, as well as the geological structure of the territory characterized by Hercynian plutonites (Leucogranites and Granodiorites of the Upper Carboniferous - Permian plutonic complex), periodically exposes the encountered terrains, formed by alteration materials and related pedogenic horizons, to intense surface flow events that fuel important movements for solid transport.

From the analysis of the archive data recovered it was possible to highlight a differentiation of the vulnerability parameters detected during the flood events that occurred over time. In fact, the demonstrations of the first half of the 20th century highlighted huge problems localized above all in the countryside and therefore in agricultural activities (typical of generalized flow regimes, i.e. non-organised/non-channeled flow networks).

The subsequent flood events (late 20th century and first decades of the 21st) also caused extensive damage to roads, works of art, bridges and embankments (built in these periods). The latter, responsible for regulating the large flow contributions on artificial drainage networks, have historically been sized on the basis of scientific knowledge of the time and basin planning which is no longer appropriate.

The morphometric, geolithological, hydrometeoric study, carried out at the time by the author on the Rio Corr'è Pruna Basin, was partially revisited and updated by the same during the planning of the 9 safety and refunctionalization interventions carried out by the Southern Province Sardinia (financed in accordance with the provisions of O.C.D.P.C. n° 558 of 15.11.2018).

The greater in-depth studies carried out using the aforementioned study as a basis have made it possible to use part of the data in order to evaluate and size the safety interventions according to the geological-hydraulic hazard zoning of the Rio Corr'è Pruna Basin.

Hazard from endogenous gas emission in the north and center Lazio Region

Ranaldi M.*, Carapezza M.L., Tarchini L. & Barberi F.

Istituto Nazionale di Geofisica e Vulcanologia, Sezione Roma 1.

Corresponding author email: massimo.ranaldi@ingv.it

Keywords: carbon dioxide -CO_2, hydrogen sulfide -H_2S, gas hazard.

Lazio Region is characterized by the presence of several endogenous gas discharges, mainly hosted in the Quaternary volcanic complexes, which release large quantities of CO2 into the atmosphere. The total CO_2 emission varies from few to hundreds tons/day, and some discharges have gas fluxes comparable to those of quiescent volcanoes. The origin of CO_2 is attributed to a deep mantle source or to a magmatic source, as for the dormant volcano of the Colli Albani. In many areas, H_2S is also present and is the second most abundant gas. Both CO_2 and H_2S are toxic and tend to accumulate in morphological depressions where dangerous or lethal concentrations can be reached. In Lazio Region, several accidents have occurred to people and animals due to the inhalation of endogenous gases, as reported in the catalog of Italian dangerous degassing sites (Googas Catalogue, 2009). The most recent lethal accidents are worth mentioning: in 2000 two hunters in Vejano (VT); again in 2000, at Cava dei Selci gas discharge (Marino, Rome) the gas killed 29 cows, then over time also six sheep and many other animals (Carapezza et al., 2003); in 2001 a man also died in Cava dei Selci; in 2005 in Fiumicino (RM) an entire family suffered gas poisoning without lethal consequences; in 2011 a man died and three others were poisoned in Lavinio (Anzio, RM) (Barberi et al., 2019) and two people died in a spa in Suio (Castelforte, LT). Obviously, the number of episodes of intoxication due to natural gases is much higher. Gas discharges are found in rural areas (i.e., Palidoro, Vejano and Latera), in natural reserves (i.e., Tor Caldara, Caldera di Manziana, Canale Monterano) as well as in urban areas (i.e., Cava dei Selci-Marino, Ciampino, Lavinio, Fiumicino) and here the risk associated to the gas emissions is higher due to the presence of people living nearby. We present the results of a systematic study carried out on most of the gas discharges of Lazio Region aimed at investigating their chemo-physical characteristics and at assessing the gas hazard.

Keywords: sinkholes, risk perception, urban context.

Collapse sinkholes (Gutierrez et al., 2014) may occur in territories characterized by both anthropogenic and natural underground voids. In both cases they force local communities to deal with significant sinkhole hazards that are characterized by the absence of clear precursory signals and the rapid kinematics. In most cases, communities seem to underestimate the sinkholes formation since the underground voids are out of sight. Collapse sinkholes have occurred above galleries of the underground quarries (Pepe et al., 2013) in the municipality of Altamura (Apulia Region, Southern Italy) causing problems and fear among the population.

Starting from these considerations, the purpose of this research is to investigate the perception of the sinkhole risk among the local residents with the aim to uncover patterns of perception or lack thereof and to understand their correlates. By examining the residents perceptions of the sinkhole risk, this study aims at identifying the specific factors influencing the individuals awareness and understanding of the sinkhole hazard. Moreover, it aims to discern whether there are consistent patterns in perception across demographic groups. Understanding these patterns can inform targeted risk communication strategies tailored to address the needs and concerns of different segments of the population. Additionally, insights gained from this research could contribute to the development of more effective policy actions for sinkhole risk mitigation and management. These might potentially include the improvement of land-use planning regulations, the implementation of early warning systems, and the enhancement of infrastructure resilience in vulnerable areas. Ultimately, the findings of this study have the potential to enhance the community resilience and minimize the societal impacts of sinkhole occurrences in Altamura and similar places.

Citizen Science for seismic risk reduction strategies and sustainable management

Sandron D.*, Saraò A., Tamaro A. & Rebez A.

Istituto Nazionale di Oceanografia e di Geofisica Sperimentale - OGS.

Keywords: volunteers, trained citizen, Civil Protection.

Volunteer-based initiatives and trained citizen science projects both engage the public in scientific research. However, they diverge in the level of expertise and training participants receive. Volunteers typically join out of interest or passion without formal training, while trained citizen scientists undergo formal instruction in scientific methods, ensuring data accuracy and consistency.

In this study, we introduce two case studies concerning seismic risk mitigation, focusing on the engagement of citizens and societal stakeholders. The first case involves a volunteer-based citizen-science initiative implemented in Trieste, located in north-eastern Italy, following the 2020 Mw 6.4 earthquake in Petrinja, Croatia. We analyzed data gathered through online macroseismic questionnaires disseminated via social media showing their capacity to assess the geological characteristics of the city. We also demonstrated the importance of social media platforms in facilitating the crowd-sourcing of data.

The second case presents findings from a trained citizen science project that has operated for nearly a decade in partnership with the Civil Protection of Friuli Venezia Giulia. This initiative involves training civil protection volunteers in essential seismological principles and guiding them through the completion of a macroseismic questionnaire. Upon receiving notification of a seismic event, the trained volunteers promptly assess impact within their local community . The collected questionnaires from volunteers across the region augment the impact assessment derived from analyzing recorded ground motion data.

Assessing and mitigating natural gas risk at Cava dei Selci (Colli Albani volcano) through combined geochemical, epidemiological and agro-environmental studies

Tarchini L.*, Carapezza M.L. & Ranaldi M.

Istituto Nazionale di Geofisica e Vulcanologia, Sezione Roma 1.

Corresponding author email: luca.tarchini@ingv.it

Keywords: volcanic gas hazard mitigation

Cava dei Selci is a residential neighbourhood of Marino (Rome) hosting a natural gas discharge, where in 2000-2001 a man and dozens of cows and sheep have been killed by gas asphyxiation. Gas originates from Colli Albani quiescent volcano and consists mostly of CO_2 (up to 98 vol.%) with ~1 vol.% of H_2S.

A densely urbanized zone with 4000 residents surrounds the gas discharge. In recent years, several gas-related accidents occurred in this urbanized zone, including gas blowouts during shallow drillings, road collapses and permanent evacuation of four families because of hazardous air gas concentration inside their houses.

The related gas hazard has been assessed by soil CO_2 flux and concentration surveys and indoor and outdoor measurements of CO_2 and H_2S air concentrations. All open spaces of the zone, including house gardens, released a high quantity of CO_2 (32.23 tonnes*day-1 from 0.4 m2) and in-soil CO_2 and H_2S concentrations at 50 cm depth reached values up to 90 vol.% and ≥1000 ppm respectively. Inside most houses, CO_2 air concentrations exceeded ALTER (Acceptable Long Term Exposure Range, 0.1 vol.%) and, in several houses, both CO_2 and H_2S exceeded the IDLH level (Immediately Dangerous to Life and Health, 8.3 vol.% and 100 ppm respectively).

An epidemiological cohort study was carried out on the residents of two Cava dei Selci zones with high (zone A) and medium (zone B) gas hazard exposure, using the rest of Marino as reference zone. We found excess mortality and emergency room visits (ERV) related to high exposure to CO_2 and H_2S. In particular, an increased risk of mortality and ERV for diseases of central nervous system (HR 1.57, 95% CI 0.76–3.25 and HR 5.82, 95% CI 1.27–26.56, respectively) was found among men living in zone A (Carapezza et al., 2023).

Given that the main gas emission occurs from a 6000 m2 former stone-quarry very close to houses, we conducted studies on the quarry soils in order to pick the most resilient and promising trees and bushes to be inplanted as CO_2-absorbers and barriers against the diffusion of endogenous gases towards houses.

Carapezza M.L. et al. (2021) - Health impact of natural gas emission at Cava dei Selci residential zone (metropolitan city of Rome, Italy). Environmental Geochemistry and Health, 45(3), 707-729, https://doi.org/10.1007/s10653-022-01244-6.

Protects and heats

Tavecchio W.*

Freelance geologist.

Corresponding author email: emme.vu.ci@gmail.com

Keywords: earthquakes, seismic waves, geothermal probes.

Ongoing climate change is the cause of recent geo-environmental disasters, such as floods and landslides, which occur more and more frequently and derive from the growing consumption of energy and the consequent increase in CO_2 emissions. A change can only happen with the belief that the first thing to do is to reduce energy consumption derived from fossil fuels.A positive contribution in this sense could be given by a new "Protect and heat" project. This project aims to safeguard the environment, reduce CO_2 emissions and reduce the risk of collapse of buildings affected by earthquakes.The "Protect and Heat" project is a way to heat and cool buildings, which uses a low-enthalpy, zero-emission geothermal system to simultaneously protect and attenuate seismic vibrations produced by earthquakes on buildings located in seismically sensitive areas.To mitigate the catastrophic and destructive effects produced by earthquakes on the soil and existing structures and to produce geothermal energy, it will be necessary to create a series of works outside the buildings to be protected that intercept the vibrations and dampen them before they reach their final objectives.

The works will mainly consist of a double row of vertical poles placed side by side made of ferrous and plastic materials which allow the emptying and replacement of part of the surface soil. By taking advantage of the perforations of the works carried out for the attenuation of vibrations, of the vertical poles, it will be possible to lay low-cost closed-circuit geothermal probes in the ground outside the buildings to be heated/cooled using the energy poles. It should be underlined that, since specific tests have not yet been carried out for this new project, even if the tests on energy poles, with which it shares many aspects, have been widely documented (see Delmastro's manual and Savino Basta's publications), the tests Yield GRT of the new coaxial geothermal probes will have to be planned and executed during the first testing phase of the works. Encouraging results, even if only partial, for the damping of vibrations produced by mechanical presses have been successfully obtained with the use of vertical HDPE poles, located outside production warehouses, while the use of energy poles is commonly used for cooling and heating buildings.

Data and maps on natural hazards to support risk mitigation measures

Trigila A.* & Iadanza C.

Keywords: landslides, hazard, Italy.

Landslides and floods represent a very important issue for Italy due to the impacts on population, environment, cultural heritage, communication infrastructures and economic activities. Over 622,000 landslides (2/3 of those in Europe) have been mapped in the Italian Landslide Inventory by the Italian Institute for Environmental Protection and Research (ISPRA) together with the Regions and Autonomous Provinces. 28% of Italian landslides are rapid phenomena, such as rock falls or debris flows, characterized by high rate of movement, up to a few meters per second, often with serious consequences in terms of loss of human lives. Every year a few thousand of landslides occur on the national territory and a few hundred of main events cause dead, injured, evacuated people and damage to buildings, cultural heritage, and primary transportation infrastructures. In addition to a territory naturally prone to instability, the urban growth that has occurred in Italy since the Second World War, often in the absence of correct territorial planning, has led to a considerable increase in the elements exposed to risk (artificial surfaces have gone from 2.7% in the 1950s to 7.1% in 2022). Moreover, Italy is located in the so-called "Mediterranean hot spot", an area identified as particularly vulnerable to climate change, which is causing an increase in the frequency of intense rainfall, and therefore of extremely rapid debris flows. The increase in temperature in high altitude areas is causing permafrost degradation, with a consequent increase in slope instability phenomena in the Alpine area.

ISPRA develops the National mosaics of landslide and flood hazard maps and risk indicators which constitute key information to support risk mitigation strategies at national, regional, and local scales, management of civil protection emergencies, design of civil infrastructures, and environmental impact assessment. Data and maps can also be useful for sustainable finance and for assessment and management of financial risk of climate-related hazards and natural disasters.

In 2021, ISPRA estimated that 20% of the Italian territory was classified as landslide hazard zones, of which 8.7% in high and very high classes. 1.3 million inhabitants, almost 548,000 families, over 565,000 buildings (3.9% of the total), 84,000 industries and services, and 12,500 cultural heritage were exposed to landslide risk in Italy (Trigila et al., 2021).

Data and maps are published on the national IdroGEO web platform (Iadanza et al, 2021), an easy-to-use, multilingual, multi-device, open access and open source web application. IdroGEO, which is currently being upgraded in the framework of Geosciences Research Infrastructure funded by Next Generation EU, allows to view, query, download and share information, providing services to Public Administrations, companies, professionals, and citizens. It contributes to increase citizens' awareness of the risks affecting their territory.

Beyond fault scarps: the role of geologists in the assessment of seismic hazard and risk

Valensise G.*

Istituto Nazionale di Geofisica e Vulcanologia, Roma.

Corresponding author email: gianluca.valensise@ingv.it

Keywords: earthquakes, seismic hazard.

Geologists are the "historians of the planet", as they investigate its evolution and preserve the memory of past natural events. But earthquakes are sudden and instantaneous occurrences: how can geologists contribute effectively to the assessment of seismic hazard?

Geology is governed by basic laws, such as Lyell's motto "The Present is the key to the Past", from his Principles of Geology (1830); combining it with David Hume's principle (1777) "...all inferences from experience suppose... that the future will resemble the past..." allows us to state also that "The Past is the key to the Future".

Geologists know that an earthquake is just a snapshot documenting how and how fast tectonic deformation adds up over time. They do not and should not guess what the Earth may do in the future, but simply learn from earthquakes and project it in the future, to make the planet safer for everyone.

Earthquake Geology is a youthful discipline, especially in Italy. Nevertheless, in less than 40 years geologists have overturned and profoundly innovated the understanding of Italy's active tectonics, active faulting and seismogenic processes. It was not an easy task: the complexity of the recent tectonic evolution of the Italian peninsula is almost legendary, mostly due to the superposition of the effects of subsequent tectonic regimes, and specifically to the youthfulness of the regime that is responsible for the largest earthquakes.

Other geologists have further developed the methodologies used for seismic microzonation, thus contributing to assess more precisely the hazard posed by the identified seismogenic sources.

Italian geologists have learned how to interact profitably with instrumental seismologists, historical seismologists and geodesists, filling in effectively the inevitable gaps among these rather distant disciplinary fields.

Thanks to the manifold contributions of geologists, Italy is currently the most advanced European country in the assessment of seismic hazard, and one of the most advanced in the world. Our community may be proud of this accomplishment, that rightly honours the memory of the fathers of Italian geology.

It has been long known that local conditions are often responsible for earthquake-induced damage exacerbation. These observations, came out of both to recent and historical seismic events, stress out the need to implement an effective urban planning and optimize the territory use in relation to local amplification and the co-seismic effects. In this respect, the Seismic Microzonation (SM) represents a fundamental tool for assessment and mitigation of the seismic risk in urban areas and cultural heritage sites. SM identifies and maps zones characterized by homogeneous seismic behavior (Level1), but above all, besides to give information on susceptibility to main ground instability (soil liquefaction, landslides, fault ruptures), associates a synthetic quantitative parameter representative of the ground shaking intensity to each one (Level 2/3). To this end, 1D or 2D numerical analyses of local seismic response represent a key point to realize an adequate Level 3 seismic microzonation study. In particular, the 2D response analysis is mandatory for complex geometries surficial or buried morphologies (e.g. alluvial valleys, sedimentary basins; elongated reliefs).

The equivalent linear 2D finite element QUAD4M code represent one of the most used computer tools for site response analysis (Hudson et al., 1994). The program operates in the time domain and incorporates a compliant base. The code has been compiled in Fortran language and can be run under Microsoft Windows or DOS starting from input text files. No graphical interface is available from the developers of the code. In this contribution we present P4Quad a pre- and post-processor to help QUAD4M users in setting up the input files and elaborate the numerical results. In particular, the pre-processor allows the creation of the mesh using triangular finite elements starting from a sketch of the subsoil model, the input of geotechnical parameters for all layers and bedrock, the loading of input accelerograms by a simple graphical interface. Moreover, a library of several literature nonlinear curves (i.e. normalized stiffness modulus and damping curves) is provided to the users. The input text files to be run with QUAD4M executable file (not provided with P4QUAD) is finally produced. The post-processor loads the text output files produced by QUAD4M allowing the processing of the results in terms of most relevant ground motion parameters: acceleration time histories and response spectra at selected nodes, peak ground and maximum shear strain distribution at selected profiles, amplification factor, spectral acceleration and spectral amplification contouring at the surface of the model. The P4Quad code can be downloaded together with an user's manual from the web site of the Center for Seismic Microzonation - CentroMS (https://www.centromicrozonazionesismica.it/it/strumenti/software/) and the license for research, educational and academic use can be requested for free at the CentroMS mail address.

Keywords: dynamic properties, soils, laboratory tests.

In seismic risk assessment procedures, the vulnerability factor plays a remarkable role and involves comprehensive evaluations of the Local Seismic Response. The last one relies on an adequate knowledge of the soil geotechnical properties, especially the stress-strain relationships under dynamic and cyclic loading, to be determined through specific field and laboratory investigations and tests. Within the framework of the Seismic Microzonation studies of Italy, the third level of investigation is applied to stable areas susceptible to local amplification, *i)* in cases of complex geological and geotechnical conditions that cannot be solved using abaci, *ii)* for significant structural projects requiring special calculations, or *iii)* for areas prone to particularly severe instability, not resolvable through simplified methods.

For the third-level Seismic Microzonation studies currently on-going in the Apulia Region, combined resonant column and cyclic torsional shear tests were carried out to derive the normalized shear modulus (G/G0) and damping ratio (D) curves as a function of the shear strain level for the involved soils.

The main objective was to establish empirical reference trends in the analysis of the Local Seismic Response for the tested soils, as well as for those having similar physical characteristics, but that are difficult to sample, or for which undisturbed specimens cannot be easily obtained. Among the physical parameters, Plasticity Index and OCR were used for soils with a predominant silty-clayey component, while grain-size distribution, relative density, and lithostatic stress were considered for those with a predominant sandy-gravelly fraction. Lastly, a comparison was made between the experimental curves and those found in the literature for similar materials, aimed at defining reference models of the soil dynamic behavior based on the basic physical properties.

From top to bottom: characterizing the strategic site of Palazzo Valentini (Rome)

Keywords: local seismic response, Palazzo Valentini, strategic building.

The historical Palace Valentini, built in the first half of the 18th century, is located in the centre of Rome, besides the Trajan Column. Consistently with the millenary history of the Eternal City, the Imperial Fora area underwent many transformations over the centuries (Clementi, 1978). In 113 A.D., the Emperor Trajan entrusted the architect Apollodorus of Damascus with the construction of his own Forum, excavating the saddle between the Quirinal and Capitol Hills. In the Middle Age, the area became a marshland fed by the runoff of the Quirino Valley (the present-day Via Nazionale). In the late 16th century, the Cardinal Michele Bonelli, great-nephew of Pope Pius V, ordered the reclamation of the so-called "Pantano" (swamp) area; hence, the architect and Dominican friar Domenico Paganelli designed a new palace, completed in 1585 over the remnants of the Deified Trajan temple, and later renovated and expanded in 17th century. With the decline of the Bonelli family, it changed owner, passing to the cardinal Giuseppe Spinelli, and then to Vincenzo Valentini, banker and politician, husband of Luciano Bonaparte's daughter. Following the annexation of Rome to the Kingdom of Italy, the Provincial Deputation of Rome bought the Palace in 1873. Nowadays, it hosts the Metropolitan City of Rome Capital (CMRC) and the Prefecture of Rome. Therefore, besides its historical, artistic and architectural value, the building has a strategic importance for emergency management as well, being the venue of the "Centre for the Coordination of Rescue" in case of relevant disaster, according to Italian seismic and civil protection legislation.

Considering its strategic purposes, we investigated and verified the stability of Palazzo Valentini, considering aboveground structures, underground spaces and foundation soil.

In the framework of an agreement of cooperation between CMRC and the National Department of Civil Protection (DPC), a permanent system of instrumental monitoring has been installed in 2020, including the building in the national Seismic Observatory of Structures (OSS). Concurrently, vibration measurements on each floor were performed, as a first step towards the application of the SMAV methodology (Spina *et alii*, 2019). In addition, a permanent station of the National Accelerometric Network (RAN), managed by DPC, is installed in the archaeological spaces of basement. Conversely, as part of the agreement between CMRC and the National Institute of Geophysics and Volcanology (INGV), a detailed Local Seismic Response study of the substrate was performed, considering available subsurface data. Ambient noise measurements at single stations were made as well, to investigate the fundamental resonance frequency.

The "top to bottom" characterization of the strategic site of Palazzo Valentini allowed thus the identification of its dynamical properties and the observation of the building/subsoil complex behavior over time.

The Italian seismic code (NTC18) provides indications about the expected effects of some morphological configurations on the expected ground motion during earthquakes. In particular, two main 2D morphologies are identified as reference: cliffs and crests. Based on numerical simulations, the value of St is assumed to depend on the steepness of the cliffs and aspect ratio of the crest. A critical aspect of these estimates is that the considered configurations are defined in terms of steepness angles and aspect ratios, without any scale indication. Moreover, the considered morphologies are very schematic, and this prevents their simple application in the natural context: in most case an expert judgement is necessary, and this makes the final estimates potentially controversial and difficult to validate on the basis of empirical observations. To face this problem, in the frame of the PRIN project "SERENA", a procedure has been developed for the automatic identification of areas prone to morphological amplification effects by following NTC18 prescriptions, based on the Digital Terrain Model. The proposed approach allows the full exploitation of topographical data at the maximum resolution available. After a first application to restricted areas, the proposed procedure has been applied at National scale at the seismometric and accelerometric sites managed by INGV. The aim is twofold: first comparing outcomes of the new approach with the ones proposed by other Authors at the same sites, second to provide a sound basis of a coherent and reproducible estimate of St values to be compared with possible empirical evidence. In the presentation, the results obtained about the first aim will be presented and discussed.

Multirisk analysis of the city of Naples (Italy) using the Rock Engineering Systems (RES) method

Bausilio G., Tufano R.*, Calcaterra D., Guerriero L. & Di Martire D.

Dipartimento di Scienze della Terra, dell'Ambiente e delle Risorse, Università di Napoli "Federico II".

Corresponding author email: rita.tufano@unina.it

Keywords: RES, MaxEnt algorithm, multihazard and damage maps.

Cities can be defined as an "*agglomeration of people and economic activities*" (Scott & Storper, 2015). As such, they tend to grow and expand despite the constant presence of negatively impactful events throughout history. Their expansion can be a source of safety problems when it includes areas affected by geohazards. The city of Naples (Italy), located between the Somma-Vesuvius and the Phlegraean Fields volcanic districts, is an example of a city impacted by geohazards (Totaro et al., 2020). Volcanic hazard, earthquakes (caused by either the activity of the Phlegrean Fields or by tectonic processes related to the Apennines), landslides, and sinkholes also affect the urban fabric. A multirisk analysis of the city of Naples has been conducted using the Rock Engineering Systems (Hudson, 1992) methodology. As a first step, the Maximum Entropy (MaxEnt) (Phillips & Dudìk, 2008) algorithm was employed to obtain landslide, sinkhole and flood susceptibility maps, implementing two techniques to increase the performance of the algorithm: i) the K-Fold Cross-validation and the ii) Variance Inflation Factor (VIF). The sinkhole and the landslide inventories were obtained from literature data. The Susceptibility maps obtained showed satisfying performances (ROC/AUC score above 0,85). The Susceptibility (Relative Hazard) was used instead of the Hazard, as two out of three inventories did not contain exhaustive temporal data. The Multihazard was evaluated using the Rock Engineering Systems (RES) method. The Multihazard was set as the system of the Interaction Matrix, using the Relative Hazard maps as parameters. The Interaction Matrix was then compiled by attributing the (i) cause scores (C - impact of one parameter over the other ones) and (ii) effect scores (E - impact of the other parameters against the analyzed one). In the following step, the interactivity of all the parameters was evaluated as the percentage ratio of C+E for the parameter against the sum of all the parameters' scores (ΣC+E). The Vulnerability evaluation, due to the heavily complex and heterogeneous territory, is a challenging task. As a precautionary measure, the Vulnerability has been set as the maximum (1) to the entire area, making the Damage map equal to the Elements at Risk map. The latter includes various layers such as i) population density, ii) railroad network, iii) road network, iv) natural reserve areas, and v) buildings. The product between the Interactivity Map (Multihazard) and the Damage Map is the Multirisk map. The results obtained are adequate to expectations, although a specific validation process is difficult to perform, due to the heuristic nature of the RES. In the future, the integration of further geohazards which have a recognized influence on other parameters would allow a more detailed definition of the Multirisk system in an urban context.

Keywords: post-disaster management, modelling, ecosystem services, landscape and urban planning.

The impacts of not-climate related hazards such as landslides, tsunami, volcanic activities and earthquakes determine towns reshaping and planning, thus the post disaster management must be handled under sustainable urban development framework following the 'build back better' and 'greener' approach (Mabon, 2019). Considering that earthquakes are not only a natural phenomenon, but also a cultural one, the natural component represents a chance to highlight fragile relationships among communities and the landscape (Albarello, 2011). Italian risk management policies based on public emergency actions are driven by economic compensation and physical rehabilitation, ignoring a strategic planning and prevention vision (Galderisi et al., 2020). This approach neglects socioeconomic, environmental, and cultural spheres. During the early recovery phase post-disaster temporary settlements usually change the urban morphology (e.g., sprawl when new settlements are built at the urban peripheries, but also densification when new settlements occupy urban voids and open spaces within the existing urban matrix), generally lacking social integration (e.g., people displacement, and job loss), while causing soil consumption (i.e., habitat fragmentation and biodiversity loss as well as reduction of urban green spaces). This means having a multiplicity of small post-event territorial interventions, without a systemic and organic approach. Such interventions exploit many resources for the construction and preparation of the temporary urban reconstruction areas. Eventually, these areas often have been integrated within urban planning tools, as a new building zone while changing the previous land use mostly irreversibly.Therefore, the early recovery phase constitutes the crucial moment in which the progress of recovery begins and when it is possible to intervene with actions to change the current trend of post-earthquake reconstruction.

In this work we aim at evaluating the opportunities, advantages and limitations related to the implementation of Nature-based Solutions (NbS) (UNEA, 2022) during the early recovery phase and at developing a multidisciplinary approach to identify the areas for temporary settlements. For this reason, we developed an environmental accounting model based on the integrated use of spatial analysis tools such as i-Tree canopy and industrial ecology tools such as life cycle analysis (LCA). The modelling endpoint is to determine environmental cost-benefit profiles for the post-disaster early recovery interventions. Considering past seismic events in Italy, it is possible to investigate ex-post land use change impacts on a range of ecosystem services (i-Tree modelling framework) and simulate ex-ante NbS-based scenarios (LCA analysis) in comparison with business-as usual practices. In other terms this approach can constitute a decision-supporting tool also in other contexts vulnerable to earthquake risks as well as other calamities.

Keywords: geogenic radon, gamma-ray spectrometry, logistic regression.

Radon is a geogenic radioactive gas originating from the decay of uranium contained in rocks and soils. When it accumulates indoors, it can reach dangerous concentrations to human health. Since extensive monitoring over wide regions is often impracticable and radon measurements in dwellings are generally irregularly distributed, mapping potential high-hazard areas is troublesome. In this paper, we investigated whether the lithological features and in particular the uranium content can be used as a proxy of indoor ^{222}Rn levels. Our study combined various techniques: uranium content measurements on outcrops by using gamma-ray spectrometry, soil radon concentration analyses with an ion-chamber meter and direct assessment of indoor radon concentration with alpha-track detectors (CR-39). The study was conducted in Liguria (northern Italy), an area geologically belonging to the western Alps and characterised by considerable lithological variability. Gamma-radiation measurements revealed that metamorphic rocks, particularly acid lithotypes, have the highest uranium concentration (up to 7 ppm). Metasedimentary rocks, like quartz and mica schists, also showed elevated uranium levels (about 5 ppm) compared to sedimentary rocks (3 ppm). Alpha-track detectors showed that nearly half of the surveyed buildings exceeded the indoor radon reference threshold of 200 Bq/ m^3. The radon concentration in soils was investigated at a depth of 50-80 cm, i.e. where radon gas is expected to diffuse from the soil into buildings. The highest radon concentrations (from 40 to more than 400 kBq/ m^3) occurred in soils derived from acid lithotypes, i.e. gneiss and metarhyolites. Metasediment soils exhibited radon concentrations of 20-40 kBq/m^3, whereas soils formed from sediments are characterised by less than 20 kBq/m^3. The lowest concentrations (< 10 kBq/m^3) were typical of metaophiolitic soils. In addition, high radon values (from 40 to 100 kBq/m^3) were recorded near faults and tectonic contacts. Although a significant number of data was collected, the uneven distribution of the radon measurement sites made it difficult the detailed mapping of potentially high-concentration areas. To overcome this problem, a machine learning algorithm was applied to predict the probability of exceeding the attention threshold of indoor radon based on lithology. In the study area, a background uranium content of 3 ppm implies a 50% probability of exceeding the attention threshold. The probability increases to 85% for an increase of U concentration of 1 ppm. Further logistic regression pairing U concentration measured in buildings with indoor radon pointed to no influence of the building fabric in controlling the indoor radon. Therefore, a significant relationship between indoor radon concentration and rock uranium content is confirmed and geological data can be effectively utilized to identify high-risk areas of radon exposure.

Update of the Level 2 Seismic Microzonation in Umbria Region: methodology and perspectives

Keywords: level 2 seismic microzonation, Umbria, amplification factors, seismic risk.

The quantitative assessment of the stratigraphic amplification of seismic motion at the site is an essential element for seismic risk reduction and mitigation. The distribution of amplification factors (AFs) over the territory is represented in Seismic Microzonation Maps as foreseen by Level (or Grade) 2 of Seismic Microzonation (SM) according to Guidelines and technical standards. In the Umbria Region, the Level 2 SM studies, carried out until now, present calculated AFs only for some localities. A cartographic updating project was started up to know the AFs of all ISTAT localities over the entire territory of 53 selected municipalities, to guarantee effective planning for reduction of seismic risk. A multidisciplinary working group, composed of geologists, numerical modelers, cartographers, and database reviewers from CNR (IGAG and IGG), University of Siena, and the Geological Section of Umbria Region, worked in synergy and continuous exchange to revise the Level 2 SM studies. The workflow began with the analysis and interpretation of available geognostic, geophysical, and geotechnical data, analyzed to identify representative parameters of each geological-technical (GT) unit. Then, the geophysical and mechanical parameterization of the stratigraphic columns necessary for the Afs calculation was carried out, with each column considered representative of a MOPS: Homogeneous Microzone in Seismic Perspective. These data were used by numerical modelers to calculate the AF for each MOPS. AFs were calculated through numerical simulations adopting a linear-equivalent approach using the NC92Soil software (Acunzo et al., 2024). Damping and decay curves of the shear modulus taken from the available scientific literature (Gaudiosi et al., 2023) were associated with each GT unit composing the stratigraphic columns. Following this phase, the team of cartographers and database reviewers proceeded to update the database and cartographies following the current technical standards (Technical Committee MS 3907, 2020). The activity used the MzS Tools plugin, created for the cartography and data management of SM studies (Cosentino et al., 2018).

The workflow adopted revealed several critical issues following the processing of a test sample of studies:

- previous studies following obsolete standards led to the absence of some information or the presence of obsolete codes.
- the discrepancy between the past information and that derived from the updating studies: this necessitated a global revision of the study taking into account the new elaborations.

The work carried out allowed an improvement of the MS study in terms of coherence and understanding of the territory and cartographic production: spatial coverage of the study, updating to recent standards of archiving and cartographic representation and uniformity of products and graphic rendering.

Keywords: landslide, SAR, geophysics.

The geomorphological fragility of territories along the entire Italian Apennine range stems from stems from various factors including lithology, relief morphology, neotectonics, seismicity, climate, and vegetation. The gradual abandonment of lands surrounding small towns and villages in this area, along with other factors such as inadequate urban planning and construction, improper management of water and wastewater, and insufficient measures against landslides, has worsened soil erosion and increased the frequency of landslide events. These areas, abundant throughout Italy, where the primary concern is not uncontrolled urban growth but rather unchecked urban decline, serve as laboratories for experimenting with and refining methodologies for studying natural processes that lead to increased risk in urban settings.

Here, we present the results of a methodology for studying hydrogeological instability phenomena based on the use of remote sensing, both satellite-based and ground-based, as well as in-situ geophysical techniques. The study aims to provide valuable information for assessing residual landslide risk to facilitate planning and implementation of risk mitigation actions. The investigation focused on the urban area of a small town located in the low mountain region (~800 m a.s.l.) of the Basilicata region in southern Italy. In the municipality of Gorgoglione, which has approximately one thousand inhabitants, a state of emergency was declared, evacuation orders were issued, and, when necessary, demolition orders were issued for buildings used for residential and/or commercial purposes. The assessment of the instability phenomenon's activity was supported by interferometric techniques using SAR data acquired from satellite and ground-based platforms. The reconstruction of the geological and lithostratigraphic setting of the subsurface was achieved by integrating geological and geomorphological knowledge of the area with geophysical discontinuities, electrical and mechanical, derived from the use of electrical resistivity tomography (ERT) and horizontal-to-vertical spectral ratio (HVSR) analysis performed on single-station recordings of ambient seismic noise. Given the pronounced directional characteristics revealed by the HVSR analysis, efforts are underway to understand whether this can be related to the direction of landslide movement highlighted by SAR interferometry.

Accelerogram selection for site response modelling in seismic microzonation

Keywords: site response modelling, seismic input, spectrum-compatibility.

Seismic microzonation studies of Level 3 involve in-depth analysis in order to define the characteristics of the local seismic response through numerical simulations.

A critical stage in such a procedure is the definition of the seismic input, a set of accelerograms representative of the ground motion locally expected at the bedrock for seismic scenarios most contributing to the local seismic hazard. However, in strong motion databases there may be insufficient availability of recordings that, for certain scenarios, satisfy spectrum-compatibility requirements. A new approach is proposed to solve this problem by integrating 4 real accelerograms with 3 simulated ones, calculated with the non-stationary stochastic procedure proposed by Sabetta et al. (2021). The simulated accelerograms are selected among a large number of them, stochastically generated for relevant seismic scenarios.

The new procedure is organized into different steps. First, the spectral parameters of the local design spectrum used as reference are defined according to the local building code provisions (for Italy, cf. Ministero delle Infrastrutture e dei Trasporti, 2018). Then, a seismic hazard disaggregation analysis provides the earthquake parameters (magnitude, source distance and style of fault) of a number of seismic scenarios most contributing to the basic seismic hazard: for such scenarios, real accelerograms are extracted from available accelerometric databases. The final seismic input is provided by a code that optimizes the selection of 4 accelerograms, among the real ones extracted, and 3 simulated accelerograms, among a large number of them obtained for all the previously identified scenarios, so to best fit the design spectrum. This allows to cover relevant scenarios not represented by the real recordings and to improve the median spectrum compatibility of the total set of accelerograms.

The procedure has been applied to the 84 Apulian municipalities involved in seismic microzonation studies. For each seismic input, the spectrum-compatibility has been verified, with special reference to the tolerance limits prescribed by the Italian Building Code, which admits deviations only between -10% and +30% from the design spectrum.

The compliance with such rules was checked on the mean response spectrum of the accelerogram set. This was first regularized so to conform to the standard spectral shape required by the Code, according to the procedure recommended by national technical bodies (cf. Commissione Tecnica per la Microzonazione Sismica, 2022).

The effectiveness of the seismic inputs so obtained was finally tested through 1D modelling of the local seismic response in a variety of geological and seismo-tectonic contexts, carried out by the code STRATA (Kottke et al., 2013). In such modelling, set of accelerograms provided by this new procedure and by the tools currently in use for this purpose were comparatively adopted.

Keywords: seismic microzonation, site response analysis, map of amplification factors.

The amplification of ground motion during earthquakes is widely recognized to be caused by the interference of seismic waves trapped between the free surface and impedance contrasts in the shallow subsoil. Seismic Microzonation (SM) studies focus on assessing these site effects, but applying them in large contexts can be hard and costly. To estimate seismic site effects at a regional scale, the most practical approach is to utilize detailed geological and geomorphological data (scales of 1:10,000 to 1:50,000), which are widely available for large parts of Italy. As part of the national research project "SERENA," this study introduces and tests a procedure aimed at quantifying 1D seismostratigraphic ground motion amplification using geological information. Specifically, amplification factors are estimated for different Seismically Homogeneous Microzones (SHM) defined according to the information contained in the geological map. Each SHM is represented as a stack of flat, homogeneous layers, with each layer characterized by engineering-geological units according to the SM standards (Commissione Tecnica, 2018; SM Working Group, 2015). The seismic properties of each layer (Vs, density, damping, and G/G0 curves) along with their respective ranges of variability, are determined based on the most recent literature (Romagnoli et al., 2022; Gaudiosi et al., 2023).

To take account of the uncertainties which affect the construction of the SHMs, 100 random profiles were created for each SHM based on the variability of the parameters just mentioned. The relative expected seismic response at each profile is computed considering the Inverse Random Vibration Theory (Kottke and Rathje, 2008) and a linear-equivalent approach. In this way, distributions of the three amplification factors were obtained for each SHM. This methodological approach has been applied to the Tuscany, Marche, and Umbria Regions, which boast detailed geological maps covering their entire territories. In this process, tens of thousands of SHM were initially identified using dedicated ArcGIS Pro™/ArcPy™ scripts, and then analyzed as described above to obtain the seismic response in terms of amplification factors (AFESM). The 50th percentile of the AFESM distribution for each SHM was assigned to the corresponding outcropping formation, aiming to generate a new map of amplification factors for the study areas with an optimal spatial resolution. To evaluate the reliability of the results obtained from numerical simulations, the outcomes (AFESM) were compared with those provided by detailed SM studies (2° and 3° levels) available in the three study regions. This comparison aimed to validate and verify the accuracy of the amplification factor maps. This analysis revealed significant differences in the AFESM based on the geological composition and surface conditions of the SHMs. Moreover, despite the extensive nature of the actual approach, it proves to led to unbiased estimation of the amplification factors. It is important to emphasize that the proposed approach should not be viewed as a replacement for detailed local studies. However, it can be valuable for conducting preliminary evaluations and serving as a reference for large-scale risk analysis.

Keywords: seismic microzonation, numerical analysis, geotechnical model.

Relevant site effects related to impedance contrast can be expected in basins filled by a thick sequence of soft sediments above a stiff pre-Quaternary carbonate bedrock such as in the intermontane basins of the Italian Apennines.

We investigate the Sulmona basin, a tectonic depression elongated for ~22 km in the NW-SE direction and up to 5-7 km wide, in the Abruzzi's Central Appennines. The origin of the basin is due to the Quaternary activity of the Mt. Morrone normal fault which dips to the southwest limiting the NE edge of the basin, able to produce Mw 6.5-6.7 earthquakes.

The basin infill of such a half-graben shows a typical triangular geometry thickening toward the Mt. Morrone fault plane, where the fluvial-lacustrine sequence should reach up to 500-600 m of thickness (Miccadei et al., 1999). However, the entire sequence has never been observed in either an outcrop or in a borehole.

The detected unfavorable local site effects condition that emerged from level 1 of Seismic Microzonation determines a high seismic hazard level for the city of Sulmona and neighboring villages. The present work focuses on the geotechnical characterization of lacustrine soils cored and sampled hundreds of meters deep. The shear wave velocity profile and the cyclic nonlinear properties in the lacustrine sediments have been determined.

A stiffness-depth relation from cyclic laboratory tests is derived and calibrated with available in-hole tests. Results have been integrated with VS profiles from 2D seismic arrays that constrained the whole thickness of fluvio-lacustrine sediments. A validation of the Vs profile has been finally realized by comparing computed resonance frequencies with experimental values derived from HVSR analyses on microtremor measurements.

We present a geological cross-section, selected to investigate the seismic response through 2D numerical analysis in the 3rd level of the seismic microzonation study, as a representative geotechnical model of the Sulmona city center.

Keywords: Python, stratigraphies, amplification factors.

In the frame of the PRIN project "Mapping seismic site effects at regional and national scale – SERENA", we have developed a collection of both standalone and QGIS-based Python scripts for the identification and spatialization of stratigraphies starting from outcropping geological units. Our aim is to divide a given territory into stratigraphically homogeneous areas defined by a representative stratigraphic column, needed to model and spatialize the seismic amplification factor (AF).

Several criteria for the reconstruction of the columns are available, allowing scripts to operate from a fully-unsupervised to a semi-supervised mode. This latter provides user with greater control over the results, allowing the progressive check of the reconstructing stratigraphic column by working on vector cartographic bases in a GIS environment. Our scripts process an input raster geological map in a pixel-wise fashion, identifying the lateral contacts between the outcropping units, placing them in a stratigraphic order based on a pre-defined geometric position index (Cesarano et al., 2022), and calculating the cumulated thickness. At the same time, this raster-based approach allows for a punctual spatialization of the reconstructed stratigraphies.

The scripts were validated on the 428 km2 wide Territorial Context (TC) of the town of Cariati (Calabria, Italy), where the reconstructed stratigraphic columns are already available (Cesarano et al., 2022). As input, we used the Engineering-Geological Units (EGU) (Technical Commission for Seismic Microzonation, 2020), since they had already been geometrically indexed for the test area (Cesarano et al., 2022). We found that our scripts successfully reproduced, just in a few minutes, the same stratigraphic columns manually obtained by Cesarano et al. (2022), confirming the efficiency of our approaches.

The achievable results, combined with geophysical and geotechnical data, such as the variability of shear wave velocity in relation to EGUs (Romagnoli et al., 2022) and shear modulus reduction and damping ratio curves (Gaudiosi et al., 2022), represent a significant advancement in the analysis of seismic hazards on a wide scale. The detailed and realistic stratigraphies provided for local seismic response analysis greatly contributes to improve the calculation of seismic amplification factors.

Keywords: seismic microzonation, MOPS, database.

Seismic Microzonation (MS, sensu ICMS) has as key element the determination of areas (the so-called "Microzone Omogenee in Prospettiva Sismica**"** or MOPS) within which the expected seismic effects are assumed to be homogeneous. From the geometrical point of view, the MOPS is made up of one or more portions of the morphological surface, also not contiguous with each other, whose seismic-structure stratigraphic makes assume values like the parameters that determine the seismic effects found or expected on the surface. The structure of a MOPS is usually schematized by a succession of horizons characterized by a series of parameters detectable in the countryside (and if necessary, in the laboratory) and by direct and indirect (geophysical) underground investigation techniques. These parameters include: the depth with respect to the p.c. of its upper limit (or lower or its centre of gravity), a thickness, a geological-technical class according to defined standards (the so-called Technical Geological Units or UGT), a mass density, a representative value of the propagation velocity of the S-waves, a decay curve of the shear modulus and one of the damping. Where appropriate, each layer may be assigned a speed value representative of the P-waves from direct measurements or assuming a standard value of the Poisson module. Each MOPS is also characterized by the representative values of the resonance frequencies of the S-waves assuming that the fundamental one (f0) is the lower one in the range 0.5-10 Hz. The MOPS can also be characterized by a value representative of the average speed (harmonic) of the cutting waves in the first 30m from the ground plane and the estimated depth of the water table. The synthesis of the conceptual aspects that define the MOPS and consequently the activity of MS shows how in fact the quantity and the quality of the parameters of MOPS is currently rather articulated and above all has evolved and refined in recent years, due to the consistent commitment expressed by the scientific context (Research Organization) and executive (Regional and Municipal Administrations and Professional Associations) that have been involved in the activities of MS. Despite the effort to homogenize the quality standards adopted over time and in the different areas of MS are rather heterogeneous and especially poorly comparable with each other. If the development of MS activities has led to the availability of a large amount of data related to the MOPS of the municipal territories, the same cannot be said about the actual increase in knowledge about territorial seismicity, based on the comparison of the data constituting the individual MOPS. To overcome this problem, we have created a database that, based on an analysis of the requirements and a subsequent development of a conceptual and logical model, allows as well as a systematization of the detailed knowledge of the individual MOPS, also their comparison and correlation between different areas, so as to allow an effective capitalization of knowledge.

Why should we bother about risk reduction at the urban scale? A methodology to assess the effectiveness of seismic prevention measures on urban system functionality

Fontana C.*, Tomassoni V. & Giuffrè M.

Istituto di Geologia Ambientale e Geoingegneria, CNR.

Corresponding author email: cora.fontana@igag.cnr.it

Keywords: urban risk prevention, post earthquake recovery, urban functionality indicators.

Earthquakes that occurred in Italy in the last 50 years have produced indirect damages of around 108 billion euros (Coviello & Somma, 2021). Despite these numbers, the predominant position in the field of risk management keeps being oriented towards emergency public actions of physical restoration of individual assets, instead of comprehensive urban prevention strategies.

This approach has very high costs, strongly impacting both territorial functionality and local communities: losses, services interruption, population and businesses displacement, socio-cultural disequilibria. So, the role of speed in the recovery process is crucial, because it can affect whether community members decide to stay and rebuild or leave a community for good (Arendt & Alesch, 2014).

To accelerate post-quake recovery, disaster risk reduction policies based on prevention strategies are fundamentals. But, they remain a difficult goal, due to high costs implied, long time needed to achieve objectives, and a general lack of a seismic risk culture regarding both the civil society and the political leadership.

A step toward this direction has been made by the Italian government, after the 2009 Abruzzo earthquake, issued the National Plan for seismic risk prevention. This represents the first initiative that tries to see prevention issues also from an urban point of view, overcoming the single building perspective.

Urban vulnerability, in fact, depends not only on building features but also on functional systems (Braga et al., 2015). Prevention, therefore, has to be framed in a wider urban vision, aiming at a broader goal, that is maintaining the vital settlement functions (Fiore et al., 2018). But it is evident that to protect the entire settlement is unrealistic. So, the challenge is to identify a minimum core of functions, whose preventive safety measures could avoid, in the event of a quake, the total collapse, reducing urban vulnerability and consequently enabling the recovery to begin. In this paper we hypothesize a system composed by the strategic elements for the emergency management, healthcare facilities, schools and the areas for temporary settlements, called Early Recovery System (ERS). ERS may represent a further step towards the construction of an urban seismic prevention instrument for early recovery. To evaluate its effectiveness, a set of indicators was built to assess urban functionality decrease. The indicators, calculated in different time intervals, were calculated on a pilot case study: the city of L'Aquila, severely affected by the 2009 earthquake. For each progressive scenario of urban safety, two diverse configurations were hypothesized, to demonstrate how the different ways to systemize the ERS elements may have different impacts on the recovery speed. This work aims at demonstrating that looking at seismic prevention from an urban perspective could guide the public actor in the construction of a strategic prevention programme based on common goals of territorial safety.

Modelling site amplification as factor of slope susceptibility to co-seismic failures in hill-top towns

Fredella F.*[1], Del Gaudio V.[1], Wasowski J.[2], Venisti N.[1] & Capone P.[1]

Keywords: co-seismic slope failures, ambient noise analysis, local seismic response.

Seismic Microzonation of hill-top town requires identification of peri-urban slopes that may be affected by co-seismic failures. Therefore, we are developing and testing a procedure for the identification of slopes potentially susceptible to earthquake-induced failure by i) estimating the resistance demand placed by local seismicity on the slopes, ii) comparing it to the actual slope resistance and iii) classifying slopes according to their susceptibility. A step forward in this effort consists in considering the increase of the resistance demand caused by site amplification effects that can occur on slopes, especially where softer slope materials overlie a stiffer substratum. In the first phase of this work, we are incorporating site effects through 1D modelling of the local seismic response. For our tests, we benefit from the large amount of data acquired in the Seismic Microzonation studies ongoing in the Apulian region, especially in the Daunia Mts., which include many hill-top towns characterized by slopes consisting mainly of clay-rich flysch materials susceptible to rainfall-triggered landsliding (Wasowski et al., 2010). It is likely that some moderate magnitude earthquakes that occurred in the surrounding areas could have also caused slope failures, but the direct evidence (e.g., historical records) is limited (Wasowski et al., 2022). In particular, we are using the results of pre-existing borehole and geophysical investigations, collected during the level 1 Seismic Microzonation studies, integrated with purposely conducted geological surveys and ambient noise data analysis. On this basis, simplified geological models of the study areas are first obtained to calculate the local seismic response through 1D modelling, whereas, further insights will be obtained through more advanced numerical modelling (2D and 3D) when more data have been made available from level 3 studies. At this stage, among the investigation techniques used, the analysis of ambient seismic noise recordings plays a special role. These were first analysed through the Nakamura method (Nakamura, 1989) and, then, using the HVIP technique (Del Gaudio, 2017). Indeed, the HVIP technique, measuring the ellipticity of Rayleigh waves isolated within noise recordings, generally provides more stable H/V values, which are better correlated to the local amplification factor. The HVIP technique can thus provide: i) a useful support for modelling site conditions (through the inversion of the ellipticity curves of Rayleigh waves in terms of Vs vertical profiles) and ii) a comparison term for the possible definition of empirical relationships to estimate amplification factors directly from the noise analysis results. Such estimates could be used where ambient noise data are available or can be easily obtained, while data from more costly investigations are lacking or are insufficient to provide a reliable modelling of the local seismic response.

Keywords: seismic microzonation, geological mapping, Gravina di Puglia.

The correct mapping of boundaries between different geological-tecnical units is a fundamental objective for seismic microzonation (SM), but is particularly challenging in urbanized areas, where SM is mainly focused. Indeed, irregularities of the boundary geometries can lead to conditions for local site amplification (cf. Commissione Tecnica MS, 2020; 2021), but they are difficult to reconstruct in built-up areas. Equally important is the evaluation of the age, geometry, kinematics and lateral extent of fault zones affecting the geological-tecnical units. These structures can modify physical-mechanical properties and Jv values of the geological-tecnical units so to lead to a further subdivisions into distinct sub-units. The SM studies carried out for the town of Gravina di Puglia offered site conditions favouring the use of different investigation techniques to analyse the above-mentioned issues. Gravina in Puglia is located on the south-western margin of the Apulian foreland, on the border of the Quaternary Apennine Foredeep. From bottom to top, the geological-technical column characterizing the urbanized area of the town, following the representation standards of Commissione Tecnica MS (2021), consists of: i) LPS and SFLPS, both corresponding to upper Cretaceous Calcare di Altamura, with the latter differentiated for the high Jv values along faults; ii) GRS (Calcarenite di Gravina, Late Pliocene – Early Pleistocene); COS (Argille subappennine, Early Pleistocene). GRS and COS belong to the transgressive succession of the Plio-Pleistocene Apennine foredeep on the Apulia Foreland and are both bounded by a regular surface. These two units rest on LPS (bedded limestones of the Cretaceous calcareous platform) through an important regional unconformity. This is characterized by a buried complex morphology shaped by subaerial erosion and fault steps, from the Late Cretaceous to the Early Pliocene. The analisis of geognostic boreholes in the urbanized area coupled with data from large-scale geological mapping carried out on natural exposures along the Gravina stream allowed to partially reconstruct the geometry of SFLPS. In order to fill this gap, the integrated use of different investigation methodologies was planned including: i) analysis of high quality fotogrammetric models based on the collection of high-resolution drone photos; ii) analysis of fracture distribution, density, and orientation by scan-line and scan-box methods on key exposures; iii) kinematic and geometric analyses on the fault zones and related damage zones; iv) active and passive seismic surveys. The whole dataset will make it possible to categorize the geological-technical units with homogeneous Jv value, whereas the comparison with the results of geophysical investigation should improve our understanding of how fracture distribution (and related Jv value) and geometrical setting of the unconformity can impact on the local seismic effects.

Keywords: social vulnerability, multi-hazard, GIS.

Floods and landslides cause continuous damage to ecosystem, infrastructures and population. Particularly, the occurrence and the existence of different natural hazards in the same territory highlight the need to improve risk mitigation strategies for local authorities and community resilience solutions for inhabitants. Analyzing and mapping social vulnerability provides information about the capacity of a specific community to anticipate, cope with, and recover from a natural event. Specifically, the interaction between multi-hazards and the socio-economic environment suggests multidisciplinary assessments that merge the physical and the socio-economic features of the affected territories providing a useful approach to support risk reduction planning. In this context, the article focuses on integrating landslide and flood hazard scenarios with social vulnerability in Basilicata Region (southern Italy) at census track level. 13 municipalities were chosen as a multi-hazard hot spot, whereas open-source platforms were selected for hazard and social vulnerability data collection. A Geographic Information System (GIS)-based approach was applied to combined different hazard scenarios with social vulnerability distribution among 1331 census tracks to detect the most vulnerable sub-municipality areas that need special attention in multi-risk reduction strategies. The results are presented in form of maps which highlight their relevant use in local emergency planning.

Uncertainties of soil profiles for seismic response analyses

Licata V.*

ISPRA, Roma.

Corresponding author email: valeria.licata@isprambiente.it

Keywords: seismic response analyses, soil profiles, shear wave velocity.

When planning in areas affected by earthquakes, a reliable estimation of the seismic site response should take into consideration all possible sources of uncertainties. Among these, the most relevant highlighted in the scientific literature are: the variability of the input signals; the geometrical configuration of the buried settings; and the constitutive properties of soils in terms of stiffness, damping and strength.

The present work shows some results inferred from seismic site response analyses considering the variability of the stiffness properties profiles and the position of the bedrock in two districts of Naples (Licata et al., 2019).

Specifically, in order to provide a more robust estimation of ground shaking, the analyses were performed on seven soil columns by Monte Carlo method, in one-dimensional (1D) conditions and by adopting the linear-equivalent method.

The selected soil columns are representative of the geo-litological complexes of the study area and the geotechnical models were addressed on the basis of the wide collection of VS data: for each profile the median values of Vs were defined. Moreover, the results of the cyclic torsional shear tests allowed defining the shear modulus decay and the damping curves.

The analyses were performed by propagating twenty accelerograms with different features in terms of duration and peak ground acceleration, PGA. For each soil column, the surface amplification was determined considering the dispersion of the shear wave velocity, VS, profiles, and the variability of the depth of the bedrock by assuming a log-normally distributed random variable.

The results are synthetized in terms of amplification factors, AF, of PGA and Housner Intensity, distinguishing the response due to the weak and the strong motions. The major conclusions highlighted that the distribution of the amplification factors is quite homogenous in the reference area and the uncertainty of VS significantly affects the soil response. Moreover, the effect of bedrock depth is very significant, since ground amplification at high periods increases with its depth.

A new soil constitutive model for nonlinear 1D seismic site response analyses

Licata V.*[1] & Conti R.[2]

[1] ISPRA, Roma. [2] Università di Roma, Tor Vergata.

Corresponding author email: valeria.licata@isprambiente.it

Keywords: seismic site response analysis, constitutive soil model, nonlinearity.

This work presents a simple nonlinear constitutive model to perform one-dimensional (1D) seismic site response analyses considering both nonlinearity and strength parameters of the soils. The main advantage of the proposed model consists in providing a good compromise between an accurate representation of the soil response under cyclic loading, along the whole strain range, and the definition of simple constitutive laws, whose parameters should be easy to calibrate based on standard laboratory and in situ tests.

The 'Modified Hardin-Drnevich' (MHD) model, thoroughly described in Conti et al. (2020), combines the hyperbolic functional form, originally introduced by Hardin & Drnevich (1972) for the backbone, with the unloading-reloading rule suggested by Phillips & Hashash (2009). The key idea of the MHD model consists into using the soil shear strength, τ_{lim}, as a constitutive ingredient both to limit the allowable shear stress and to describe the dependence of the nonlinear soil properties on the effective mean stress, p', and the plasticity index, PI.

The MHD model is completely described by just six parameters: the soil shear strength, τ_{lim}, the initial stiffness, G_0, easily inferred from conventional in situ investigations tests (such as SPT, CPT, VS measurements), and four fitting parameters.

To highlight the accuracy of the MHD model, it was applied to a case study and compared with another nonlinear model. The reference site is located in the Eastern Napoli (Italy) and twenty natural strong earthquakes, selected based on a site specific hazard analysis, were propagated thorough a representative 1D soil profile. The results highlighted that the MHD model provides a better interpretation of the amplification phenomena of the soil deposit and a better estimation the stress state of the deeper soil layers, which are far from reaching failure under the earthquake-induced shear stresses.

Keywords: Po Plain, 3D geological model, geological and geophysical data.

The Po Plain (northern Italy) hosts many urban areas where a large population lives and numerous economic activities and historical and cultural sites are located. Moreover, this area is historically affected by different geological hazards (i.e., seismic, subsidence and flooding hazards) which, in some cases, interfere each other and with human activities. For these reasons it is necessary to implement strategies for safeguarding the population, the economy and the historical and cultural heritage, first of all the evaluation and mitigation of geological hazards and the impact of human activities. This requires an accurate knowledge of the subsurface geology which, in the study area, is made possible by the availability of a large amount of subsurface data acquired for hydrocarbon exploration purposes since the early 1950s (i.e., seismic reflection profiles and wells) and many literature data.

In this work, geological (i.e., stratigraphy information) and geophysical (i.e., Spontaneous Potential, Resistivity, Gamma Ray and sonic logs) public data from 160 deep wells, 61 geological cross-sections and 10 geological maps of the Po Plain and the facing northern Adriatic Sea were collected, georeferenced and digitized. The data of five geological horizons (i.e., from bottom to top, magnetic basement top, carbonate succession top, Pliocene base, the Calabrian base, and base of recent continental deposits) were also interpolated and the related unfaulted surfaces were reconstructed. In this way a simplified 3D geological model of the study area subsoil was reconstructed.

The resulting dataset, consisting of both the digitized geological and geophysical data and the reconstructed geological surfaces, may be used in a wealth of applied and scientific studies, including studies for the assessment and the mitigation of geological hazards and the impact of human activities. Through the elaboration of the digitized logs, for example, it is possible to directly extract or derive mechanical and geophysical properties of the rock volume interposed between the reconstructed surfaces, such as Young's modulus or Poisson ratio, that find applicability in geomechanical simulations aimed at evaluating the ground subsidence/uplift phenomena or the stress field change in a specific area in response to natural processes or anthropic activities, and seismic velocity values, which may be used to improve the earthquake location procedure and to reduce the uncertainties. The reconstructed 3D geological model may also be used as input-model in seismic wave-propagation and ground-motion simulations performed for defining the local seismic response.

This dataset, available in open access format (Livani et al., 2023), can therefore represents a useful tool to define the most effective territorial protection strategies, particularly for urban areas, and to detect areas where further data collection and more detailed studies are needed.

Keywords: seismic active, long period analysis, site effects.

Milan is located in the north-western sector of the Po Plain, a large and deep sedimentary basin between the south-verging thrust system of the Alps and the north-verging thrust system of the Apennines. The paper shows the results of a detailed urban-scale seismo-stratigraphic model for the metropolitan area, in a context where the understanding of the spatial variability and influence of seismic site response of the shallow and deep (~1.5 km) alluvial deposits for the Milan urban area (Massa et al., 2022), is fundamental as a contribution to reducing seismic risk. In this perspective, in 2023, a 1.4 km long high-resolution reflection seismic profile was acquired at Vettabbia Park (south of the city) through a linear spreading of 240 4.5 Hz-geophones and a high-frequency vibratory source (IVI-Minivib). Despite the challenge posed by the urban context (Picozzi et al., 2009) of a metropolis like Milan and its significant noise, the resulting seismic image reveals in detail the stratigraphic setting of the area, showing a good agreement with the previous geological reconstruction based on existing geological data (Villani et al., 2024). Since it is widely recognized that a significant proportion of the variability of earthquake ground motion is related to local geological conditions, the seismic site effect estimation plays a crucial role. In order to determine the Rayleigh-wave dispersion curves from passive array, the data were analysed by the frequency-wavenumber, the modified spatial autocorrelation and the extended spatial autocorrelation methods. The obtained shear-wave velocity profiles, together with other required geotechnical parameters, were used to perform a 1D equivalent-linear hazard analysis at the studied site. Seismic inputs are selected on the basis of compatible combinations with target-spectra derived from the Italian building code. Amplification factors obtained from numerical analyses were suggested as a benchmark for future more advanced analysis, such as 2D/3D non-linear models important to address a site response analysis in a metropolis context.

Natural and anthropogenic sinkhole in Italy: the importance of an interdisciplinary approach

Nisio S.[1], Madonna S.*[2], Ruggiero L.[1] & Gentili F.[2]

[1] Dipartimento del Servizio Geologico d'Italia, ISPRA, Roma. [2] Università della Tuscia, Viterbo.

Corresponding author email: sermad@unitus.it

Keywords: natural sinkhole, antropogenic sinkhole, urban areas.

Understanding the relationship between geology, anthropogenic factors, and sinkhole hazards is crucial for effective risk management and land-use planning. Over the last few decades, the Italian Geological Survey (ISPRA) has analysed collapse phenomena (sinkholes) in Italy, but now, as part of the PNNR project Geosciences-IR (WP.3.2), the previous censuses have been extended and expanded, especially regarding the anthropogenic sinkholes. Because of their thousand-year history, the urban centres of the beautiful Italian art cities have a subsoil rich in cavities, mostly anthropic, but in some cases also natural. These cavities may be subject to sudden collapse, damage to the above buildings and infrastructure, and loss of historical monuments or human lives. There are sometimes extensive tunnels networks and hydraulic structures of archaic and Roman times that extend to peripheral and rural suburbs. The dimensions and purposes of these underground environments are very varied, and to be understood and mapped requires interdisciplinary knowledge from historical and archaeological research to field surveys (Madonna et al., 2023). A wide body of literature connects natural sinkholes to the underlying lithological characteristics, but the relationships between lithology and anthropogenic sinkholes have been little investigate. If we exclude areas where marine units are subject to karst and pseudokarst phenomena, the majority of natural sinkholes developed (sedimentary cover) within alluvial sediments, followed by pyroclastic and volcanoclastic deposits, continental carbonate deposits (travertine and calcareous tufa), and coastal sandy and clay deposits (Nisio et al., 2007). However, Recent studies (Puzzilli et al., 2023) have shown that the natural sinkhole hazard in volcanic deposits is often underestimated. Regarding the anthropogenic sinkhole, this distribution changes completely. The census of the anthropogenic cavities and the related sinkholes is still in the early stage of making representative statistics. However, with extensive layers of volcanic deposits such as Lazio or Campania, pyroclastic deposits become the main units. However, this type of phenomenon generally can affect any widespread lithology with mechanical properties suitable for supporting underground cavities. Each region presents specific challenges that require tailored approaches to mitigate risks associated with natural and anthropogenic sinkholes. Urban areas in Italy also face the risk of anthropogenic sinkholes due to human interventions such as altering natural water paths. These activities can lead to the collapse of subterranean spaces or exacerbate the leakage from subservice networks like sewage and water pipelines. Notably, channelling rivers into underground conduits in cities such as Rome has sometimes led to unexpected and dramatic sinkhole incidents, posing risks to buildings and infrastructure.

Keywords: hazard mapping, geological risks.

Urban areas with historical buildings are susceptible to disasters, which can cause detrimental effects to both humans and the historical structures themselves. In this situation, the risks can be determined by the combination of multiple potential hazards (including those related to climate change), the vulnerability and exposure of historical building users, and the physical characteristics of the environment, such as its morphology, typology, and grade of urbanization.

The coastal area of Rome, located on the eastern Tyrrhenian margin along the Tiber delta, includes the village of Ostia Antica, a significant location encompassing important cultural, environmental, and archaeological sites. However, over the past few decades, the area has experienced considerable urbanization mostly because of its proximity to Rome and the Fiumicino International Airport.

Due to its cultural and natural heritage, the expansion of the urban area and the presence of an international airport, it is crucial to safeguard this area from significant local geological risks, including flooding, subsidence, and hazard due to endogenous gas emissions.

The area is affected by subsidence processes and rates up to 30 mm/yr as highlighted by Synthetic Aperture Radar-interferometry datasets (SAR interferometry). Actual subsidence rates, mainly due to soil compaction, represent a risk to cultural heritage and buildings. The area is also highly susceptible to floods, both Tiber floods and groundwater flood (e.g., floods triggered by intense rainfall and consequent rising of the shallow groundwater level). Furthermore, over the past few years, the occurrence of spontaneous gas explosions during shallow drilling has emerged as a novel hazard for the region; the existence of gas vents that emits at surface high levels of CO_2 (up to 90%) poses a serious risk to human health, especially during construction-related activities.

This study describes a comprehensive multi-hazard risk assessment model for an urban area, aimed at the evaluation of three distinct hazards such as floods, subsidence, and gas release from soil. The relationship between hazard susceptibility and predisposing factors was evaluated by using machine learning algorithms. Then, the maps of single hazards were summed obtaining the map of the complete multi-hazard assessment. In addition, the model integrated various other factors, including the socioeconomic background.

Places reborn. Two cases of regenerated historic villages in Liguria and Umbria (Italy)

Keywords: abandonment, rebirth, vulnerability, damage, earthquake.

The recovery of historical places affected by collapse and depopulation is explored by focusing on two recovered Italian villages: Colletta di Castelbianco (Liguria) and Postignano, Sellano (Umbria), located in two areas relevant for the development of seismology. These settlements also represent emblematic examples of the redevelopment of ghost towns emptied following significant natural phenomena. In fact, they were initially abandoned and subsequently underwent major restoration interventions that brought them back to life. The analysis of the aspects of material and immaterial regeneration of places underlines the importance of those actions that can trigger virtuous processes in the territory in order to save an important heritage, otherwise destined to be lost.

Geological complexity vs. seismic risk reduction strategies: preliminary results from level III seismic microzonation studies of Etnean municipalities (eastern Sicily, Italy)

Keywords: seismic microzonation, field geological surveys, subsurface model.

The Mt. Etna (eastern Sicily) is an active volcano composed of lavas and volcanoclastic deposits, over a substratum of sedimentary rocks having a complex buried topography. The eastern flank, affected by active and capable faults (FACs), was hit by a Mw4.9 earthquake on 26/12/2018. Starting from 2022, the Regional Department of Civil Protection of Sicily funded a scientific project aimed at: 1) produce new investigation protocols for the study of FACs in active volcanic areas, and 2) apply these new protocols to carry out the third level seismic microzonation studies (SM3) for 23 municipalities. The project is managed by the Centre for Seismic Microzonation and its Applications, consisting of Universities and Research Institutions, including ISPRA which is involved for the SM3 studies in 9 municipalities.

The Etnean territory is peculiar due to lithological-geotechnical aspects, 3D subsurface geometries, and presence of FACs. This is compounded by intense urbanisation, which makes geological surveys and geophysical measurements extremely difficult. In SM3 perspective, these features imply numerous uncertainties in identifying the location of FACs, the depth of the seismic bedrock and the correct assessment of the local seismic response. In order to define a reliable subsurface model for the SM3 purposes within this complex framework, the most suitable approach to be adopted consists of: proper processing of borehole data, very detailed engineering geological surveys, combined with extensive use of various geophysical investigation methods, integrated with each other.

Starting from a critical review of the SM1 studies, at present we carried out detailed field geological surveys, integrated with new geophysical and geotechnical investigations: n. 4 boreholes with downhole tests, 100 microtremors recordings (HVSR), 1 seismic refraction survey (SR), 3 ground probing radar profiles (GPR) and n. 24 surface-wave surveys (MASW).

We present the two case studies of Motta S. Anastasia and Pedara (S and SE of Mt. Etna). In the first, the substratum, made of marly clays covered by sands and gravels, is well exposed but the whole sequences show no remarkable differences in terms of stiffness (i.e. shear-wave velocity values, Vs). In Pedara, a thick, highly variable alternation of lavas and volcanoclastic deposits, shows velocity inversions (Vs ranging from 500-700 m/s to 300-400 m/s). Despite the different geological setting, the HVSR investigations at both locations show very similar frequency-peak values (1 Hz or less) suggesting the presence of a buried impedance contrast at depth greater than 50 m.

The results obtained so far provide evidence that, in active volcanic areas, detailed geological survey integrated with borehole data and multi-method geophysical investigations can be an effective strategy for the characterization of FACs and also to define and/or constrain the subsurface model on which the numerical modelling of the local seismic response is based on.

Exploring the relationship between anthropogenic sinkholes and pluvial flooding in the urban area of Rome: a comprehensive evaluation of multiple hazards

Ruggiero L.*[1], Ciotoli G.[2], Mori F.[2], Varone C.[2], Di Salvo C.[2], Finoia M.G.[1], Annunziatellis A.[1], Moscatelli M.[2] & Nisio S.[1]

[1] Dipartimento per il Servizio Geologico d'Italia, ISPRA.
[2] Istituto di Geologia Ambientale e Geoingegneria, CNR, Monterotondo (RM).

Corresponding author email: livio.ruggiero@isprambiente.it

Keywords: anthropogenic sinkholes, pluvial flooding, Rome.

Anthropogenic sinkholes represent a frequent and significant danger in urban settings. They have the potential to cause significant and unexpected damage to buildings, infrastructure, and humans. Over the past twenty years, Rome, a major city in Italy, has experienced significant ground subsidence events, known as anthropogenic sinkholes. These sinkholes are caused by the collapse of man-made underground cavities created for various purposes throughout the city's extensive history spanning over two thousand years. They can also be triggered by water leaks from hydraulic pipelines (Ciotoli & Nisio, 2023) and by pluvial flooding occurring during extreme storming events in areas characterized by topographic depressions and/or in proximity to the sewer network (Di Salvo et al., 2017).

The susceptibility map to sinkhole probability in the urban area of Rome was created by using machine learning techniques taking into account various layers (i.e., predictors) including geological, geomorphologic, and anthropogenic data. The susceptibility map categorizes the Rome territory into five distinct classes. The pluvial flood hazard (PFH) map results from an easily replicable procedure applied to the city of Rome. It was developed using the spatial density of observed floods occurring between 2004/2007 and recorded by the Civil Protection of Rome municipality (Comune di Roma, Ufficio Extradipartimentale della Protezione Civile, 2008), and ground morphology factors (i.e. depressions, DTM, fill volume). Available data were processed by weighting depressions by flood density, ranking flooded areas by fill depths and combining these grid layers through a sequence of tools in a GIS environment (Di Salvo et al., 2018).

This work aims to classify and analyze the occurrence of natural multi-hazards, specifically pluvial floods and sinkholes, affecting the urban area of Rome. The procedure is based on a robust geological, geomorphological, and hydrogeological analysis performed using data collected and archived for the scope. The susceptibility is calculated based on geo-hydrological and geomorphological factors, as well as the occurrence of flooding and sinkholes. The two maps have been reclassified and combined to obtain a joint visualization of the multi-hazards. The result shows that there is a strong correlation between sinkholes and flooding, which tends to decrease and eventually disappear moving from the city center towards the Rome ring road.

Advancing seismic microzonation: integration of deep learning for high-resolution Vs30 mapping in the Central Italy

Zaragoza Alonzo A.D.* & Zambrano M.

Scuola di Scienze e Tecnologie, Sezione Geologia, Università di Camerino.

Corresponding author email: abel.zaragozaalonzo@unicam.it

Keywords: seismic microzonation, seismic hazard, deep learning.

Seismic hazard assessment in regions prone to significant seismic activity, such as the Umbria-Marche region in Italy, necessitates accurate characterization of local soil conditions. Past seismic events in the area underscore the urgency for improved methodologies in seismic hazard assessment (Vittori et al., 2000; Chiarabba et al., 2009; Chiaraluce et al., 2017). Vs30, representing the distribution of shear waves within the upper 30 meters of the Earth's surface, emerges as a crucial parameter for ground motion prediction.

My research focuses on investigating the role of Vs30 in seismic hazard assessment within the complex geological framework of the Central Italy. Geological units, including carbonate successions, turbiditic siliciclastic deposits, and Plio-Pleistocene sequences (Bucci et al., 2022), contribute to the diverse Vs30 values in these regions.

Access to an extensive dataset from regional seismic microzonation projects facilitates this investigation (https://www.webms.it/). With 15000 shear-wave velocity (Vs) profiles processed to calculate Vs30 values, spatial integration using geographic information systems enhances data interpretation.

Deep Learning and Machine Learning (ML) are employed in this research, correlating Vs30 data with geological units, building upon previous work (Gironelli et al., 2024) and utilizing QGIS for exploration. Concurrently, supervised ML techniques, particularly the Random Forest Regressor, demonstrate promising results but we the use of Deep Neural Networks push the boundary providing better results.

The primary objective is to create high-resolution Vs30 maps tailored to the Central Italy regions, enhancing the accuracy of seismic hazard assessments. This research provides insights into the advancements in investigation methods and product requirements outlined in the Italian Guidelines and Standards for Seismic Microzonation.

Keywords: landslides monitoring,natural risk, San Vito Romano.

In the metropolitan area of Rome, the high occurrence of low intensity, small-sized landsides represents a critical issue, in terms of risk prevention and territorial government. The 2000 km long provincial road network is often affected by rockfall and topples, shallow landslides, roto-translational/earth slides, or less frequently debris flows, depending on local geological and hydro-geomorphological setting. In some cases, construction features of the transport infrastructures represent predisposing factor for localized instabilities. Conversely, deep-seated gravitational slope deformations are rare. Because of the described framework, the Metropolitan City of Rome Capital (CMRC) promoted in recent years, consistently with its institutional duties, technical/ scientifical projects on such topic: landslides susceptibility analyses; landslide inventory and modelling; periodic monitoring; geophysical investigations (Esposito et al., 2021; Rotella et al., 2022; Seitone et al., 2023). In 2021, CMRC and the University of Torino- Department of Earth Sciences signed an agreement of cooperation, focusing on the San Vito Romano complex landslide, in the eastern sector of the metropolitan area, between the Prenestini Mts. and the Aniene River valley. It is the largest feature (surface about 1 km2) in the metropolitan area, affecting the modern part of the San Vito village and a long segment of the provincial road "Empolitana I", and thus monitored since the late '90s by local authorities. The geomorphological evolution of area indicate a strong structural control, due to the proximity to the southern part of the so-called "Olevano- Antrodoco Line". This regional shear zone controlled, during Upper Miocene, the eastward thrusting of calcareous-marl units of the Sabina transitional domain over the flysch of the Frosinone Formation, in turn superimposed on the Latium-Abruzzi carbonate platform units. Consequently, the arenaceous- pelitic hills are the surface expression of a N-S trending fold system, disrupted by tear faults and east verging thrust ramps (Corrado & Parotto, 1995). Morevover, structural setting strongly influences groundwater circulation. In reliance of the results of the pilot project completed in 2023, CMRC, the University of Torino and the Municipality of S. Vito designed and structured a remote monitoring network, consisting of several inclinometric and piezometric sensors installed in boreholes. The network, supported by web-gis, includes minor landslides along the surrounding segments of road network, one of them controlled also by means of an extensimeter. The applied methodology, which represents an absolute innovation in the metropolitan area, will guide further application in other critical sectors, which is hoped will lead to a high technology system of territorial control for risk prediction and prevention.

Keywords: geodetic-topographical monitoring.

Geodetic-topographical monitoring of active geological processes is a fundamental practice mainly used to define their kinematics and dynamics. The monitoring must be calibrated by the analysis of spatio-temporal factors that characterise the rate of deformation. These factors are analysed through a preliminary stratigraphic and structural geology surveys following by geomorphological, hydrological, and geotechnical study. In this work, the research team of the Geodynamic & Geomatic laboratory (University of Catania), after signing an agreement with the municipality of Motta Sant'Anastasia, has designed and implemented a programme of geodetic measurements to monitor the kinematic of a landslide affecting the north-eastern edge of the Motta Sant 'Anastasia urban centre, located in the lower southern slope of Mount Etna (Catania).

The landslide body is formed by chaotic clayey-sandy materials (Servizio Geologico d'Italia, 2010). It develops to the east direction, affecting part of the urban area. The crown of the landslide is delimited by fractures crop out on low walls, asphalt and buildings.

The shallow geological succession is constituted, from the top to the bottom, by thin alluvial deposits and marly-clay. In the marly-clay, the sandy lenses represent preferential paths of infiltration and storage of water. This horizon has been identified as the sliding surface.

To restore the landslide body, consolidation works were carried out from January 1984 and never fully completed.

From May to July 2023, we have monumented a permanent and a discontinuous GNSS networks. The permanent network consists of one station located outside the landslide area; the other two stations are localised close to the crown, one located within and the one outside the landslide. The discontinuous network consists of 11 benchmarks located transversally to the landslide, above the diaphragm created for the consolidation of the landslide, and now partially damaged since reactivation of landslide.

After 25 surveys, the GNSS stations and the points, outside the landslide, shown no significant movements, while the other stations and points shown an eastward movement of about 8 mm per month, associated to the landslide sliding. GNSS data show the dynamics and kinematics of the landslide above and along the 1984 diaphragm which is no longer effective.

Keywords: dry-stone wall, Cinque Terre, stability analysis, hydrological scenarios, terraced slope

In the last decades, the variation in rainfall regimes along with the abandonment of rural areas that affected Cinque Terre's UNESCO World Heritage site (Liguria, Italy) have contributed to a significant degradation of the cultural asset of the area, namely agricultural terraces sustained by dry-stone walls. Indeed, these two factors have played a relevant role in driving landslide and erosion processes, which in turn caused important social and economic damages. In order to better understand mechanisms behind these hydro-geological events and the potential conditions for their initiation, this study presents a stability analysis of terraced slopes that accounts for land-use condition, identified as a key factor for rainfall-induced shallow landslide susceptibility, as well as potential hydrologic scenarios (i.e., combination of initial soil hydrologic conditions and rainfall). Two terraced slope sections located behind the Manarola village and characterized by different land-use (i.e., cultivated and abandoned) and engineering-geologic setting (e.g., different stratigraphy) have been considered for the analysis. Specifically, land-use features have been integrated into a finite elements slope stability analysis implemented into the ADONIS software in the form of soil properties. In this regard, different values of total cohesion, namely resulting from both the effective soil cohesion and the contributions of roots systems, have been considered in the stability analysis according to the following land use settings: (i) cultivated terrace, (ii) abandoned terrace from short-term periods and (iii) abandoned terrace from long-term periods, (iv) absence of root reinforcement. Moreover, hydrologic scenarios in the form of positive pore water pressure have been considered in the stability analysis. In the simulations, the dry-stone wall has been assimilated to a fractured rock mass; namely, the size, arrangement, and mechanical properties of the stone elements and of separating joints, have been taken into account to estimate the slope failure potential through the Mohr-Coulomb criterion. They have been consistently obtained by modelling rainfall scenarios derived by a Gumbel distribution-based statistical modelling of up to 24h cumulative annual maxima derived from the nearest meteorological station of Levanto. Hydrological modelling has been completed through the VS2D code for simulating rainfall infiltration. Soil hydrological monitoring data acquired at the research sites providing potential initial humidity conditions for pore pressure generations have been used. A preliminary model validation has been conducted considering available monitoring data and rainfall data for hydrologic scenarios generation scenarios have been. Significant hydrologic scenarios corresponding to return periods of 100, 300 and 500-years and three different initial soil water content conditions have been considered for the analysis. The results indicate the substantial stability of the selected terraced slope sections in response to rainfall events with return periods of 100, 300 and 500-years and under both different initial hydrological and land use. The first results presented in this study indicated the suitability of the proposed procedure in predicting the stability of terraced slopes in the study area, also providing a basis for evaluating the influence of land-use in slope stability from a physically based point of view. Future improvements of the followed methodology may allow to effectively identify areas require the adoption of adequate risk mitigation strategies.

A combination of deep learning and InSAR techniques for landslide hazard assessment

Di Muro C.*, Calcaterra D., Di Martire D. & Guerriero L.

Dipartimento di Scienze della Terra, dell'Ambiente e delle Risorse, Università di Napoli "Federico II".

Corresponding author email: chiara.dimuro@unina.it

Keywords: InSAR, CNN, LSTM.

Landslides are among the most significant and widespread natural hazards on Earth, which frequently cause victims and huge economic damage. Over time, landslide mapping, susceptibility and hazard assessment have been carried out with physical-numerical methods, but often based on data that cannot be obtained in real time. For this reason, they have been joined in recent decades by methods such as remote sensing and machine learning. These algorithms are a way of quickly tackling problems related to analyzing the spatial distribution of landslides and mitigating their impact on the territory and population. This work contributes to analyze landslide hazard using a combined approach characterized by Differential Interferometry SAR (DInSAR) technique and deep learning algorithms, specifically the integrated model CNN (Convolutional Neural Network) – LSTM (Long Short-Term Memory). The study is conducted at an inter-municipal scale in an area which falls between Umbria and Marche, in Central Italy. This area is affected by several landslides threatening urban settlements and infrastructures, and many of them were triggered by the strong earthquake of magnitude 6.5 with epicentre in Norcia, occurred on 30th October 2016 (Fortunato et al., 2012). The purpose is to assess landslide hazard by analyzing and comparing predisposing factors and cumulative surface deformations, to process spatial and temporal data at the same time and predict future cumulative deformations based on the combination of both. Regarding to spatial data elaboration, predisposing factors such as slope, elevation, aspect, curvature, geology, flow direction, land use, Stream Power Index, Topographic Wetness Index, Normalized Difference Vegetation Index are analyzed with the CNN algorithm. The latter, introduced by LeCun et al. (1998), uses these factors as inputs and considers them separately, creating a multidimensional matrix, in which there are layers that automatically detect landslide susceptibility. On the other hand, as regards temporal data, the analysis refers to the surface cumulative displacements, induced by landslides, which are derived from satellite data and obtained with DInSAR technique. SAR data has been useful for the training of LSTM algorithms (Hochreiter & Schmidhuber, 1997), to model the temporal progression of cumulative ground deformations. They are suitable at storing information for prolonged periods and managing data sets to model cumulative deformations by temporal factor. The integration of the two algorithms allows to grasp the space-time relation existing between predisposing factors and cumulative deformations, to predict future deformations and have a more accurate and complete prediction.

Large-scale landslide mapping based on deep-learning paradigms

Doglioni A.*

Dipartimento di Ingegneria Civile, Ambientale, del Territorio, Edile e di Chimica, Politenico di Bari.

Corresponding author email: angelo.doglioni@poliba.it

Keywords: landslides, deep-learning, large-scale mapping.

Landslides pose significant hazards to communities, infrastructure, and the environment, necessitating accurate mapping and monitoring strategies. Traditional methods of landslide mapping often rely on manual interpretation of remote sensing data, which can be time-consuming and subjective. In recent years, there has been a growing interest in leveraging deep learning techniques for automated landslide mapping at large scales. This work explores the advancements in large-scale deep learning-based mapping of landslides. Deep learning models, particularly convolutional neural networks (CNNs) and recurrent neural networks (RNNs) (Hakim et al., 2022), have demonstrated remarkable capabilities in feature extraction and pattern recognition from various types of remote sensing data, including satellite imagery, LiDAR data, and aerial photography (Azarafza et al., 2021; Ghorbanzadeh et al., 2022). Key components of deep learning-based landslide mapping include data preprocessing, feature extraction, model training, and post-processing. By utilizing large-scale datasets and powerful computing resources, deep learning models can learn complex spatial and spectral patterns associated with landslide-prone areas, leading to more accurate and efficient mapping results (Ngo et al., 2021). Furthermore, the integration of multi-source remote sensing data, such as optical, radar, and topographic data, enhances the robustness and generalization capabilities of deep learning models for landslide mapping across diverse landscapes and environmental conditions. Here the potential of deep learning-based approaches to revolutionize landslide mapping by providing timely and cost-effective solutions for landslide hazard assessment, mitigation, and disaster management on a large scale. Future research directions may focus on improving model interpretability, addressing data scarcity issues in certain regions, and integrating real-time monitoring systems for proactive landslide risk reduction. A proactive policy of management of landslide-prone areas is a key point for their development and preservation. The spatially diffuse availability of medium-high resolution geological, geomorphological and topographic data is boosting the use of artificial intelligence approaches, like deep learners. Deep learners will return a spatial map of points, representing if there is an earthflow or not.

Nutcracker-like masonry bridges deformation and failure due to slow gravitational deformation

Doglioni A.*[1], Di Taranto L.[1], Fiorentino A.[1], Guerricchio A.[2] & Simeone V.[1]

[1] Dipartimento di Ingegneria Civile, Ambientale, del Territorio, Edile e di Chimica, Politecnico di Bari.

Keywords: slow landslides, bridge deformations, nutcracker.

Italy is a geologically young territory still subject to tectonic and orogenic action, originating in a relevant and continuous geomorphological evolution (Guerricchio, 2022). The slow deformation of the slopes with landslide expresses this. These are sometimes seemingly imperceptible but may have severe effects in long-term damage to infrastructures (D'Ambrosio et al., 2023; Doglioni, 2024).

It is the case of the Albiano Magra bridge failure or the famous Lagonegro bridge. These are phenomena that are often overlooked, due to the difficulty of grasping slow deformations often attributed to age. This is true especially for some very old masonry bridges, which can be considered real monuments, or even for bridges made of different materials as in the case of the Lagonegro bridge (Southern Italy). Anyway, very small deformations may be detected by modern technologies allowing us to objectively document and monitor the very slow deformations by satellite images. These images, when appropriately analyzed and elaborated, contribute to understanding the dynamics of territory.

The work presents a series of historic arched bridges deformed by slow movements due to gravitational phenomena which generate compressive deformations of the abutments which can give ogivalization and "nutcracker-like" deformations of the arches (Simeone et al., 2024). A roundup of Italian examples shows how slow gravitational slope deformations can lead to severe problems for bridges. A preliminary investigation on bridge deformation based on satellite techniques is also presented. Some case histories of this kind are here introduced: the12-arches railway bridge of the dismissed Paola-Cosenza railway line; the masonry arch bridges in Basilicata along provincial roads 15 and 5 in the province of Matera and the dismissed railway bridge of Cassano allo Ionio in the province of Cosenza. Finally, it is noteworthy to mention the Albiano-Magra bridge failed in 2020, and the Lagonegro bridge still existing by dismissed since 1952. These are all examples of how slow deformations can affect arch bridges creating the condition for the failure or the final compromise of the bridge.

Keywords: wildfires, landslides, RETURN.

Impacts of wildfires in forest areas can lead to new avalanche-prone slopes with a higher risk of landslides (e.g., shallow landslides, debris flows, rock falls), soil erosion, and water quality problems. The scarce maintenance of vegetated lands can increase the risk that fires may affect areas closer to human settlements, raising both the risks associated with the fire and those linked to landslides. Wildfires constitute one of the most relevant preparatory factors for shallow landslides, that are investigated, among other preparatory processes, in PE3 RETURN. Wildfires are responsible for changes in watersheds' hydrologic and geomorphic response, and they also lead to the denudation of hillslopes and the consequent reduction of the root strength, which mainly contributes to the soil cover stability (Abdollahi et al., 2023). Depending on vegetation resistance and resilience, the effects of the wildfires on the territory can last for years, during which heavy rainfall or earthquakes can more likely trigger shallow landslides. The unpredictability of wildfires phenomena is one of the main challenges in studying their characteristics, as on field measurements of its effects are difficult to collect. Future scenarios linked to the effect of climate change predict that forest fire frequency and severity will likely increase, as will the extreme rainfall events. As both probability of occurrence and magnitude of wildfires can change over time in relation with climate changes, more efforts should be made to deepen knowledge of interacting disturbances and to understand how to mitigate the related risks.

In this work, a multidisciplinary approach to quantify time-dependent scenarios of shallow landslides prepared by wildfires is presented, evaluating the environmental conditions before, during, and after the wildfires occurrences. This allows understanding how wildfires can affect slope stability and how long this effect persists over time as well as how the ground reacts. All these aspects are very important to be defined since they constrain the quantification of how the soil can change in its chemical and physical characteristics as well as in evaluating the heat transfer at different depths below the ground (Chicco et al., 2023). The used approach involves specific in-situ and laboratory geotechnical investigations on surface soil layers to determine the physical, hydraulic, and mechanical interactions between soil, vegetation, and fire, together with back-analysis approaches as well as numerical models aimed at reproducing how wildfires can affect soil depth and slope stability. To calibrate these models, controlled burning, simulating a small-scale fire, was used, allowing the evaluation of the relationship between the combustion of biomass on the ground and the heat transfer in the subsoil, its duration, and the thermophysical characteristics of geological materials within which the heat pulse propagates.

Keywords: landslide modelling, remote sensing, augmented and mixed reality.

In the last two decades the advent of new tools and methods for landslide analysis has completely changed our approach to study such phenomena. Satellite, aerial and terrestrial remote sensing techniques remarkably improved amount and quality of data while the increasing number of numerical codes made the use of numerical simulations more and more common. However, the combination of remote sensing data and numerical simulations is not an easy task, as well as the definition of geotechnical input parameters for these simulations. In this research we aim to shows advantages and limitations of these new survey and analysis tools with a particular focus on the potential risks associated with the use of numerical simulations without proper and rigorous validation/calibration procedures. Different codes will be used and compared at this purpose. Finally, we will introduce the use of new data visualization and management methods through the use augmented and mixed reality.

Landslide susceptibility, vulnerability, and risk assessment based on remote sensing and GIS data models: a case study at the eastern Hindukush Mountain ranges, Pakistan

Keywords: landslides, vulnerability, risk.

Landslides are one of the most devastating and frequently occurring natural hazards worldwide, impacting communities, infrastructure, and the environment. The northern regions of Pakistan are characterized by rugged terrain, high seismicity, and complex tectonics structures, making it highly prone to landslides and debris flow events. The only possible way to mitigate the socio-economic impacts of these natural hazards is to assess and evaluate the zones of future events and highlight the landslide risk areas for further planning and development. However, such assessments are frequently deficient in regions characterized by complexity and scarcity of data. This research study suggests an integrated approach for evaluating landslide zonation, vulnerability, and risk utilizing a variety of freely available geospatial data and semi-quantitative techniques in a highly landslides-prone area in the eastern Hindukush Mountain ranges of Pakistan (Shah et al., 2023). Satellite imagery with high spatial and spectral resolution (Spot-5, Worldview) is employed to depict the distribution of landslides and predisposing factors. A bi-variate statistical model is here used to develop a landslide susceptibility map (Shah et al., 2024). A geospatial database containing element-at-risk data, i.e. building footprints, topological data, road network, population, and land cover is acquired using remote sensing tools and field excursion (Abella & Van Westen, 2007). Subsequently, this dataset is evaluated using multi-criteria decision analysis for vulnerability mapping. These analyses are incorporated using a semi-quantitative approach to generate a risk index map in relative classes from very low to very high-risk zones (Althuwaynee & Pradhan, 2017). The risk index map has a significant impact on future urbanization and development, enabling targeted efforts for mitigation and risk reduction.

Landslides are critical natural hazards that can cause significant impacts in mountainous regions. Their characterization is primarily oriented towards the interpretation of failure mechanisms, controlling factors, and involved volume. To this aim, the combining remote sensing and numerical techniques proved instrumental in investigating the factors controlling the instability evolution. Remote sensing techniques are fundamental tools routinely employed for geological data collection, as well as monitoring slope deformation. Such data can be employed as input or constraint for numerical simulations, to reliably identify the factors and process that control the instability. One of the major challenges is the uncertainty that affects the subsurface configuration of the landslide in terms of material characteristics and morphology of the basal surface. Several methods have been proposed and used to reconstruct the basal surface, which are largely based on geomorphic interpretations or monitoring data processing (Jaboyedoff et al., 2020).

In this work, we present the application of an algorithm that takes advantage of the method of inversion to infer the spatial variations in landslide thickness, based on surface deformation monitoring data. Originally, the technique was developed for the analysis of inland glaciers, before being applied to landslide studies (Booth et al., 2013). We implement significant improvements to the original algorithm, by accelerating the convergence using a faster optimizer and by applying a different criterion for selection of the regularization parameter, which does not require approximations on the noise level. The main advantage compared to earlier versions lies in its improved ability to give an estimate of the depth without imposing extra assumptions in the model. Furthermore, we investigate the role of different regularization functions which incorporate a priori knowledge on the solution.

To evaluate the accuracy of the approach, we first develop a series of conceptual, three-dimensional models, characterized by pre-defined sliding surfaces that are accurately reconstructed by the algorithm using modelled surface deformations as input data. Then, we test the method on selected landslide sites to evaluate the performance of the algorithm in practical applications.

We observe that the algorithms perform well in most conditions, however, some challenges remain to be solved, including the need to constrain the reconstruction with one or more known points, and the inability to investigate the displacement of rigid blocks. Additionally, the correlation between some of the input parameters with landslide rheology has yet to be explored. Despite these limitations and challenges, we show that the inversion method can represent, in some cases, a very important tool in landslide characterization and modelling, providing a means to reduce the uncertainty of numerical model geometry.

With the aim of producing regional/basin scale landslide susceptibility maps, time/costs effectiveness suggests exploiting the available regional P.A.I. (Piano Assetto Idrogeologico – the Management Plans for hydraulic and geomorphologic risk) landslide inventory (PAI inventory, hereafter), which all the Italian Basin Authorities adopt for their territories having, what is more, a recognition at the administrative level. However, these types of inventories are frequently affected by incompleteness and bias as they are mainly fed by past and reported phenomena which have been associated to damages occurrences rather than being produced down to expert and systematic landslide recognition surveys.

In this contribution, a test was carried out in the Platani river basin (Sicily, Italy) for evaluating the actual quality of landslide susceptibility models which were calibrated by exploiting the PAI inventory prepared by the Basin Authority of the Sicilian hydrographic district.

Starting from the available slide and flow PAI landslide inventories, after a critical review of the mapped landslides, two LIP (landslide identification point) archives (714 slides and 1983 flows) were prepared so to assign stable/unstable status to each of the slope units (SLUs) in which the whole basin was partitioned. By applying multivariate adaptive regression splines (MARS), the SLU status was then regressed on a set of 11 geo-environmental predictors, obtaining the two different (slide and flow) basin-scale susceptibility models. By applying recursive calibration/validation SLUs random partition, excellent values of the Area Under Curve (AUC) were obtained (slide: 0.89; flow: 0.9) together with high values of sensitivity (both: 0.86) and specificity (slide: 0.78; flow: 0.76).

To test the actual prediction skill of the susceptibility models, a new validation subset was prepared through a systematic remote/on-field landslide recognition of a randomly selected set of PAI landslide-free SLUs (11245: ~500 km2). Critical model performances were then observed, especially for the flow model, with a marked lowering of prediction skill for new unstable SLUs, missing 1289 out of the 3132 positive cases (84 out of 334 positive SLUs missing, for slide landslides).

To solve this limits, two new models were prepared by including 70% of the new unstable SLUs in the calibration subset finally obtaining high predictive performance in recalling the whole basin SLUs status (AUC: 0.85 and 0.86, sensitivity: 0.87 and 0.85, specificity: 0.69 and 0.72, respectively for flow and slide) as well as focusing on the blind hidden 30% (sensitivity: 087 and 0.82, specificity: 0.84, 0.73, respectively for flow and slide).

According to the test in the Platani river basin, using biased uncomplete landslide archives, can lead to apparently performing models, which can paradoxically constitute a severe threat in terms of risks if formally adopted as tools for land-use planning and civil protection aims.

Multi-temporal geomorphological analysis and seismic surveys as tools for the investigation of a complex slow-moving landslide: an example from the southern Apennines

Multitemporal geomorphological analysis and mapping of landslide-related landforms of unstable slopes are critical, but frequently underestimated, activities to investigate the spatiotemporal evolution of slow-moving landslides, identify predisposing and triggering factors, and plan mitigation actions. Innovative remote-sensing techniques must be integrated with traditional geomorphological analysis based on multitemporal analysis of historical images and multi-year DEM comparison. This is necessary for a comprehensive investigation of large, slow-moving landslides with a long history of intermittent dormancy and activity, even though recent technological advancements in space and drone platforms have made it easier to quantify the evolution and kinematics of short-term landslides. Through the use of near-surface seismic survey, DEM comparison, and multitemporal geomorphological analysis, the spatial and temporal evolution of a multistage complex landslide has been reconstructed. The impressive complex earthflow identified as the slow-moving Tolve landslide is located in the landslide-prone catchment of the frontal sector of the southern Apennines chain. The study area includes an unstable slope near Tolve, a small town located about 10 kilometres east of Potenza town (Basilicata, southern Italy). The slope is interested in a complex landslide (hereafter Tolve landslide) that shows a high variability of its active sectors in space and time. In order to: i) investigate the multi-decadal spatial and temporal evolution of the landslide; ii) estimate the mobilized volumes during the recent stages of the slope's reactivation; iii) reconstruct the subsurface features of the landslide body and the geometry of the sliding surface; and iv) infer the predisposing and triggering factors of the intermittent activity of the earthflow, we integrated traditional geomorphological analysis with DEM comparison and seismic surveys.

Sentinel-1 SAR-based globally distributed landslide detection by deep neural networks

An effective response to widespread multiple landslide events (MLEs) on a large scale requires swift and accurate landslide detection. Despite considerable efforts using optical remote sensing, there are limitations in achieving global coverage, day-and-night operation, and all-weather capabilities. To address these challenges, we propose a method that combines Deep Neural Networks (DNNs) with Synthetic Aperture Radar (SAR) backscatter data. This method is developed by analyzing 11 earthquake-induced MLEs, which involved around 73 thousand landslides globally in various geographical settings. We validate the model's performance on unseen earthquake-induced landslides in Sumatra and Haiti, achieving a test F1-score of 82% in rapid assessment, signifying substantial advancement over previous approaches. Our method utilizes Google Earth Engine for Sentinel-1 SAR image processing and employs local computing resources for advanced DNN-based image classification. Through explainable artificial intelligence, our study highlights the effectiveness of change detection bands in better distinguishing landslide features, surpassing the use of backscatter data alone. Additionally, we demonstrate improved landslide detection using multi-temporal information stacks rather than single post-event SAR images. Finally, we introduce the SAR-LRA Tool in its Beta version, offering a valuable resource for swift and comprehensive all-weather global landslide assessment. The systematic application of this tool promises to enhance timely responses to future MLEs. Our research provides a solid foundation for future endeavors, where SAR and DNNs can be leveraged to identify natural hazards and earth surface changes in mountainous regions. Given the frequent occurrence of MLEs, developing a robust modeling approach is crucial for promptly assessing their spatial distribution. This research sets the stage for efficient rapid assessment of MLEs in the future.

Integrated geophysical and geotechnical investigations of Upper Sarbala Landslide: a case study of Himalayas Mountain ranges, Pakistan

Niaz J.*[1], Lollino P.[1] & Niaz A.[2]

[1] Dipartimento di Scienze della Terra e Geoambientali, Università di Bari "Aldo Moro".

Keywords: landslide, electrical resistivity tomography, specific gravity.

Landslides are gravitational mass movement that occurs as an effect of some change in the factors controlling the equilibrium of the sliding mass. In this contribution, landslide case study situated in the northwestern Himalayas of Pakistan, located near Sudhan Gali, District Bagh, Azad Jammu and Kashmir, with coordinates ranging from 73°43'31.38" to 73°43'22.04" E longitudes and from 34°5'25.22" to 34°5'25.11"N latitude, is discussed. In mountainous regions such as Pakistan, landslides are the main cause of loss of life, damages to buildings and infrastructure lines, and financial losses (Basharat, 2012). The Himalayan Mountains are among the most dangerous areas in the world for landsliding, due to weak geological components, and seismically very active zones (Khan, 2006). To characterize the Sarbala Landslide, techniques including geological fieldwork, electrical resistivity tomography (ERT), geotechnical laboratory characterizations, and GIS mapping were applied to evaluate the surface and subsurface dynamics of the Sarbala Landslide. In order to understand the geometry and failure mechanism of landslides, the ERT survey is widely used (Perrone et al., 2014). Soil samples were collected during multiple field surveys, and six ERT profiles were acquired using the Schlumberger array in various parts of the Sarbala Landslide. According to the ERT results, the sliding mass of the Sarbala landslide consists mostly of saturated colluvium and debris, which causes low resistivity in tomograms. Saturation of the slope-forming material can be considered as a major factor controlling the instability of the Sarbala Landslide. Based on resistivity contrast, a well-developed slip surface is observed between the unconsolidated landslide mass and the underlying bedrock. Atterberg properties, which have a strong influence on mass movement, include soil texture, porosity and permeability, soil mineral content, and soil water content (Kristyanto et al.,2017; Kitutu., 2009). The Atterberg limits of the landslide material indicate low to medium plastic behavior of the landslide. The reconstruction of the slope lithological setup has indicated that the sand deposit, with large permeability values, in the upper portion of the landslide, works as a water recharge tank for the downslope area, providing a large amount of water for the landslide mass, mainly formed of clayey material, , which then results in slope failure. Therefore, the hydrogeological setup of the slope-forming mass can be considered as a major factor controlling the stability of the Sarbala Landslide. Furthermore, this area is tectonically active, and faults play an important role in the activation of this landslide. Landslide scarps and large-scale tensional cracks show the active nature of the landslide. According to this research, the Sarbala Landslide is an active mass movement. A limit equilibrium back-analysis has been also carried out for the landslide mass in order to derive information on the shear strength parameters mobilized at failure as well as on the whole slope conditions leading to instability.

Keywords: landslide susceptibility, prediction modeling, mathematical functions.

This study utilizes mathematical models to assess landslide susceptibility in the vicinity of Lake Albano, a volcanic crater and tourist destination near Rome, Italy. The region has experienced various types of mass movements for over 2,100 years, posing ongoing risks exacerbated by urban expansion and socioeconomic activities.

Spanning 30 km², the study area is represented by a digital raster of 1002 pixels × 1202 lines at 5 m resolution, comprising 975,093 pixels above water and 229,311 below. Within this area, 8,867 pixels denote 150 sub-aerial landslides, and 34,028 pixels denote 65 sub-aqueous landslides, indicating high densities of mass movements.

A comprehensive database compiled information on landslide distributions, types, shapes, and locations, both sub-aerial and sub-aqueous (Patera & Fabbri, 2021; Patera & Fabbri, 2023). Categorical maps of land use classes and lithology units, along with high-resolution topographic elevation data, characterized the physical environment. Utilizing a dense grid of elevation points (Bozzano et al., 2009), continuous value maps at 5 m resolution were generated for aspect, digital elevation model, slope, curvature, planform, and profile.

Prediction modeling employed a fuzzy set membership function and logistic discriminant function, yielding digital images ranking the study area by relative susceptibility levels. Spatial support varied based on landslide types and physiographic conditions, integrating empirical likelihood values to contrast settings with and without landslides for each pixel. Despite overlaps in predictions between models and landslide types, the feasibility of assessing landslide susceptibility with low uncertainty is demonstrated. However, challenges persist due to the volcanic nature of the area and socioeconomic factors, complicating hazard mitigation and risk management efforts.

Keywords: landslides, physically-based deterministic models, remote sensing technology.

Each year, landslides pose significant hazards, causing loss of life, destruction, and financial setbacks. Physically-based models for rainfall-triggered landslides offer advantages over empirical methods by evaluating rainfall, soil hydrology, and shear strength during infiltration. However, their complexity, especially regarding distributed soil parameters, is a major obstacle. To address this, we propose integrating remote sensing, enhancing landslide research. Our methodology integrates remote sensing and InSAR technology with a distributed model, focusing on estimating soil parameters and understanding soil moisture's correlation with deformation history. Accurate assessment of soil thickness is crucial for landslide prediction. We utilized pedotransfer functions and in-situ data to derive additional factor of safety components. The framework integrates the tRIBS-VEGGIE model with a landslide component, utilizing Richard's equation for soil moisture transport. However, the hypothetical failure surface depends on specific soil characteristics and must be constrained. To determine soil thickness, we plan to explore thickness inversion, using displacement rate estimation from InSAR measurements and mass conservation principles (Xu et al., 2019; Xu et al., 2020). Synthetic Aperture Radar Interferometry (InSAR) data from Sentinel-1, via the European Ground Motion Service (EGSM), provides European-scale ground motion information. This dataset will be validated in the Friuli-Venezia Giulia region, focusing on documented alluvial events triggering shallow landslides. Analyzing soil parameters emphasizes the importance of assessing geological characteristics identified through InSAR technology. To document and detect landslides, we use the Italian Landslide Inventory (IFFI), supplemented with open data from the IDROGEO project.

Anthropogenic sinkholes' susceptibility assessment in Palermo, Italy, using a machine learning algorithm

Bausilio G.*, Di Martire D. & Calcaterra D.

Dipartimento di Scienze della Terra, dell'Ambiente e delle Risorse, Università di Napoli "Federico II".

Corresponding author email: giuseppe.bausilio@unina.it

Keywords: Palermo, sinkhole, susceptibility.

Sinkholes are a widespread geohazard related to the subsidence or collapse caused by underground cavities presence. In urban areas, the latter is related to anthropic activities, such as building stone extraction, or subsurface utilities (aqueducts, sewers, cables) installation and leaking. This type of sinkholes, called anthropogenic sinkholes (Parise, 2015), usually cause fewer deaths compared to other geohazards, but their impact on the urban fabric is still relevant. Damage to the road network, for example, can lead to economic loss to the local socioeconomic fabric, especially if repair works require the interdiction of the road. Anthropogenic sinkholes are widespread in the historic city centres of the Italian Peninsula: Palermo, regional capital of Sicily, is among these cities. The machine learning algorithm Maximum Entropy (MaxEnt) (Phillips & Dudìk, 2008) was employed to evaluate the sinkhole susceptibility in the city of Palermo. The presence inventory was obtained by combining the available data from ISPRA, the Universities of Palermo and Siena, and national/local news. As the inventory is limited to 274 events, a k-fold cross-validation technique was employed (with k = 5). This means that the modelization process is iterated using one of the k sets as the validation set (a different one for every iteration), while the remaining data is used as the training set. The final model is a mean of the k models obtained through the algorithm iteration process. The Variance Inflation Factor (VIF) technique has been performed to minimize the influence of multicollinearity during machine learning modelization. The VIF analysis has been executed in R (R Core Team, 2023) using the usdm package (Naimi et al., 2014). The predisposing factors implemented in this analysis describe geological characteristics (land use, slope angle, geological map) and anthropogenic factors (underground cavities, road and underground railroad networks, and areas influenced by the extraction of building materials). The performance of the model is evaluated using the ROC/AUC score. Due to the implementation of the k-fold cross-validation technique, the score obtained is a mean of the iterated models. The good performance achieved for the resulting map makes it a useful new step towards a better understanding of anthropogenic sinkhole susceptibility assessment in urban areas. These tools can be a valid contribution to the work of local administrations and stakeholders aiming at risk mitigation and protection of cultural and monumental heritage.
